Fig. 1—End view of the Koecklin two-cycle motor

Koecklin Motor Distinct in That It Uses Sleeve Valves Although Operating On the Two-Stroke Cycle

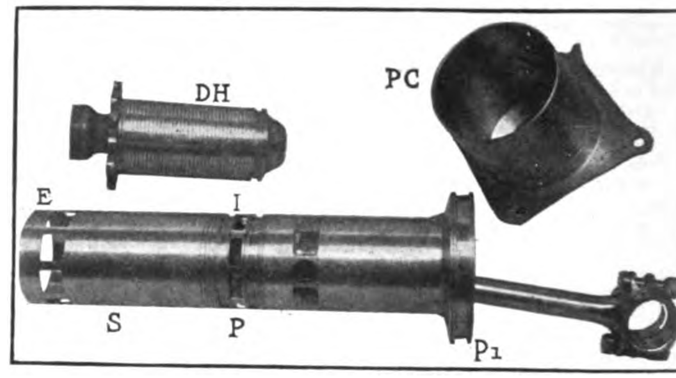

Fig. 2—Koecklin piston with the long integral sleeve carrying the two sets of parts; above is the cylinder head, DH.

THE AUTOMOBILE, through its French correspondent, W. F. Bradley, has obtained, and is able to reproduce this week the first series of photographic illustrations of the positive Koecklin two-cycle motor described in the issue of August 1. Contrary to any two-cycle practice up to the present, the Koecklin uses a sleeve valve to control the admission of gases and also employs a rotary distributer valve between the carbureter and the cylinders. Fig. 1 shows the end view of the motor with its ribbed intake and exhaust manifolds on opposite sides and with its front transverse shaft driving a Bosch magneto at each end. The two flexible motor supports at the forward end are shown as well as the unique form of integral brackets for carrying the magnetos. The position of the rotary distributer on the side of the steering column, or the right side of the car, can be noted.

As described in the August 1 article, the piston has formed integrally with it a long upward continuation sleeve carrying two series of ports, Fig. 2, the sleeve being indicated at S, the intake ports I and the exhaust ports E. The position of the combined piston-sleeve is further shown in Fig. 4 where it is coupled through the connecting-rod to the ball-bearing crankshaft.

It will be noticed that the lower part has a greater diameter than the upper part. This is the part that works in the pump chamber P C, draws in the fresh charge, compresses it and delivers it under pressure to an adjoining cylinder. D H is the removable cylinder head which is shown in a partially removed condition in Fig. 3. The tubular sleeve when at the upper end of its stroke completely surrounds the lower part of the cylinder head around which it works and is cooled owing to the water circulation through the cylinder head.

When the piston is on its lower path of travel, the sleeve is cooled all around its circumference except at the point where the distributer valve is located. The spark-plug, which is placed in the depressed center of the cylinder head, is also amply cooled, thereby recalling one of the advantageous points of design used in the Knight motor. There are also three compression rings used to insure gas-tightness at the point of passage of the sleeve around the lower end of the head. Furthermore, there are five compression rings used to provide a gas-tight joint between the piston-sleeve unit and the cylinder wall.

The crankshaft, C S in Fig. 3, is carried on 5 S. K. F. ball bearings, there being a bearing between the throws, one at the front and one at each side of the distributer pinion at the rear of the shaft. For the purposes of lubrication the shaft is bored throughout, the oil being drawn from the base chamber, through the hollow shaft to the connecting rod ends, and up the tubular connecting rods to the wrist pins. In addition to this, there are, as already mentioned, a couple of oil deliveries to opposite sides of the head of the sleeve and six leads to the rotary distributer. On the forward end of the crankshaft is a bevel pinion driving a transverse shaft with a Bosch high tension magneto at each end. Intake and exhaust taking place entirely around the cylinder, there are a pair of exhaust manifolds, to the left and right of the motor, the left-hand side one passing behind the rear cylinder and connected up to the right-hand one. The intake manifold is cast with the cylinders, the carbureter, a Vapor, being bolted up direct without the use of any piping.

So far as chassis features are concerned the car is on standard lines. The clutch is of the cone type; the gear set provides four speeds and reverse with the lever mounted directly on the box, and being operated by the left hand. The car is shaft driven, with a universal at each end, has a full floating type of live axle, and no differential. The frame, which has its greatest depth opposite the flywheel, is inswept at the front axle and outswept again at the extreme front. It is sharply upswept over the rear axle. The chassis has neither distance nor torsion rods.

Air Suction Aids Root's Muffler

A minimum loss of power in the muffler is said to characterize the design recently evolved by J. D. Roots & Company, 231 Strand, London, W. C. The new and principal feature of this design is the application of the external atmospheric air as the medium which helps to exhaust the dead gases of the motor and to silence them at the same time, this being attained by the use of an apparatus embodying the same traits which give its character to the ejector type of apparatus. The outlets of the muffler, there being a considerable number of them, are so arranged and directed that when they are moved through the atmosphere by the travel of the car, the air represents an all-surrounding jet the suction of which exhausts the interior of the muffler, very much in the manner of a water-jet condenser such as are used in steam engine practice.

While the Roots vacuum muffler, as it is called, is made in several types, the same fundamental points of design are incorporated in all. In every case the muffler consists of a central pipe into which the exhaust coming from the motor passes. This pipe is tapped with several series of holes all along its length and is surrounded with a series of gills which overlap each other and thereby provide constricted passages from the interior of the muffler to the air. The effect of this design is obvious: the waste gases are silenced by being passed through the small holes of the muffler pipe and passages formed by the gills, while the back pressure thereby encountered is compensated for by the suction of the surrounding air jet.—*The Autocar*, August 10.

Mafam Has Automatic Advance

Refinement of detail which tends toward increased efficiency and reliability gives the new German-made Mafam magneto a very favorable appearance. There are a number of original features in this apparatus, foremost among which stands the automatic advance and retarding mechanism operating on the principle of a centrifugal governor. The latter consists of two chains set at an angle of 180 degrees to one another and inclosed in a rotating drum. One end of each spring is attached to the spindle of the magneto armature and the other to the drum; and to each link of the chains is secured a short steel spring which bears against the drum and the pressure of which keeps

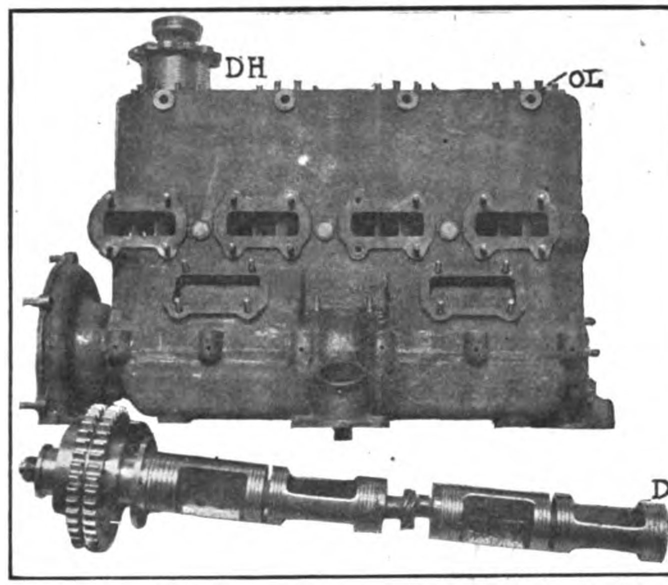

Fig. 3—Four-cylinder block casting on Koecklin motor and the rotary sleeve

the magneto in a somewhat retarded position. As the magneto speeds up, the tendency of the chains is to fly away from the spindle, but this tendency is counteracted by the increasing spring pressure, being thus kept in proper bounds.

Another nicety of construction which, according to the claims of the manufacturer, increases the efficiency of the motor is the method of attaching the pole-pieces to the magnets. The latter are mounted on a base plate, being fixed thereto by a pair of cruciform clamps each having three right-angle grips taking hold of the lower surface of the base-plate and of the end surfaces of the permanent magnets. Only one screw on each side of the magneto is required to fasten the magnets to the base. The pole-pieces are kept in contact with the magnets, however, without the use of screws, obtaining this end by shaping the pole-pieces and their base out of one piece of steel and bracing their top ends by a cross-plate. This construction permits of very high accuracy in grinding the bore of the pole-pieces. This magneto is made by the Mafam Motor Apparate, Frankfurt-on-the-Main.—*The Autocar*, August 24.

Germany has produced another pneumatic speedometer, manufactured by Peerboom & Schuermann, Duesseldorf, Rheinland. It consists of a light metal drum rotated on a flexible shaft and on whose inner end there are a number of strips of metal arranged radially. On these strips fan blades are mounted and when the flexible shaft is rotated the body of air in the drum is rotated also and moves the fan with it.—*Auto Motor Journal* Sept. 21.

Ansonia Positive Lock Windshield; Rossman Casing Repair Machine; Standard Company's Q. D. and Demountable Rims; Elevating the Ford Timer; Latest Trade Literature

WHAT is claimed to be the last word in windshields is the Positive Lock type manufactured by the Ansonia Manufacturing Company, Ansonia, Conn. This company manufactures one- and two-pane shields, in which every pane may be adjusted to a variety of positions and is positively held in place after the position has been selected. This great adaptability is obtained by the use of four ball-lock joints, one pair of which is used in connecting the two panes in combination with two short vertical supports and the other pair to provide the fulcrum around which the upper pane may be turned and, if necessary, rotated.

The units of which the two-pane shields are made are the brass frame and the two plate-glass panes. The frame is composed of two rectangles embracing the panes and a pair of long stay rods by which the shield is fastened to the floorboard. The hinges or joints above referred to which constitute the principal parts of the shield are shown in detail in the sectional view, Fig 4. As this illustration shows, each joint consists principally of two cup-shaped members, C, C1 which contain steel disks S, S1 of which S is formed with semi-spherical depressions, into which suitable projections of S1 fit. The part C is fastened to a clamp C2 bearing against the tube which is part of the shield pane frame. C and C1 are provided with central holes through which the bolt B passes, the latter screwing into a thread tapped in the tube T. The end of the bolt carries a head H, the inner side of which is shaped with a cylindrical projection holding the spring S2 in alignment with the bolt B it encircles. The part C1 is fastened to the short vertical support V and it will be seen that, if the pane held in the frame of which tube T is a part is turned, the depressions and projections of C and C1 are alternately brought into and out of engagement, providing a series of positions which differ from one another by angles of 45 degrees. The head H is held in place on the bolt by a nut N locked by a cotter pin, whereby the outward movement of the head which the spring pressure tends to bring about is checked. A slight internal movement of the head on the bolt is allowed for by leaving one turn or so open toward the tube. By this expedient the head H may be screwed farther in on the bolt, thereby compressing the spring and positively locking the disks S and S1, as well as the cups C and C1 in their relative position. The spring pressure makes the engagement of the disks positive as it always causes the projections and depressions to grip each other. It is therefore necessary in order to change the position of the pane held by the tube T to first screw head H as far outward as possible, then bring the pane to the desired position and fasten it therein by closing the head upon the bolt. The tightness of the engagement of the disks is determined by the spring pressure which is adjustable.

Practically the same joint is used to attach the vertical support V to the upper corner of the lower pane frame. This joint permits the change of the angle of the support V to the upright side member of the lower pane's frame and for this purpose is made with two pieces of tubing each threaded for two bolts. Figs. 4 to 7 show the attachment of the joint to this side member and to the support V. The latter is threaded with two holes for the bolts passed through a piece of tubing integral with the joint, the side member of the frame is threaded with four holes above each other, but at varying distances. If the uppermost (first) and the third hole are used in securing the lower tubing attached to the joint the lower windshield pane is held in a vertical position, as the pane and the length of the stay rods determine two sides of a triangle, the third side being the distance from the lower edge of the lower pane to the line connecting the footboard ends of the stay rods. If the bolts are passed through the second and fourth holes of the side member and the length of the stay rods—which is adjustable by a joint connecting its two telescoping parts—is decreased, the lower pane may be inclined toward the driver.

The shield comes in widths of 38, 41 and 44 inches, the upper pane being 12 inches high and the lower one 12 or 13 inches. The standard finish is polished brass, but the company also furnishes nickel, black or other popular kinds of finish.

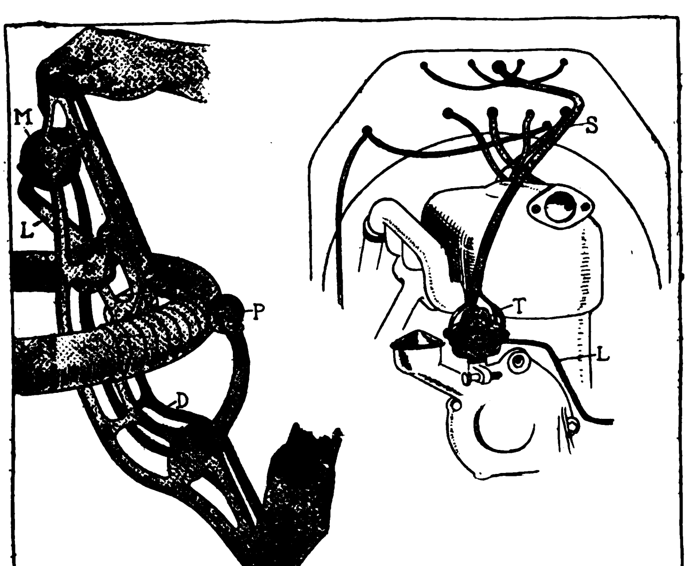

Fig. 1—Rossman tire-wrapping machine. Fig. 2—Device for elevating the timer of Ford automobiles

Rossman Tire Bandage Wrapper

Wrapping a tire casing is such a frequent and at the same time not too easy operation, that Roy G. Rossman, 707 East Pike street, Seattle, Wash., considered it a worthy end to design a machine for the application of bandage to a casing undergoing repairs and has applied for a patent of the same. The device, Fig. 1, consists of a frame which is 30 inches long and weighs about 16 pounds, being so shaped as to provide at once a mechanism for storing the wrapping material, wrapping it around the tire and tightening it thereon. The material is carried on a spool as at M and is conducted over two rollers so as to be kept straight. Tight winding of the tire is obtained by the use of the roller R against which one side of the tire bears, the other being pressed by the pulley P. A lever L whose end is shaped with a plate holds the material taut on the spool, preventing any slack.

Manifold Line of Stanweld Rims

The Standard Welding Company, Cleveland, O., has brought out a line of rims, both of the quick-detachable and demountable types. While the demountable types are specially rich in improvements over past rim practice, the Q. D. designs are by no means poor in new ideas. The following notes referring to the new products give the most important points characterizing the rims of the Standard Company. There are three types of Q. D.'s and four types of demountables, known by the name Stanweld. Types 50, 51 and 52 are of the Q. D. design, the first being a universal type adapted for straight side of clincher tires. It has two side rings, one of which is continuous and the other split, both being removable. Type 51 is designed for straight-side tires exclusively, while type 52 is a clincher rim. If, however, the detachable side ring on the last type is reversed and a rim filler is used, it may be adapted for straight-side tires. The most original detail of the construction of these rims is the detaching mechanism, Fig. 3, shown in the two lower sketches. It consists of a latch attached to the continuous ring and adapted to engage a projection on the lower side of the split ring, which is inserted in the continuous ring through a groove in the latter. If this part is engaged by the latch a projection on the free end of the latter is caught in a groove on the inner side of the continuous ring. When this is the case the split ends of the ring contact with one another, but the projection of this ring may be released and the engagement broken by prying the latch off the continuous rim, using a screwdriver for disengaging the latch projection from the hole containing it when the rim is intact for operation.

The demountable types use the same simple and efficient detaching feature. Four types of parts, the felloe band, rim base, adjusting ring and clamping members characterize the demountable types. The felloe band F, held in place by the ends of the clamping bolts B, supports the rim base B1, which is held under tension by the pressure exerted by the clamping bolts on the adjusting ring A. E is the continuous ring supporting the tire on one side, while the detachable ring D supports the other side. The adjusting ring is split transversely and fits the flange on the inside of the rim base so that the tendency, due to the weight of the car, is to force the rim toward the retaining flange which resists it on the strength of its continuous bearing against the rear of the rim base. The bolts which positively hold the adjusting ring in position carry the clamps C bearing against it. The clamp which bears upon the adjusting ring and the washer has a universal movement on the clamp nut.

Ford Timer Elevator Gear

Ford owners will be interested in the new device, Fig. 2, which serves to elevate the timer on Ford cars, thereby bringing it out of the range of water, if the cars are run through streams, etc. It is also put in a place by itself where the chance for short-circuiting is reduced. Fig. 2 shows the timer T in position close to the filler hole of the crankcase. It is driven from the timing gear by a hard-steel spiral gear with 1-2-inch face and 1 5-8 inches diameter. Attention is called to the new position of the cable suspension S, which takes this part out of the range of the fan-belt adjustment screw and makes both more accessible.

New Trade Literature

The Duryea System of Automobile Construction is the title of a 29-page pamphlet issued by the Duryea Motor Company under the authorship of Charles E. Duryea. The advantages of the Duryea car are dwelt upon at length by Mr. Duryea, who is one of the pioneers of the industry. Of special interest are his comparisons of the two and four-cycle type of motor, air cooled vs. water cooling, the distribution of weight and the control system.

The Halladay News for September, published by the Streator Motor Car Company, has arrived. It is a lively little pamphlet of eight pages containing the latest news of the Halladay selling organization and factory. In it we learn of the addition of the electric self-starter on the Halladay cars after the 15th of September, that the Streator Motor Car Company has enlarged its plant by adding that of the Streator Metal Stamping Company which adjoined it and the intention of the company to establish at least two more service stations.

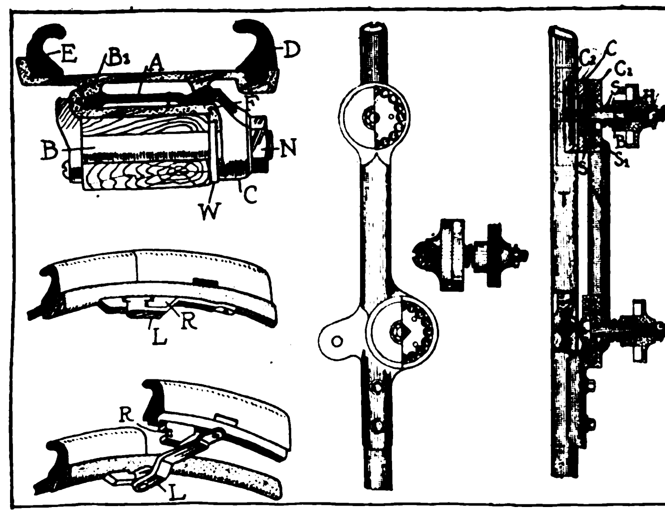

Fig. 3—Standard Q. D. and Stanweld demountable rims. Fig. 4—Section of Ansonia windshield hinge

How to Put Truffault-Hartford Shock-Absorbers on Your Car, an eight-page brochure issued by the Hartford Suspension Company, tells the user of these absorbers how to keep their efficiency at par by giving them the proper care and adjustment. This pamphlet is clearly written and well illustrated and should be of value to the automobilist using the Truffault-Hartford shock-absorber.

The Bosch News for September contains a short article on salesmanship and the fallacy of the knocking policy. It is largely a motor boat number devoted to the Harmsworth trophy races in which England took the cup and to the transatlantic voyage of the little motorboat Detroit. A description of the newer types of magneto is also given in this organ of the Bosch Magneto Company.

September is the birthday month of the B. F. Goodrich Company and therefore this month's issue of *The Goodrich* is called the birthday number. It is quite a comprehensive affair of 31 pages and is exceedingly well gotten up, containing both news and a mass of valuable data of interest to the car owner. The humorous side of the motoring situation has not been overlooked and a very interesting number is the result.

Something new in the way of instruction books is that issued by the Overland Company, which has gone a step further than usual in the preparation of the booklet, which is often seized as the drowning man seizes the proverbial straw by the perplexed motorist. Too often in the past the instruction book has proved a straw indeed containing a number of bootless generalities which, as the automobilist declared, "got him nowhere." The owner's record and identification car contained therein is also of special interest.

One of the cleverest trade-literature stunts that has been laid upon our desk is a small pamphlet in the shape of a radiator, being the menu of the "Car with a Conscience" dinner, recently given by the Oakland Motor Car Company at Hotel Ponchartrain, Detroit, Mich.

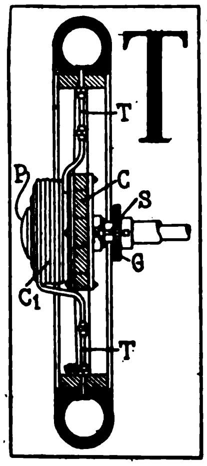

Fig. 1—Craig tire cooler

TIRE Cooling Device—In which the rim is cooled by a water current circulated by a pump through a radiator coil.

In Fig. 1, the subject matter of this patent, a tire-cooling mechanism is shown. It consists in principle of a coiled radiator pipe surrounding a wheel hub and having passages which are in contact with the rim portion of a wheel. The Coil C1 is mounted upon the casing C which is arranged around the wheel hub in the manner of a false hub. In this casing a pump is located eccentrically, the shaft of which S is driven by gearing G. The water is circulated through the coil, to the rim and back, through a system of radial tubes T. A removable plate P closes the side of the casing and affords access to the interior of the same as well as the end of the axle.

No. 1,038,092—to Andrew B. Craig, Tarkio, Mo. Granted September 10, 1912; filed January 31, 1912.

Automobile Engine Carbureter—In which additional fuel jets are brought into action when the opening of the throttle is increased by the driver.

The principal feature of the carbureter described in this patent and illustrated in Fig. 2 is the construction and location of the auxiliary fuel jets K. Reference to the figure shows that all fuel, after passing through the float chamber F flows through the passage P controlled by the needle valve N which is operated like the needle valve of the ordinary carbureter. The fuel then flows past the needle, through the conduit Q and up to the main jet J where it is sprayed. The throttle T extends across the mixing chamber M, leaving open a small portion of the latter's cross-section for the minimum air supply. As the throttle is opened to a greater extent air is drawn through the lower space M1 of the mixing chamber and the jets K are brought into action, first the one nearest to the jet J, then the next, and so on. The level in the horizontal passage H and the vertical one V is determined by the fuel level in F, as the passage P1 has the effect of insuring atmospheric pressure within the passage V.

No. 1,038,040—to Arthur J. Weiss, West Orange, N. J., assignor to Maxi Company, New York City. Granted September 10, 1912; filed January 25, 1912.

Automobile Turntable—Which is rotated by small wheels bearing on a circular track and driven by friction wheels which bear upon the floor of the establishment wherein the turntable is installed.

This patent refers to a turntable, Fig. 3, which comprises a rotary table T, a track T1 and wheels W running upon the latter and journaled to the table. Friction wheels F, which are journaled on the table, operate the wheels W, means being provided for preventing one of the friction wheels from rotating in one direction. A wheel depression D in the table is designed to hold the driving wheel of an automobile in position.

No. 1,038,309—to Albert Dellamore, Los Angeles, Cal. Granted September 10, 1912; filed April 16, 1912.

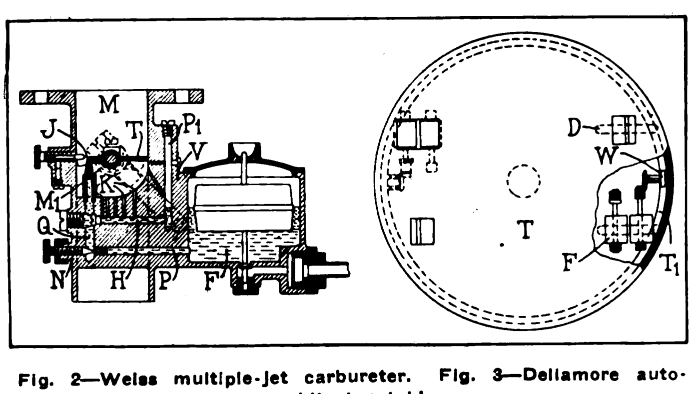

Fig. 2—Weiss multiple-jet carbureter. Fig. 3—Dellamore automobile turntable

Shock-Absorber—In which road shocks are taken up by a liquid in which a piston moves.

The subject matter of this patent, a shock-absorber, Fig. 6, consists of a cylinder C which is partly filled with a fluid in which a piston rod carrying a head is positioned and adapted to move. In the cylinder there is also a floating cage composed of a series of solid spindles, each of which passes through a passageway in the piston head and being so formed that when the piston moves through the cage the passageways in its head are constricted.

No. 1,037,052—to Frank Maxwell, New Rochelle, N. Y. Granted August 27, 1912; filed November 2, 1911.

Pipe Wrench—In which a spring holds the two jaws in positive engagement with the pipe.

This patent relates to a pipe wrench, Fig. 4, which consists of a fixed jaw F and its shank to which a handle H is hinged by a rule-joint connection. The shank has the form of a segment one side of which is faced with ratchet teeth, being engaged by a pawl P which is pressed against them by a spring S.

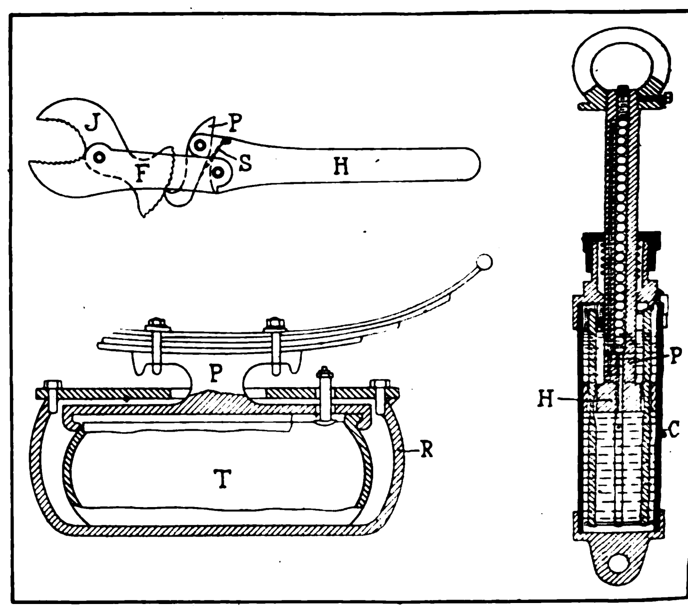

Fig. 4—Bessolo wrench. Fig. 5—Stovel suspension. Fig. 6—Maxwell shock-absorber

No. 1,037,109—to William Louis Bessolo, San Diego, Cal. Granted August 27, 1912; filed May 14, 1912.

Pneumatic Automobile Suspension—In which the springs supporting the body rest on inflatable tubes carried in a hollow axle.

The patent refers to a suspension method, Fig. 5, comcomprising an automobile axle in which a receptacle R is formed. The latter contains an inflatable tube T held in an outer casing which is provided with an opening through which the tube is inserted in the receptacle. A plunger P is mounted in the receptacle so that it reciprocates therein and fits into the opening of the receptacle. The spring which supports the body of the automobile is carried by the plunger.

No. 1,037,360—to Charles J. Stovel, San Francisco, Cal. Granted September 3, 1912; filed January 22, 1912.

FIAT Wins Grand Prize

Upper—Caleb Bragg swinging his winning Fiat around the Graveyard turn on the Wauwatosa course in the thirty-sixth lap of the Grand Prix race at Milwaukee last Saturday. Lower—The finish of the Grand Prix—Bragg slowing up at the line to tell Starter Wagner of De Palma's accident

Bragg Covers 410-Mile Course at 69.3 Miles Per Hour—Benz Second—Stutz Third—De Palma Badly Hurt in Last Lap

MILWAUKEE, Oct. 6.—Fiat 41, driven by Caleb S. Bragg, won the 1912 Grand Prize race for the international trophy of the Automobile Club of America over the Wauwatosa course of 7.88 miles. The race was fifty-two laps of the course, or approximately 410 miles.

Benz 40, handled by Erwin Bergdoll, was a distant second, leading the Stutz entry across the line by a narrow margin. Oldfield's Fiat was a good fourth. The winning Fiat averaged 69.3 miles an hour.

The Fiat car driven by De Palma collided with the winner in the final spurt to the wire and was ditched when at least second place appeared certain for it.

It was a hair-raising race up to the time disaster met De Palma.

Cold type fails when it comes to describing the finish. The tables show that Bragg had 15 minutes 24 seconds over the second car, but they do not show how close Ralph De Palma, winner this year of the two big races at Elgin and the Vanderbilt Cup, came to snatching away from Bragg the international honors. Neither do they tell of how De Palma flirted with death and how lucky he was that his fate was not similar to that which robbed the motor world of Bruce-Brown. As a result of the daring attempt which he made to add to his laurel wreath, De Palma now is in the Trinity hospital in this city, suffering from abdominal injuries which will confine him to his bed for a week or more. On the final lap De Palma ran into Bragg from the rear, his Mercedes turned over, throwing out both driver and mechanician.

With De Palma eliminated in this sensational manner, Bergdoll in the Benz ran into second place after a hot finish with Anderson in the Stutz, whom he beat by 31 seconds for the position, while Barney Oldfield in a Fiat was fourth, 4 minutes

Oldfield's Fiat, which won fourth place, nearing grandstand

32 seconds back of Anderson. Clark in a Mercedes and Burman driving Horan's Benz were still running when the race was called off because of the crowd refusing to be held in check any longer. Twelve cars in all started in the race, but half of them were eliminated for one reason or another.

But it was the Bragg-De Palma struggle that stirred the crowd of 150,000 to a frenzy, and the accident at the eleventh hour undoubtedly robbed the motoring public of the greatest finish that ever had been put up in a grand prix race. Bragg always had been a factor in the race, never being worse than third and having led the field from the thirty-first lap when Tetzlaff went to the side lines for keeps. De Palma had been plugging along grimly, fifth and sixth at the start, then going up to third, then second and finally leading in the twenty-second, twenty-third and twenty-fourth laps, then dropping to third for four laps when Tetzlaff and Bragg were battling, and finally becoming runner-up to Bragg when Tetzlaff went out. It was a plucky battle that De Palma put up, for while Bragg had all the earmarks of a winner, the Italian never relinquished his efforts to catch him.

With four laps to go, De Palma was 4 minutes 19 seconds to the bad. He made a lap in 6:28 to Bragg's 7:21 and cut the margin to 3 minutes 26 seconds. The fiftieth lap was made in 6:36 by De Palma and 7:26 by Bragg and the gap was reduced to 2 minutes 36 seconds, when Starter Wagner waved his green flag for both of them. De Palma was chasing his rival with deadly intensity, and upon reciving a signal from his pit to "beat it" he stepped on the throttle and had the accelerator flat with the boards when he swung into the North Fond Du Lac road. He rushed up on the Fiat with great leaps and bounds and at station 11 he caught his rival. But it was necessary for him to do more than catch him—he had to pass him and beat him to the tape by the margin that Bragg had over him at the start, De Palma being 35 and Bragg 41.

Then came the thriller that spoiled the finish. There are conflicting stories as to just how this occurred. De Palma was trying to pass, and some say that just as he crept up to the rear wheel of the Fiat, Bragg swung over a trifle and the gray Mercedes ran into the rear of the red car. The Mercedes turned turtle and both De Palma and his mechanic, Tom Alley, were hurled to the roadside. The collision failed to disturb Bragg, who continued on his way, a certain winner now.

At the grandstand the 10,000 occupants of the seats were awaiting the finish and there was a dead silence when Bragg drove up slowly, came to a stop at the tape and whispered to Starter Wagner, telling him of the accident.

De Palma was not the only formidable rival Bragg had to dispose of. Tetzlaff as usual was a factor as long as he was running, just as he was in the Vanderbilt. Had his car stood up it is more than likely he, instead of Bragg, would have been the winner of the race. From the start the native son was aggressive, leading for the first nine laps, then dropping to second for five rounds, leading for two, second for four, leading for one, second for three and then going into the lead, staying there for six laps, when he went out in the thirty-first because of a broken radius rod. At that time he was 3 minutes ahead of Bragg and up to that time he had averaged 71.5 miles per hour. Tetzlaff made the fastest lap of the race—6:07 in the fourteenth, an average of 77.2 miles per hour.

From start to finish none of the other nine contestants had a look-in for first place.

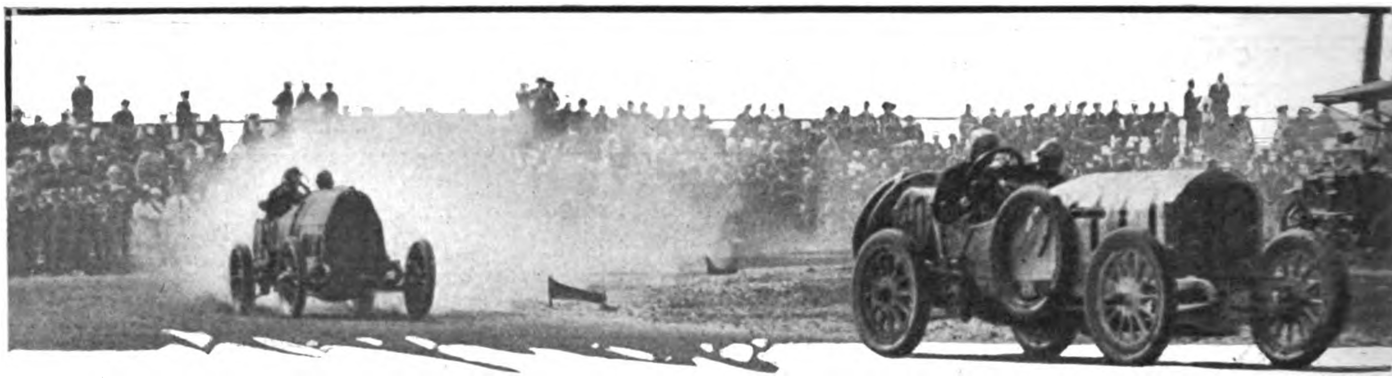
Bob Burman in the Benz went out in the third lap with a broken piston, but later on relieved Horan, his team mate, and was running at the end. Wishart in a Mercedes lasted into the fifth lap when a broken driving shaft retired him; Hughes in the Mercer quit in the seventeenth, giving a broken gasoline line as his excuse for docking his car; Fontaine, who took Nelson's seat in the Lozier, sprung a steering knuckle when he hit the straw pile on the city limits turn and he quit on the twenty-first lap; Tetzlaff went out in the thirty-first and De Palma on the fifty-second.

Standing out as a sterling performance was the work of the Stutz, driven by Gil Anderson, which was the only American car to finish. Mulford scratched his Knox because he could not get it into shape for such a gruelling grind, while both the Lozier, which was a private entry not backed by the factory, and the Mercer failed to finish. The Stutz ran consistently at all times, being in third place from the forty-fourth lap on and being beaten only 31 seconds by the big Benz driven by Bergdoll. At that it was the closest finish of the race. The Stutz averaged 65.5 miles per hour and had no mechanical trouble whatsoever, changing one tire and breaking a shock-absorber.

It rained Thursday and spoiled the small-car events, which were run, however, with only about 500 people looking on. Both the contests were made farcical by withdrawals and mishaps. In the Pabst trophy race for the 231-300 cars only two cars finished, Roberts' Mason and Hastings' Falcar, while in the Wisconsin cup Harry Endicott in a Mason was the winner with young Mason in a stripped Mason touring car second.

The Milwaukeeans now are figuring up how much it cost them to run the meet, but the outlook is much brighter than

Clark's Mercedes was still running when the race was called off



Bragg, Fiat, overhauling Bergdoll, Benz, on a sharp turn in the Grand Prix race on Saturday

anticipated. Because of the huge crowds of yesterday it is likely that Milwaukee will almost come out even, although it cost $70,000 to finance the meet, of which sum something like $28,000 was spent on the road. Undoubtedly Milwaukee would have been a big winner had it not been for its inability to collect from all those who witnessed the running of the grand prix. George Brown, one of the promoters, acknowledges now that a mistake was made in not giving property owners a percentage of the receipts as is done at Elgin. Not being financially interested, the farmers did not try to keep the crowds from getting in free. Indeed, it is related that at one of the farms the owner, armed with a shotgun, deliberately let the people onto his property at 25 cents per head and when the promoters tried to stop him he threatened to fire on them. Then again it seemed impossible to stop grafting.

Milwaukee is keen for next year's Vanderbilt and grand prix and has started negotiations to get the plums. The Badgers point out that before the next meet they will have an entirely concrete course and one that is much wider than at present. Two of the townships through which the circuit runs already have let contracts for concreting the road, while the association itself will pay for having the rest of the course fixed in a similar manner. This will require the dealers to rebuild about 4 miles of the course, but when it is done it is thought the circuit will be superior even to Santa Monica.

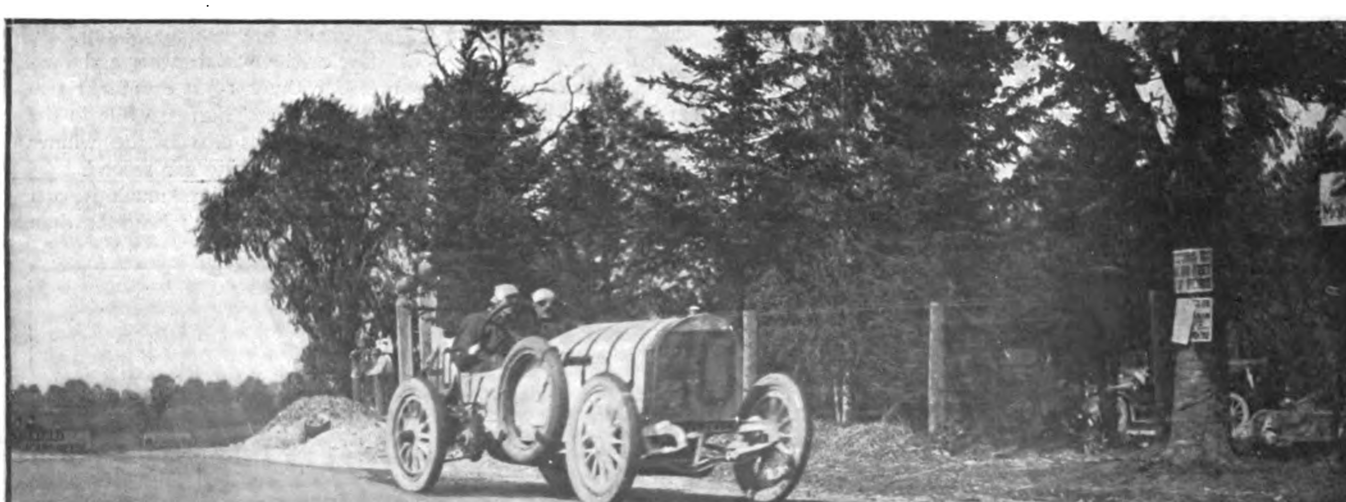
Reports from the Trinity hospital today are to the effect that De Palma passed a good night. The doctors so far have failed to find the fracture of the leg that first was reported and say that the chief injury is a punctured abdomen which is not at all terrifying. An operation was performed and it is expected that De Palma will be convalescent in a week or so. The mechanic, Alley, suffered a broken collar bone from which he will recover.

Very Little Tire Trouble

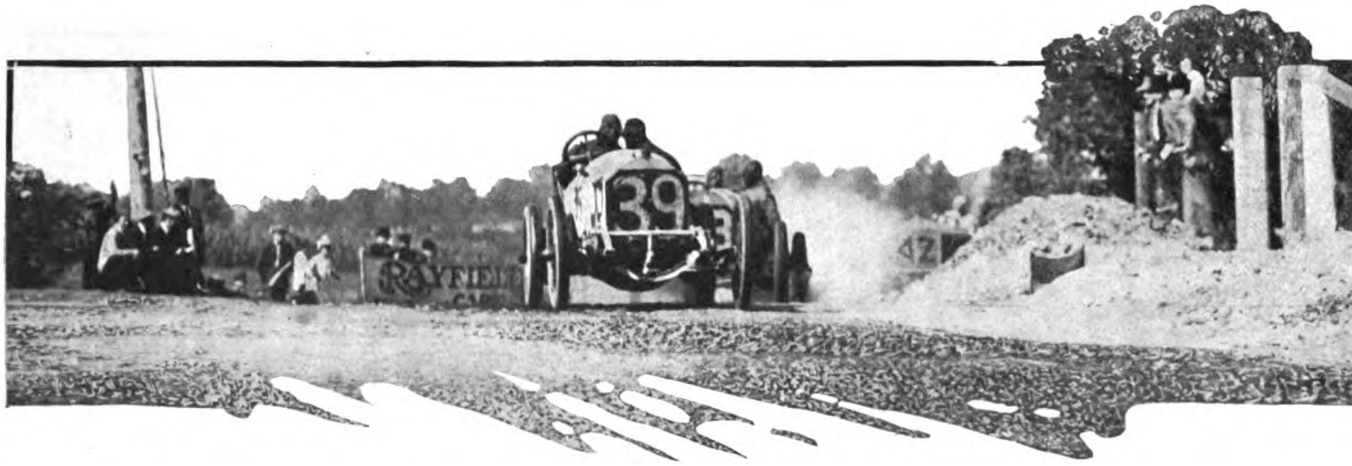
IN few of the big road races have there been so many different makes of tires represented as in the Milwaukee grand prix, and seldom has so long a contest been run with so little tire trouble. Michelin, Firestone, Miller, Goodyear and Fisk were represented in the grind. Bragg, De Palma, Fontaine, Wishart and Clark rode Michelins; Oldfield, Horan and Hughes wore Firestones; Tetzlaff had the Miller; Bergdoll the Fisk, and Anderson the Goodyear. Only twenty-four cases of tire trouble were reported.

"My count shows that Clark in the Mercedes went through without a change," says R. B. Tracey, manager of the Chicago Michelin branch. Wishart did not have any trouble, either, nor did Burman, but neither went very far. Bragg changed three shoes, De Palma two, Anderson one, Bergdoll eight, Fontaine one, Hughes one, Horan two and Oldfield three.

"Bragg used steel-shod tires all around, while De Palma had them only on the rear. The latter used the buffed tires in the Vanderbilt such as we made up for the 500-mile race at Indianapolis, and he had nine cases of trouble. For the grand prix I got him to use steel-shod tires on the rear and advocated them all around, but he wouldn't put them on in front. One of his changes was made on the road and the other, a front, at the pits. In the latter change he used only 28 seconds in switching. The tire Bragg changed in the pit was changed only as a precaution, for he really did not need a new casing. He was taking on gasoline and oil and improved the opportunity to also change the tire. The other change was made on the road. Passing the stand, the steel-studded strip on his left rear came off and he stopped in the back stretch to switch."



Erwin Bergdoll, who took second place, in his big Benz, rounding the Graveyard turn on the forty-sixth lap



Tetzlaff's Fiat crowding Clark's Mercedes in the Grand Prix race on the graveyard turn of the Wauwatosa course

Work Done at the Pits

ANNUAL grand prix races are unique from the standpoint of the observer of work at the pits, as they are international, while the others are national events. They are run therefore under the rules of the Automobile Club of America instead of the A. A. A., which governs the national contests. The A. C. A. rules do not permit the pit men to render any assistance to the contestants. That is, the driver and his mechanic must do all the work that becomes necessary about the car during the race. They must make all tire changes and fill oil, water and fuel tanks as well as make the actual mechanical adjustments. In the national races, pit attendants are permitted to change tires and replenish the supplies.

The fact that the drivers and mechanics were forced to do all the work about the car resulted in the stops at the pits requiring more time than is usual and probably cut down the average speed of the race quite materially. On the whole, however, the cars got away from the pits in shorter time than was to be expected under the circumstances, for the contestants worked like demons to cut down the time of the enforced stops. The grandstands had a chance to see the teamwork of expert racing drivers and mechanics.

When it was necessary to take on another spare tire to replace one that had been used at some other point on the course, the cars would come in to the pits with the drivers slackening speed while the mechanic was stretched over the tanks behind the seat, unbuckling the straps that held on the spare tires and would have them loosened up ready to slap on the new spares before the car came to an abrupt stop. Several times cars came pounding down the stretch to the pits for water with the mechanic stretched full-length over the hood, retaining his precarious position with one hand on the hood strap while with the other he removed the radiator cap in order to save as many precious seconds as possible.

The necessity for quick work at the pits resulted in several interesting arrangements for filling the fuel tanks. Bragg had the gasoline stored at his pit under pressure with a hose from the storage tank which was slipped into the fuel tank of his Fiat. Some of the others had small gasoline cans which could be up-ended into the tank without requiring a funnel. Two of the cars, the Stutz and Hughes' Mercer, were equipped with wire wheels in the hope of cutting down the number of tire changes and the time required to make them. Nor was any time lost in stopping and getting under way again, for the mechanic usually had leaped to the track before the car had come to a stop and nearly always had to make a flying leap to regain his seat after the driver had started.

Pit stops on the whole were fewer than were to be expected in a race of 410 miles at the speed maintained Saturday. There were in all thirty-eight, three of which were permanent, the cars withdrawing from the race, and can hardly be counted. Of the thirty-five temporary halts, only six were for tire replacements alone, although in twenty of them advantage of the enforced stop for other causes was taken to replace worn tires or spares, or other things were done when tire changes became necessary. As might be expected, the majority of the tire

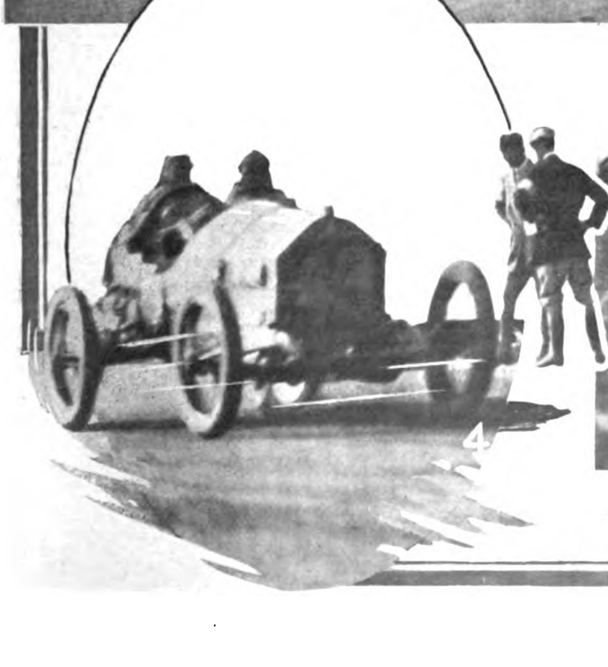
2—Hughes in Mercer Special, winning second place, less than a minute behind De Palma. His speed was 68.8 miles per hour

3—Wishart in Mercedes on backstretch. He won third place at a speed of 64.9 miles per hour



4—Anderson in his Stutz winning fourth place at 64.2 miles per hour

5—Nelson in Lozier, who made twenty-six laps of the course

Pope Earnings $251,290

Gross Receipts During Fiscal Year Amounted to $3,734,112—New Truck Is Success

Final Plan of Reorganization Adopted By U. S. Motors—New Securities to Replace Old Stocks

THE annual report of the Pope Manufacturing Company for the year ending July 31 has been issued. It shows that the company has enjoyed net earnings during the past year amounting to $251,290 on a gross business of $3,734,112.

According to President Pope's report, the assets of the company consist of the following items:

Real estate, patents, good will, etc.	$5,781,293
Construction	36,276
Additions, adjustments and installation	243,681
Cash items prepaid	534,177
Inventories	1,477,312
Good accounts	396,608
Cash and cash items	253,829
Total	$8,723,176
Less deductions for reserves, replacements, etc.	440,998
	$8,282,178
The liabilities are as follows:	
Capital stock issued	$5,989,000
Two-year 6 per cent. gold bonds	1,000,000
Accounts payable, payrolls, deposits, etc.	260,098
Contingent liability	20,159
Surplus, 1911	936,430
Net earnings, 1912	251,293
Total	$8,457,070
Less dividends	174,892
	$8,282,178

The surplus of the company stands over $1,000,000 after writing off $440,000 for reserves and for future replacements, scrapping of machinery and deterioration. No doubtful accounts are included in the statement.

The company paid 6 per cent. on its preferred stock and made one payment of 1 per cent. on the common.

President Pope says that the plants have been kept in the most efficient condition and the cost of up-keep charged to operations. The inventory was made at actual cost and the item of accounts payable covers invoices that had not matured on July 31. All bills have been discounted.

The truck has met with success, according to the report and a 5-ton model will be added to the present output of 3-ton commercial vehicles.

U. S. Motors Plan Settled

The plan of reorganization of the United States Motor Company has been settled.

All the existing securities of the company amounting to about $11,500,000 of preferred, $12,200,000 common and $6,000,000 debentures will be wiped out and new securities will be issued in their places. In addition, $13,000 of the preferred stock of the Columbia Motor Car Company and $118,000 of the common will be subjected to the same treatment.

The basis of the new issue will be an assessment of $24 a share on the common and preferred stocks of the United States Motor Company and the Columbia company as outlined. The total capitalization will be scaled down as follows:

For and in consideration of the payment of $24 a share, the new company will issue in exchange for the preferred certificates, 24 per cent. of new first preferred, 25 per cent. of second preferred and 30 per cent. of common.

For the common certificates outstanding on payment of the assessment of $24 a share, the new company will issue 24 per cent. of first preferred, 17.5 per cent. of second preferred and 30 per cent. of common.

This assessment means that the new company will start out with a clear capital for working operations of about $3,000,000.

It is proposed to raise by this method the sum of $5,720,000. The remainder will be used for funding the matured obligations.

At this time there is still remaining in the treasury of the company the sum of $1,000,000. The disposition of this fund was one of the chief matters in contention in the deliberations of the merchandise creditors. At first it was proposed that the creditors of the various companies that had supplied parts, materials, etc., should not receive any cash allotment. Then the proportion offered was raised to 10 per cent. Neither of these early proposals was considered as equitable by the creditors and a counter demand was made for 30 per cent. This was refused by the general creditors, including the banking claim-holders and a compromise was reached by which the merchandise creditors will receive 25 per cent. of their claims in cash; 25 per cent. in first preferred, 25 per cent. second preferred and 15 per cent. in common, thus making a settlement of approximately 90 cents on the dollar.

The return day of the suit filed in the United States District Court has been fixed as October 28 and it is considered likely that the plan will be approved as presented and the embarrassment of the company relieved at that time.

To Build Knight Motors for Trade

The F. B. Stearns Company, Cleveland, O., has announced that it is prepared to manufacture Knight type sleeve valve motors for the trade.

When the Knight licenses were first granted to American manufacturers, the Atlas Engine Works, of Indianapolis, succeeded in securing one of them, the understanding being that they were to build motors for automobile manufacturers. As soon as this

Automobile Securities Quotations

Automobile and accessory securities were dull and featureless in the markets as a general thing throughout the past week. The one spot that had some appearance of life was International Motors common which broke sharply at the same time that the dividend was paid on the preferred shares. The volume of selling was not large but the market was not well supported and was marked down rapidly under small offerings.

announcement was made the Atlas people booked an enormous number of orders for motors, and up to the time of the failure of the Atlas Engine Works a number of prominent American manufacturers planned to use Atlas-Knight motors. With the failure of this pioneer firm, however, the car manufacturers who had so confidently counted upon using the Knight type motor were left stranded, and for some time speculation has been rife as to where they would turn for motors, inasmuch as no more licenses are to be given out in America to manufacture motors direct.

The Stearns people, under their agreement with Knight & Kilbourne, have the right to manufacture motors for the trade, and they have been laying plans for the past 6 months to put this idea into force.

Atlas Attached for Accessories

SPRINGFIELD, MASS., Oct. 7—The Atlas Motor Car Company, of Springfield, Mass., which was forced to suspend operations some weeks ago because of the failure of the Atlas Motor Car Company in the West, preventing the former company from securing motors, has been attached again. Three suits were filed against the company during the week. The Hampden Brass Company, of Springfield, Mass., filed an action for $1,500; the R. E. Dietz Company, of New York, one for $200 and the Firestone Tire & Rubber Company, Akron, O., one for $200 also.

The Havers Motor Car Company, Port Huron, Mich., has just closed its fiscal year, which is the second year it has been engaged in building the Havers six-cylinder car and have declared a stock dividend of 40 per cent. and a cash dividend of 5 per cent. This pleasant news to the stockholders came on the completion of an audit by R. H. Hollis & Company, chartered accountants of Detroit.

Market Changes for the Week

The most important changes in the market during the past week was the gain in price of Bessemer steel and open-hearth steel. Both rose $1.00, closing on Tuesday at $25.00 and $26.00 respectively. Up-river Para rubber experienced a decline of $.02 owing to the annual auction of plantations. Tin dropped in price to $4.97, a loss of $.06 per hundred pounds, caused by the freer offerings by speculators. Copper and lead remained at their old quotations. Antimony and beams and channels were constant throughout the week.

Will Reorganize Knox

Tentative Plan Is to Sell the Property to a New Corporation, the Knox Motor Car Company

To Fill Present Orders Factory Must Be Operated for 4 Months—W. E. Wright Resigns

SPRINGFIELD, MASS., Oct. 5—The outlook for the Knox Automobile Company, of this city that made an assignment to Edward O. Sutton and Harry G. Fisk last week for the benefit of its creditors looks much more hopeful now than it did a few days ago. Edward O. Sutton today made an emphatic denial of the rumor that 130 men had been discharged and that the pay-roll had been cut down one-half. He stated that the company had started along the lines of intrenchment, and so it had been necessary to lay off eighty-five employees. According to Mr. Sutton, who is the superintendent and general manager, and therefore knows the real facts, the number laid off represented but 20 per cent. of the force instead of fifty as alleged. He was not prepared to say what further reductions might be made for it all depends upon business conditions.

Mr. Sutton stated that the prospects are more encouraging than could have been expected for the continuation of the business. He pointed out that at the time of the assignment there were orders on the books for seventy-one vehicles, and since that time eight more were received, two of which reached the company yesterday. To fill these orders it will be necessary to operate the factory for at least 4 months, and as the indications are that the business will be coming in as usual no necessity for a shut-down is expected.

Agents and old customers have been sending in letters to show their loyalty to the company, assuring the firm of their continued business and support. In addition to this the majority of the creditors have not been inclined apparently to press their demands, and this friendly attitude gives a brighter outlook for the future operation of the plant. Some thousands of dollars are owed the company in many cities and towns and it will eventually be paid, but the collection of these debts takes time and the pressing demands are ready cash for working capital.

Plans for the reorganization of the company have not been completed yet, but they are under way. It is the wish of the officials to continue operation until capital can be interested. The support of the Board of Trade will be solicited to aid in the reestablishment of the company on a sound basis and this will be of much help. Mr. Sutton stated that by figuring in the real estate owned by the company the assets would amount to more than the liabilities and that this would be of much value in bringing about a plan for continued operation. He added, however, that the officials would be willing to sell outright if a fair price could be secured.

SPRINGFIELD, MASS., Oct. 9—Trustees of the Knox Automobile Company have announced that negotiations are under way to reorganize the company. The tentative plan under consideration is to sell the property to a new corporation to be known as the Knox Motor Car Company. Details of the plan have not been outlined so far to the public.

W. E. Wright, vice-president and general manager of the Knox Automobile Company, Springfield, Mass., has resigned as one of the results of the financial embarrassment of the company and the new management. Mr. Wright has been a prominent figure in the automobile world for a number of years. His plans for the future have not been announced.

Exports At High Level

July Report Shows 50 Per Cent. Increase Over Last Year and 65 Per Cent. 7 Months of 1912

WASHINGTON, D. C., Oct. 7—Reports for July of the Department of Commerce and Labor, bureau of foreign and domestic commerce, show that the value of domestic automobiles and automobile parts exported from the United States is steadily growing. The total for July, 1912, was $2,096,933, as compared with $1,360,089 in July, 1911. The total for the seven months ending July, 1912, was $18,311,925, as against $11,096,271 for the 7 months ending July, 1911.

The bulletin shows that in July, 1912, the value of automobiles and parts imported was but $173,261, as compared with $197,451 in July, 1911. The total for the 7 months ending July, 1912, however, is somewhat larger than for the same period in 1911, although a big falling off for 1912 is shown by comparison with the same period in 1910.

Under the heading of exports of foreign merchandise from the United States it is shown that but three automobiles, of a total value of $7,000, were exported in July, 1912, as against six machines of a total value of $12,095, in July, 1911.

Rubber Show's Daily Attendance 3,500

WITH a banquet held at the Plaza Wednesday night and an auction of the prize-winning plantation rubber exhibit at the Grand Central Palace, on Thursday, the Third International Rubber Exposition came to an end. It was a big success in its way, although compared with the attendance at an automobile show the crowds were small.

The banquet was attended by representatives of the rubber industry in the United States as well as the exhibitors at the show, the exhibitors numbering about 120. John Barrett, director of the Pan-American Union, was a guest of honor as was also Baron da Gama, Brazillian ambassador. Mr. Barrett said that the world was just entering an era of tremendous development that will see typical expression in the rubber industry. Baron da Gama said that Brazil as the largest producer and the United States as the largest consumer of rubber would inevitably be drawn closer together in a commercial sense.

The crude rubber shown in the Brazilian space at the show was all sold to American manufacturers before the show opened, the prices ranging up to $1.15 a pound for up-river fine and correspondingly lower for the other grades on exhibit. The total amount of the sale was not announced. The plantation rubbers shown by Ceylon and Malaya, amounting to something under 30 tons, brought an average of $1.10 1-2 a pound, the top of the market being for the gold medal winning lot, $1.19 a pound.

The attendance at the show, including all visitors, averaged over 3,500 a day. This would make the total 31,500.

N. A. A. M. Elects Seven Members

The following companies have been elected to membership in the National Association of Automobile Manufacturers: Borland & Grannis Company, Flanders Electric Company, Speedwell Motor Car Company, Michigan Buggy Company, McFarlan Carriage Company, Argo Manufacturing Company and the Broc Manufacturing Company.

Past Fortnight Showed Big Car Shortage

According to the fortnightly bulletin of the American Railway Association for the period ending September 26, there was a net shortage of freight cars in the United States of 17,790. This is an increased net shortage from September 12 of 9,170 cars. Along in March of this year the unofficial figures showed that

there was no surplusage of cars during one fortnightly period but later the official figures revealed the fact that the actual surplus was 3,043. At the time the condition shown was a record of railway activity but the September showing sets an entirely new mark.

At this season of the year the shortage of freight cars is not so serious to the automobile industry as it would be in the shipping season. The cause of the present condition is the extraordinary movement of the great crops, together with general activity of business in other lines.

The prospects for the next few reporting periods are for a steadily increasing shortage, not only due to the crop movement but also chargeable to the coal mining industry, which has made new high marks all along the line. It is said that the probabilities point to the crest of the movement in November, after which the volume of shipment will gradually recede until March.

At this time last year there was a net surplus of over 50,000 cars.

S. A. E. Made $3,499 in 1912

According to the report of the Finance Committee of the Society of Automobile Engineers, submitted to the organization at the last meeting, the income of the society during the past fiscal year was $27,388 which is about $2,700 less than was contemplated in the budget. The expenditures amounted to $23,888, which is $561 less than was provided in the budget for the year.

The expenses were divided into salaries, $8,123; interest on notes, $160; office expenses, $7,259; publications, $5,674; other expenses, $2,671.

The budget for 1913 amounts to $30,000, the principal increases over the past year being in the items of postage, publications and reserve for doubtful debts.

The profits for 1912 amounted to $3,499, taking up the deficit of 1911 and leaving a surplus of over $200.

The fiscal year of the Society of Automobile Engineers ended October 1 and a preliminary statement of the membership growth of the organization shows that 505 members were added during the past season. On October 11, 1911, the S. A. E. had 900 members of all grades. On October 7, 1912, the roll had been increased to 1,405 and there is a list of applicants numbering fifty-five persons, which will be acted upon at the forthcoming meeting of Council.

While members are elected to the society at all times during the year, its period of greatest accessions is from October 1 to January 1, owing to the operation of the by-law which provides for no division of the dues charged to new members.

Big Show Indicated for Chicago

Chicago show allotments made by the N. A. A. M. last week forecast the largest automobile show ever held in the Windy City. While the total number of companies supplied with space on first allotment was slightly less than the total exhibit of last year, the overcrowding in some parts of the show building will be corrected by enlarging the spaces, thus accounting for the difference. At that, there are a dozen applicants waiting for space.

The number of pleasure vehicle companies is about equal to last year, the decrease so far being noted in the commercial vehicle section of the show. All the standard companies are represented, the absentees being mostly defunct.

Honors for Alco Truck Crew

Honors for the crew of the Alco transcontinental truck were paid October 7 when a formal dinner was tendered by the American Locomotive Company to the travelers, E. L. Ferguson, Frank Morin, Walter Dick and John Cambon. There were about sixty-five persons in the party. Harry S. Houpt, sales manager of the company made the address of welcome. George L. Sullivan acted as toastmaster.

Coroner Blames the Road

Investigating Death of Bruce-Brown, Official Finds Milwaukee Course Too Narrow for Safety

MILWAUKEE, WIS., Oct. 8—*Special Telegram*—The verdict of the coroner on Bruce-Brown's death today, holds no one to account but blames the condition of the course for the accident. It says if the course had been constructed on more solid foundation, if the crown had been smoother and harder, the course wider and the edges more even, the catastrophe might have been avoided. It recommends that the American Automobile Association be compelled to formulate laws governing the construction of road racing courses which must be at least 6 months old. Must have roadway of at least 25 feet, every foot usable; must have proper physical position edges; must be surveyed, the crown smooth, hard and even, and curves built to a safe angle. It also recommends the appointment of a commission of competent drivers and road constructors to inspect track as well as racing machines before racing is permitted on any given course.

Scudalari, Brown's mechanic, died Tuesday. Despite a deficit between $17,000 and $30,000, Milwaukee dealers will ask to run the four races again next year. The coroner's inquest testimony showed $40,000 were expended on construction of the course.

Despite announcements made in the press that a contract has been made between the Milwaukee Automobile Dealers' Association and the Motor Cups Holding Company which controls the Vanderbilt Cup and the Grand Prize Gold Cup, providing for the holding of the classic American road races at Milwaukee for a term of years, the report is flatly denied by William K. Vanderbilt, Jr., of the holding company, donor of the Cup.

MILWAUKEE, WIS., Oct. 9—*Special Telegram*—Ralph De Palma's condition this morning was reported to be favorable at Trinity Hospital. The crisis has not yet been reached but his physicians are hopeful of recovery unless further complications arise. Tom Alley, De Palma's mechanic left the hospital Sunday.

18 Elected Members of M. A. M.

The following new members have been elected to the Motor and Accessory Manufacturers:

Bijur Motor Lighting Co.—Manufacturers of electric generators for automobiles and motor boats, etc., 250 W. 54th St., New York, N. Y.

Endurance Tire & Rubber Co.—Manufacturers of Automobile Inner Tubes, 1789 Broadway, New York, N. Y.

Edward G. Budd Mfg. Co.—Manufacturers of steel bodies for automobiles and for auto-trucks, 807 N. American Building, Philadelphia, Pa.

Brown & Sharpe Mfg. Co.—Manufacturers of gears and transmissions, Providence, R. I.

Hartford Machine Screw Co.—Manufacturers of spark plugs, automatic tire pumps and all manner of special turned parts used in automobile construction, as well as screws, bolts, nuts, taper pins, etc., Hartford, Conn.

The Simms Magneto Co.—Manufacturers of magnetos, carburetors and spark plugs, 1780 Broadway, New York, N. Y.

Ignition Starter Co.—Manufacturers of gas and electric starters, electric generators, 264-268 Jefferson Ave., Detroit Mich.

Walpole Rubber Co.—Manufacturers of automobile tires and tubes, mechanical goods and accessories, 757 Boylston St., Boston, Mass.

New Jersey Car Spring & Rubber Co.—Manufacturers of casings and inner tubes for automobiles; hose, belting, packing, valves, mats, mattings, moulded springs, tubing and general mechanical rubber goods. Wayne and Brunswick Sts., Jersey City, N. J.

The Hess Steel Castings Co.—Manufacturers of wrought iron and steel castings, Bridgeton, N. J.

Schoen-Jackson Co.—Manufacturers of Feps carburetors and Schoen-Jackson flexible metallic tubing, Medina, Pa.

Gould Storage Battery Co.—Manufacturers of storage batteries, 347 Fifth Ave., New York, N. Y.

New Miller Carburetor Co.—Manufacturers of carburetors, 512 N. Capitol Ave., Indianapolis, Ind.

Marathon Tire & Rubber Co.—Manufacturers of pneumatic tires and tire accessories, Cuyahoga Falls, Ohio.

The Electric Auto-Lite Co.—Manufacturers of electric lighting and starting devices for automobiles, 133 Michigan Ave., Toledo, Ohio.

Baldwin Steel Co.—Manufacturers of Clay crucible steel castings, high-speed steel, tool steel, magnet steel, automobile steel, roller bearings steel, 30 Church Street, New York, N. Y.

Pittsburg Model Engine Co.—Manufacturers of gasoline engines, transmission and clutches, Pittsburg, Pa.

Garage Equipment Mfg. Co.—Manufacturers of auto accessories, 742-48 S. Pierce St., Milwaukee, Wis.

Salesmen Experts Gather

Convention at Indianapolis Attracts the Attendance of 400 from the Ranks of the Automobile Industry

INDIANAPOLIS, IND., Oct. 8—**Special Telegram**—Four hundred automobile dealers, members of the selling organizations of the automobile concerns of the country, and advertising agents, gathered in the auditorium of the Claypool Hotel, this city, at the opening session this afternoon, of the first general sales convention of automobile dealers, following a luncheon tendered to the visitors by the Mahin Advertising Company. Many prominent automobile dealers, manufacturers and advertising men are here for the 2-day meeting believing that the future of the motor car industry hinges upon the sales education of the dealer and on the ability of both the selling organizations and advertising departments to intensify retail sales. Men in this field of the industry responded eagerly to the suggestion of J. J. Cole, of the Cole Motor Car Company, that a convention of this nature be launched in Indianapolis, second only only to Detroit in the automobile field.

Intensity is the slogan of the gathering. Naturally, everything rests with the dealer, for if he fails, all fail. And, so, the main objects of the convention are to teach the dealer how best to increase his sales, and to impress upon him the need for absolute co-operation with the factory whose car he sells.

Almost all American cars of today are good ones and will stand rigid investigation, and it only remains to get them before the people in a business-like way.

An enormous growth of the motor car industry should result from the present concerted movement for a combined effort to sell machines to the people.

W. D. Nesbitt presided at the session, during which six speeches were heard, the first of which was an address of welcome by J. J. Cole in behalt of the city of Indianapolis. "The idea of helping the dealer in all his problems is worthy of all the effort the car manufacturer can give," he said. H. O. Smith, president the Premier Motor Mfg. Co., was the next to talk. "The selling problem is the big one, not only with the automobile but with every branch of business," he said. "A good dealer can hold up a poor car a good while, but a poor dealer cannot uphold a good car very long." Mr. **Smith stated emphatically that there is nothing today which even promises to rival the automobile as a solver of the transportation problem. To increase sales, educate the salesmen. It is most important for the dealer to select the best selling line for his particular territory. Further, he must have confidence in his line, else he cannot hope to enthuse his prospects over what he has to sell.**

C. F. Kettering, of Dayton, O., spoke on some of the human interest sides of salesmanship. "Automobiles have become so common," he said, "that we have slipped somewhat away from calling to the attention of him, who does not know about such things, what wonderful pieces of mechanism they are. Thousands still look upon them as experiments and to sell to such it is necessary to get them interested in the motor car development. Relate in a human interest way the story of the manufacture of a tire, of a gear, or of any other part of the car make up, and you have the man interested. Do not say that he must lubricate a certain part, but show him the result of not doing so. Get the novice to understand the mechanical reasons for doing this or that, and you not only have a satisfied customer, but he will return to you when in the market again."

Leroy Pelletier of the Flanders Company gave a most entertaining talk on the co-ordination of advertising and sales. He is strongly in favor of conventions such as this. The main idea of the gathering is for every man to learn to get in and boost for the product in the sales of which he is interested. The company competitor who gives him the greatest run is the one he admires most. Mr. Pelletier believes that when we get a perfect co-ordination between the advertising and sales ends of a concern, there is nothing which that concern cannot do. It is hard for the dealer to realize that the national advertising campaign is for his benefit, but this is the case, although it is a selfish interest which the car maker has in him for dealers' sales mean factory sales. It is important for the dealer to know just what has been said in the advertising, otherwise he cannot talk intelligently to those who come in response to such advertising.

There is not a large percentage of good salesmanship in the automobile business according to Pelletier. The adding machine and the cash register salesmen are much better at it, for the only reason which the factories will recognize for not securing an order from a prospective customer is the death of the customer.

The repair man should be a consummate salesman and not a knocker, as is too often the case.

Speaking further of the convention, he said that the idea cannot fail because it is a good one. Next year the attendance will be much greater.

Charles A. Bookwalter, ex-mayor of the city, was the next to speak. He traced the evolution of the automobile from the ancient means of transportation down to the present almost perfect car, he characterized the automobile industry as being one of the great strong, red-blooded businesses of today. It is so great as to be inestimable in dollars and cents. It has been for many years the backbone of the industrial growth of Indianapolis, and in 1907 was the one thing which prevented the panic of that year from seriously affecting the city. He also advocated the boosting of the products of others, for by so doing confidence in the products of all makers is infused in the minds of the buying public. Mr. Bookwalter also talked on good roads and their value to the farmer. It is the accessibility of lands to markets that fixes the value of such lands, and there is nothing which offers such accessibility as good roads and automobiles in addition to electric railroads. Good roads are also educational for they offer a means of getting about and seeing what is going on in the world.

There is no one in the industry who would not benefit by Carl G. Fisher's proposed trans-continental highway.

Elbert Hubbard, of East Aurora, N. Y., was the last speaker of the day, his topic being "Ideal Salesmanship." He was glad to see harmony and good fellowship displayed at such a convention. A few years ago automobile salesmen had trade secrets, but today they are all pulling together for the common good. Mr. Hubbard said, "When you sell a man a car you do him a favor, for you give him an opportunity to get out into the great out-of-doors, which is to his advantage."

At 5:30 a speedway dinner was given to the visitors in the banquet hall of the Claypool. Following the dinner the crowd marched to Thompson Hall where Elbert Hubbard again talked, on "Sentiment in Business."

On Wednesday morning the convention will convene at 9:30, at which session talks by John G. Jones of the Alexander Hamilton Institute, New York, on "Headwork in Salesmanship"; T. J. Zimmerman, Chicago, on "The Opportunity of the Motor Car Dealer"; John L. Mahin, Mahin Advertising Co., on "How to Use Advertising in the Retail Game"; B. F. Lawrence, Indianapolis, on "How to Get the Co-operation of Your Local Newspapers," and John Wetmore, New York *Evening Mail*, on "How to Spend Your Advertising Appropriation," will end the business of the unique convention, which bids fair to be held again next year.

Ready Graphic Method for Finding Proportions for Intermediate Gears Giving Most Convenient Operation and Best Utilization of Power—Summary of German Army Experience with Trucks and Trailers Expressed in New Rules

FREIGHTER'S Equipment on Army Plan—The demands of the German military authorities with regard to the construction and equipment of motor trucks with trailers which are to be accepted as suitable for the freighting work of the army in case of war, and which on this basis are to be subsidized while used for private purposes in time of peace, command a widespread interest in so far as they exemplify a full set of rules by whose observance it is believed that a maximum of reliability—with some sacrifice of other considerations—in heavy freighting by motor power may be secured. The rules are expressed partly in the legislative traffic regulations of the empire, to which all vehicles must conform, partly in drawings which illustrate types of construction and which are kept on file in the experimental department of the general staff, and, finally, in specific rules. The drawings and the rules are changed from year to year to keep pace with increasing experience and technical progress. The new rules, which begin to apply to vehicles submitted for approval after April 1, 1913, have just been published and comprise 90 paragraphs. They refer only to trucks intended to be used with a trailer, for the so-called army freight train, in the heaviest hauling service, and this work presents some parallels with the requirements in that extension of railway freight service by means of motor trucks and trailers which is said to be contemplated in the United States in several instances, as well as with private heavy freighting in the Far West and in the Canadian Dominion. The following brief extracts from these provisions may be of interest:

EXTRACT OF RULES FOR 1913

The army train consists of one motor truck and one trailer. [It has been found impracticable, so far, to use more than one trailer.]

The truck must be capable, winter and summer, with two men up, full equipment (as specified in other rules) and a payload of 4,000 kilograms (4 long tons) to draw a trailer with one man up, full equipment and 2,000 kilograms payload over hard roads with grades of up to 1 in 7.

The vehicle speed at normal maximum motor speed must not exceed 16 kilometers (11 miles) per hour, subject to a 15 per cent. increase by use of the accelerator, the action of the accelerator pedal being limited by a governor. The operation of the vehicle must be as noiseless as the state of the art permits Double spring suspension of the axles is desirable (meaning an extra set to go into action for heavy loads).

The weight of the complete vehicle must not exceed 4,000 kilograms, including its normal equipment, spare parts, etc., and must not exceed 8,000 kilograms with load and crew. The rear axle load is limited to 5,500 kilograms. The width of the vehicle must at no point exceed 2 meters. The track is limited to 1.55 meters, the wheelbase to 4.5 meters. The wagon box must have a volume capacity of at least 6 cubic meters and must not be more than 3.6 meters long. Rear and side boards of the box must be hinged at the floor level, opening outward and downward. To protect the load, removable iron tilts, affording a waterproof roof, must be attached to the top of the wagon box by means of staples, rings, chains and lock. The total height from the ground must be within 4 meters.

Three commodious seats for the crew must be protected against the weather. A removable dustshield is to be arranged between the truck and the trailer to protect the brakeman of the latter. A reliable signaling device for mutual use between the truck driver and the brakeman must be provided. Every part of the loaded wagon, excepting only the wheels and steering knuckles, must be at least 28 centimeters (11 1-5 inches) above the ground. The tie rod of the steering system must be behind the front axle.

The fuel feed may be by gravity (but not affected by a grade of 1 in 7) or by pressure. If exhaust gases are used, the valve regulating the pressure must be of a prescribed pattern (drawings on file). Noise from the exhaust must be reduced to a minimum. A cut-out close to the motor and controlled from the driver's seat is to be so attached that it may be removed in case of war. Lost motion in the steering system must be reduced to a minimum by suitable construction.

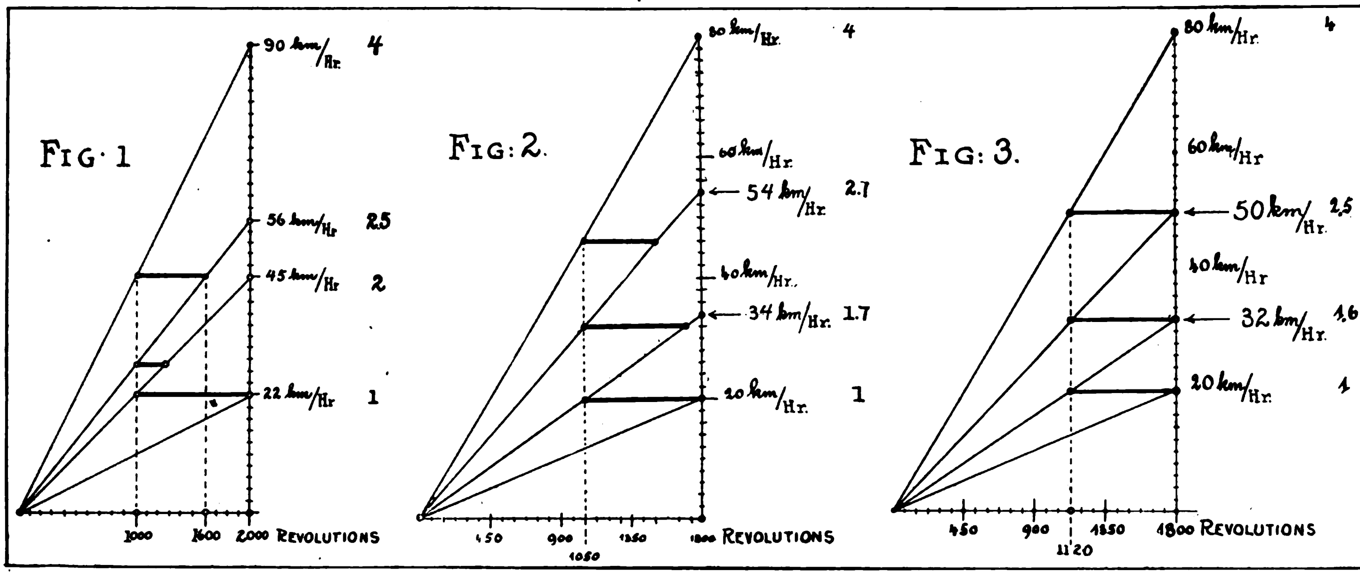
Rear wheel brakes must be compensated, internal and lockable. In a chain-driven truck the brake drum should be 450 millimeters (18 inches) in diameter and 80 millimeters (3 1-5 inches) broad. The transmission brake must be water-cooled and actuated by a pedal. It shall be possible to brake the trailer from the truck driver's seat. To this end a crank to the left of the latter connects with a rigid rod extending rearward under the middle of the truck and connecting by easily removable chain attachment (of a prescribed pattern) with the brakes of the trailer.

A two-armed sprag must be mounted so as to be secure against being overrun by the vehicle. When it is drawn up, its lowest point must not be below the rear axle. A lettered device on the dashboard must always show the position of the sprag. The sprag of the trailer must be so connected with the truck driver (in a prescribed manner) that he can work it.

The design of the coupling between truck and trailer is specially prescribed. It is at a height of about 32 inches, cushioned against both pull and thrust and so dimensioned that there is a distance of 12 inches between the nearest parts of the two vehicles when the trailer stands at right angles with the truck. The truck must be able to turn on a radius of 6.5 meters for the inside wheels. To safeguard driving on icy, snow-covered and slippery roads only solid-rubber tired wheels are allowed, and these must be provided with facilities for the attachments of traction chains, especially a sufficient number of lugs or pins projecting laterally from the felloes. The wheels must be of steel.

The front wheel tires must be 830 millimeters in diameter and 120 millimeters broad, and the rear tires 1,030 to 1,040 millimeters in diameter and either 280 millimeters broad with a deep central groove (prescribed design) or of the twin type with each tire 140 millimeters broad.

On the front member of the frame there must be two strong



Figs. 1 and 2—Diagrams of unsatisfactory gear proportions in four-speed cars with high and low gears in 1 to 4 ratio. Fig. 3—Diagram of correct gear under similar conditions

hooks for drawing the whole train of truck and trailer out of a predicament and at the rear similar hooks for the attachment of the trailer. Large sandboxes must be secured to the frame in front of the driving wheels with convenient arrangements for filling and discharging. There are further to be secured to the outside of the vehicle, with easy access from the outside, a box for traction chains, a toolbox, a baggage box and a box for firearms. The box for chains must have a perforated bottom to permit water to drain off; the others must be tight and lockable.

The motor hood must be provided with a lock and must not shut off the view of the road more than is unavoidable. Gates in the crankcasing must permit the handy replacement of connecting rod bearings. The carbureter must function properly with benzol and benzine (gasoline) of any grade as well as with other equivalent fuels. An arrangement must be provided for the use of heavy fuels which do not ignite easily. Ignition must be by high-tension single-spark magneto easily replaceable. A spare magneto must be supplied and carried. An electromagnetic motor starter which can be operated by hand must be secured to the dash, or else an equivalent device. Lubrication must be by force feed with an indicator observable at night as well as in the day time; for which purpose a lamp must be provided. The amount of oil used must be so large that its temperature will never rise above 80 degrees centigrade. Its fluidity during cold weather must be secured. The water in the radiator must never boil or run over. All low points in the water system must have drains. The connection hose must be of 22, 30 or 40 millimeter inside diameter. The fan must be driven by belts of at least 32 millimeter width.

The clutch must have an external leather facing at least 60 millimeters broad. The possibility must be established of mounting upon a shaft which revolves at the same speed as the motor shaft two separate belt pulleys of each 300 millimeters (12 inches) diameter and 80 millimeters width. The change-gear, of the sliding-gear type, must be stamped to show the lever position for each gear. Clutch and brake pedals must be independent. The gears must at normal motor speed give the following vehicle speeds: Low gear, 3 to 4 kilometers; second, 5 to 7 kilometers; third, 9 to 13 kilometers, and high, 16 kilometers. [It will be noticed that these gear ratios do not correspond very closely with those indicated as correct by Von Löw in the preceding article.—Ed.] Departures within 10 per cent. of this schedule are allowed.

The drive system—by shaft, chain or worm—is optional, but if chains are used the pattern is prescribed. The distance from the central plane of tires to that of chains should be 225 millimeters (9 inches). Sheet iron shields should be attached between the wheel fellies and the chains to protect the latter against the coarsest dirt and to prevent interference with the traction chains. Closed chain casings may be allowed on application, but must be easily removable, and shields are in such cases to be supplied as spare parts. The screw threading of the chain adjuster must be protected against rust.

—

Most of the remaining provisions in the new rules relate to the equipment and to the details of the trailer.—From *Zeitschrift des Mitteleuropäischen Motorwagen Vereins*, middle of September.

—

PROPER Proportions of Gear Speeds—The highest and the lowest gear speeds of an automobile are determined by the demands to be made of the vehicle. The required capacity for climbing hills must decide the low gear and the required maximum speed on the level decides the high gear. In this the consideration of variable loads is to be included, of course. The selection of the intermediate gears, however, should properly be decided mathematically when the extreme gears have been chosen. But a review of the gears actually used in German cars of 1912 manufacture reveals many variations from the proportions which should be observed, and these variations in every case involve a loss of convenience in managing the car. [The author here gives a tabulation of the gears in many German cars.—Ed.] When a builder is asked why he makes the interval between the high speed and the third speed greater—as he usually does—than between the third and the second, the answer is frequently that nowadays, with direct drive on the high speed, there is a saving of power from doing away with gear friction on the high speed which justifies this arrangement, but this is not in reality the most important reason for dividing the gear ratio unevenly. The author can offer a better one from his personal experience. He has driven two H cars and three A cars about 30,000 kilometers. One of the H cars weighed with normal load about 1,200 kilograms; the other H car and the three A cars 1,400 kilograms. The gear ratios were in the H cars 1—2—2.49—4 and in the A cars 1—1.7—2.7—4.

With the H cars it was always pleasant to go from the fourth to the third gear. After the third gear was in the car jumped right ahead. But in going from the third to the second the motor would hang back and, as a rule, it soon became necessary to go from it to the low. The second speed was consequently very little used with these cars; this result was unavoidable with the lighter car of this type as well as with the heavier one, which both had the same reduction (1 to 3.2) in the rear axle. Probably for this reason the builder of these cars chose the second speed considerably lower, as mentioned above, in the A cars which he built later. On the other hand, while the H cars pulled excellently on the third speed, the A cars do not share this property, although their gear ratio for the third speed really does not lie much higher than in the H cars. With the A cars it is necessary to drop to the second very soon, and on this gear the cars then work nicely again.

These experiences can be explained very clearly by diagrams. In Fig. 1 the oblique lines represent the relations between motor speed in revolutions per minute and vehicle speed in kilometers per hour for the four gear speeds of the H cars. Let it be assumed that the gear is lowered whenever the motor speed drops to 1,000 revolutions. By looking at Fig. 1 it is now seen that by going from the high to the third the motor goes from 1,000 to 1,600 revolutions, and the latter is a speed close to that at which the motor does its maximum of work. But in going from the third speed at 1,000 revolutions to the second the motor goes only to 1,200 revolutions, which is not close to its best speed, and consequently it does not pull the car so well, and if the grade of the road rises a little, pulling the motor speed down to 1,000 again, it soon becomes necessary to drop to the low gear. And by this last change a very high motor speed is reached, as the diagram shows, so that it becomes desirable to throttle down, and the diminished efficiency of the motor under the throttle has again no favorable influence on the car.

Fig. 2 applies to the A cars and shows the favorable transition from the third to the second speed in accordance with the actual experiences above referred to, it being understood that 1,800 revolutions and not 2,000 revolutions is the speed at which the motor operates most efficiently.

THE SIMPLE GRAPHIC TEST OF CORRECT GEAR RATIOS

These diagrams have shown what demands must be made of a good change-gear mechanism. In any diagram representing it the heavily drawn horizontal lines must be of equal length. Speaking without reference to the graphic mode of expressing it, the transition from one gear to another must in all cases be accomplished between the same limits of motor speed. A gear corresponding to this requirement is represented in diagram Fig. 3. Here it is seen that every time the gear is changed—at 1,120 revolutions in this case—the motor goes to 1,800 revolutions on the lower gear. This diagram therefore also supplies the correct gear ratios. Under the supposition that the low and the high gears are in proportion of 1 to 4, the intermediate gears should be at 1.6 and 2.5. Unfortunately not a single gearbox among those examined in the German cars conforms to this requirement. And were the friction loss on the lower gears to be considered, the figures 1.6 and 2.5 would be reduced even a little more, and the gear ratios used in practice, being too high, would be found still a little farther removed from the correct ones.

That the diagrams presented have been based upon revolutions alone, and not upon curves of efficiency or torque, is no error, since the favorable portion of the torque curves naturally lies between the motor speeds chosen as limits.

If a gear is to be designed for a car in which the low and high gears must be farther apart than 1 and 4 and should be, for example, in the proportion of 1 to 6, which would be suitable for a car used in hilly districts, the correct gear proportions are those shown in diagram Fig. 4; namely, 1—1.8—3.3—6.

CHECKING RESULTS BY ANOTHER METHOD

These proportions for the intermediate gears, as given in the foregoing, have been arrived at by investigating actual driving experiences with different cars by the graphic method. The results are confirmed by reasoning in another way. Let it be assumed that the gears in a car are proportioned as 1, 2, 3 and 4 and that they are intended for vehicle speeds of, respectively, 0 to 15, 15 to 30, 30 to 45 and 45 to 60 kilometers per hour. With these limits for each gear range, the number of revolutions of the motor may vary 50 per cent. from the maximum on the second speed and only 25 per cent. on the high speed. Here is the error which prevents the proper utilization of the motor power on every gear. Every motor has a favorable working range which lies between two motor speeds, for example 1,800 and 1,200 revolutions. Above 1,800 revolutions the inertia of the reciprocating parts becomes a disturbing factor, and below 1,200 revolutions the horsepower drops so low that the gait of the car is influenced too strongly by variations in the road and load conditions as well as by variations in the condition of the motor itself. If now the second gear of a car were intended for vehicle speeds from 15 to 30 kilometers per hour, the favorable working range of the motor would be materially transgressed, while the object of the gear distribution is exactly to enable the driver to utilize the favorable working range of the motor on each of the gears. Relations between gear and vehicle speeds which approximately correspond to this requirement, in the case of a motor whose best working range lies between 1,200 and 1,800 revolutions, would be the following. (Exact numerical conformity with the requirements is excluded for constructive reasons, as, for example, it is physically impossible to have a fractional number of gear teeth):

Low gear	for 10 to 15 kilometers per hour.
Second gear	for 16 to 24 " "
Third gear	for 26 to 39 " "
High gear	for 40 to 60 " "

In this schedule, it will be seen, the limit figures of the vehicle speeds are always in the same proportion as 1,200 to 1,800, or as 2 to 3.

In order to try out the results obtained by the graphic method, this schedule may be compared with the gear proportions shown in Fig. 3. By multiplying 15, which is the upper limit for the vehicle speed on the low gear in the schedule, by 1.6 and 2.5, which are the ratios of the intermediate gears in Fig. 3, the following schedule of vehicle speeds is obtained:

Low gear	for up to 15 kilometers per hour.
Second gear	for 15 to 24 " "
Third gear	for 24 to 37.5 " "
High gear	for 37.5 to 60 " "

That these figures do not correspond precisely with those in the previous schedule is due to the fact that the values of 1.6

(*Continued on page* 741.)

Foreign Constructions Designs and Practices

Cylinder Casting of Germany, France and England Compared—German Design Leads—Flares and Bulges Used

HAVING thoroughly looked into the art of casting and machining cylinders for automobile motors, beginning in England, and, after a month of diligent effort, transferring the investigation to France for fully a month, it was not so difficult to run down the German practice, whereas, in Austria there is little to be learned that is not already covered in the practices of the other countries named. The main point in view is to observe with the minutest care any differences that may exist between the practices in these countries and the cylinder work which is being done in America. It is a well-appreciated fact among American automobile engineers that good cylinders are hard to get. The question is, have we the reasons at our finger's end? Do we know why we have troubles in this important department?

Were it possible to say that all cylinder work which is being done in America presents substantially the same measure of trouble; if it might also be said of foreign cylinder work that it is equally troublesome in every way; then, as an obvious deduction, the conclusion might be reached that the difficulties observed are natural and unavoidable either at home or abroad. We are deprived of the right of reaching this conclusion for three reasons:

One—There is a wide variation in the results obtained by various designers for their cylinders in a given foundry in America.

Two—There is a marked variation in the quality of cylinder work from given patterns run off in different foundries in America.

Three—There are disconcerting deviations from expected results, using patterns which are proven to be good for the purpose, these variations taking place from time to time in the same foundry, referring again to American practice.

Do Foreign Cylinders Vary?

That there are a plurality of reasons for the variations of quality of cylinders for American practice is apparent from the statements of the actual facts as presented. Naturally, the next question is, Are foreign-made cylinders subject to the same variation; if not, why not? If so, what is to be done to improve the foundry art of making cylinders for the purpose of the automobile trade?

In answer to the first question: Foreign-made cylinders are more or less subject to the same variations as the American product, but the extent of troubles experienced in the respective directions differs from the American expectation. French foundries are capable of producing better castings from inferior designs of cylinders than the cylinders of poor design that are likely to be obtained elsewhere. It may be on this account that so many French cylinder designs are faulty. In Germany the design is always more nearly perfect than on other European countries. As a matter of fact, some of the best German cylinder designs are quite up to the best work in America. In England, while there are some conspicuously good cylinder undertakings, there is such a swarm of mediocre work done, not only in designing but in the country as well, that the good examples are difficult to pick out.

There is a great lack of uniformity in practice in the several countries referred to, as this class of work is being done. These differences are: One—In America, on account of the low standard of foundry practice, designers are compelled to pay great attention to the details of designs and the pattern work.

Two—In England it is extremely difficult to reach any conclusion that may be stated as a rule. Observation tells that some of the foundries do first-rate work; more of them must be consigned to a lower level. In matters of design it is fair to state that designers calculate upon getting first-rate foundry work, and they reduce their efforts to place a close limit on cost accordingly.

Three—In France the foundry work is so fine that designers

Preferred Cylinder Jacket Design

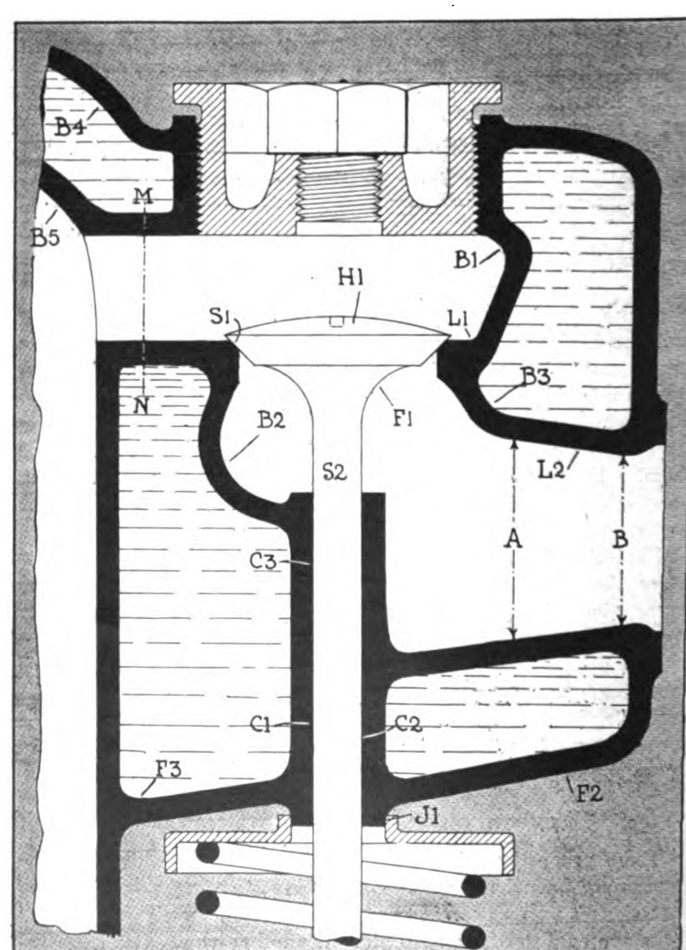

Fig. 1—Section of a poppet-valve type of cylinder through the exhaust-valve chamber, showing (slightly exaggerated) bulging and flaring walls, and a "choke" in the exhaust port

offend principle without suffering the consequences to be expected.

Four—In Germany the designs are painstaking and the foundry work is also good.

What are the hidden features of design which are only present in the best examples of cylinders?

Good Features of Design

The answer to this will be vague unless the points are brought out by illustration. Fig. 1 is a section through a valve of a cylinder. The precise difference, or difference in principal of design, between the cylinder shown in Fig. 1 and cylinders which do not perform so well in service may be noted by referring to Fig. 2, and comparing it with Fig. 1.

Referring to Fig. 1, attention is called to the uniform thicknesses of walls and to the avoidance of fillets which gather metal at intersections of walls. But these points are uppermost in the mind of the average designer when he undertakes a task of cylinder designing. If he fails to realize uniformity of section within narrow limits the fault lies between the pattern maker and the foundryman. However, there are points of design which the average designer prefers to evade. To begin with, the design principles of Fig. 1 evade all diagram effects; the walls at the respective points are anything but parallel to each other, excepting the walls of the bore of the cylinder, parallelism is unavoidable in this situation. Following the lines of the section, Fig. 1, attention is called to the bulges at B1, B2, B3, B4 and B5. In satisfaction of the same principles the walls are flared at F2 and F3. Again, the section through A-B which is not illustrated is

Non-Preferred Cylinder Jacket Design

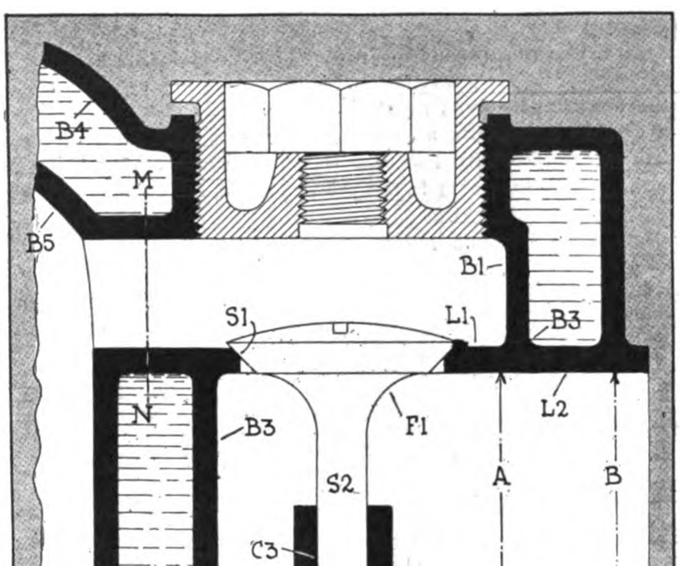

Fig. 2—Section of a conventional design of cylinder with parallel walls and a poor condition of cooling around the valve-seat metal as compared with that in Fig. 1

elliptical; just enough so to depart from parallelism. A little further observation shows a valve with a stout stem S2, with a big fillet F1, joining the stem to the head. The 45-degree seat S1 is slight; the pressure per unit area of the metal of the seat is considerable.

The mass of metal in the head of the valve is great in comparison with the flame-swept surface of the same. The idea is to conduct the heat away by the stem to the water in the jacket, limiting the increase in temperature of the head to the minimum. The water in the jacket surrounds the stem at C1 and C2, and it reaches S2, half way around the stem at C 3, Fig. 1. The stem is shown without a separate bushing for the guide.

The idea is to avoid the poor heat conductivity of a joint, as between the bushing and the bore in the cylinder metal. The valve is made of the purest steel, or, better yet, iron, possible to procure by any process, it being the expectation, founded upon research, that pure iron is the best possible conductor of heat, and impure steel is in the reverse direction. The seat of the valve is cemented or case hardened to afford great hardness, not so much due to any demand for hardness beyond that afforded by nearly pure iron, but in order to realize the polish which is assured when an otherwise pure iron is nearly satuated with carbon. Before case hardening, the valve is copper plated, excepting the seat surfaces, the idea being to prevent hardening penetrating excepting at the seat. However, any observations respecting the valves used must be taken with a grain of salt; this is on account of a wide variation of valve practice. Heat is prevented from annealing the valve spring S1 by using a thin saucer 2, which serves its purpose because of the poor heat conductivity of the joint J1 and also due to the large amount of surface of the disk in comparison with its mass. The cylinder walls W1 are about 6 millimeters thick in cylinders of the largest bore in use, and the port and jacket walls are slightly thinner, ranging between 4 and 5 millimeters.

In this particular example of cylinder the diameter A of the port is slightly more than the diameter B of the same port. This choke of the port referring to the exhaust port is not general practice. A very limited number of mostly French engineers seem to give a choke to the exhaust. It is a practice which originated in gunnery. At all events fouling of the combustion chamber due to re-entering products of combustion or visiting products from adjacent cylinders, is avoided if a choke is introduced. The gases are compacted as it traverses the length of the choke, and, like the tail of a comet, they scatter again, but in the case of the motor not before they pass to the muffler. They are beyond doing harm by the time they reach the muffler.

Returning to Fig. 2, remembering that it is of value in a comparative sense, corresponding letters of reference are used, and instead of avoiding diaphragm effects they enter at every point of surfaces in juxtaposition. Instead of bulges B1, B2, B3, B4 and B5, as shown in Fig. 1, the only bulges used in the design Fig. 2 are for the dome B5 and the jacket above the dome B4. Instead of flares F2 and F3, as in Fig. 1, flat surfaces F2 and F3 are used in Fig. 2. Instead of a choke due to the difference of A and B in the port, see Fig. 1, A and B dimensions are identical in Fig. 2. The result is, outside of any advantage due to choke, that the walls are again parallel to each other and the principle which dictates flares and bulges is again defeated.

Cooling the Valve Stem

Fig. 2 differs from Fig. 1 also in the way the valve stem is cooled. The section M-N is rectangular instead of elliptical, and, looking at Fig. 1, the position of the valve seat wall L1 is well above the wall L2 of the port, whereas in Fig. 2 the two walls L1 and L2 are in the same place, one being a continuation of the other. The result is that in Fig. 2 proper cooling C4 of the valve seat and metal surrounding the seat is impossible. Not a few French motors develop cracks and fissures of the valve seat on this account. Nor is this type of trouble confined to French motors. In other respects there is a certain similarity between Figs. 1 and 2.

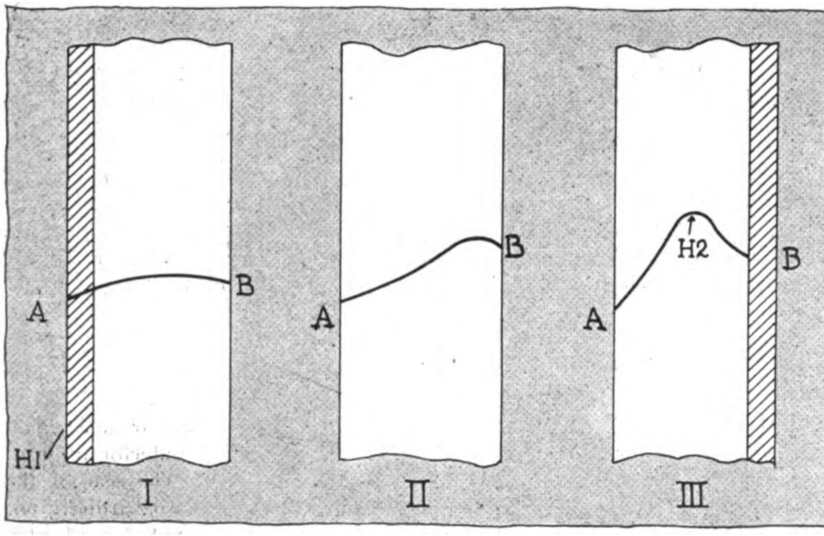

Fig. 3—A thick cylinder wall, showing how heat piles up, either in the mass of metal or in the crust and scale formed on the surfaces

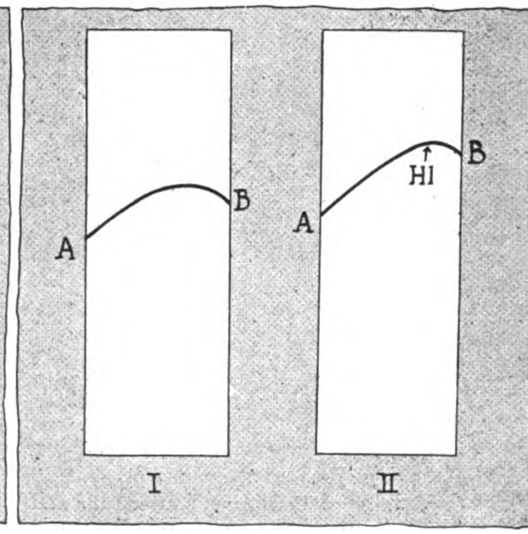

Fig. 4—Presenting three conditions of a thin cylinder wall in order to show how pre-ignition takes place

There are two prime reasons why stationary internal combustion motors deliver much less power per cubic inch of piston displacement than automobile motors. The most important of these reasons is that the cylinder walls of stationary motors are so thick that heat cannot pass through the section of metal as fast as it penetrates the flame-swept surface of that metal. The second reason is that the heat conductivity of the metal used is relatively very low. Of course, were stationary motor cylinders properly designed and were more power to be realized as a sequence, the inertia forces in these designs attending considerable speed increases would exert themselves and trouble would come from this quarter. But our story lies in the automobile field. From what has been said it must be concluded that wall thickness is a factor, but the ability of the metal to conduct heat is also of primal importance. The amount of heat that will have to be absorbed by the cooling water in the jacket can never be more than the number of heat units which will penetrate the flame-swept and contiguous surfaces in the time afforded in each case. *To limit the area of the flame-swept surface, then, is the first care of the designer. This point is given great attention, especially in Germany, but it does not go begging in any of the European haunts of the designer.*

All the heat which gets through the flame-swept surface, unless it makes its exit without loss of time through adjacent surfaces, will heat up or raise the temperature of the metal of the wall. If the wall is thick the time required for the heat to travel from face to face will be great. If the metal is of low heat conductivity, the amount of heat in heat units per unit of sectional area and per unit of time for a given difference in temperature between surfaces will be accordingly low.

Work Europe Is Doing

These points are being given fair attention in Europe, and the work already done is showing up in the better performance of the motors. It has been repeatedly shown that hot motors that pre-ignite because the cylinders get too hot are largely due to overheating of the metal, either because the cylinder walls are too thick or on account of scale, which, residing on the flame-swept surfaces, has its temperature raised to the glow point, when it serves as an igniter, or that cannot be timed: or scale which resides on the water-swept surfaces, preventing the heat from escaping to the water. But some motors heat when they are clean and even in the face of the fact that the cylinder walls are thin. In such examples it will doubtless be found that the metal of the cylinders is of very low heat-conducting powers. Figs. 3, 4 and 5 will serve to indicate the characteristic of the heat wave in cylinder walls, suggesting the distortions of the heat wave for the different conditions met with in practice.

In Fig. 3 the cylinder wall is represented as thick, as in stationary motor or inferior automobile motor practice, with conditions as follows:

Example 1—A deposit of scale, carbon, silicon and oil residuum, inside of the cylinder is shown as sectioning. The heat wave W1 rises from A, ending at B. Pre-ignition will be due to excessive heat at H4.

Example 2—The walls are represented as devoid of any scale inside or out. Pre-ignition will be due to the re-entering of the high heat shown at H3 of the curve W2; at the higher speeds of the motor this re-entering heat will be considerable.

The curve W2 shows the characteristic of the wave at customary working speeds of stationary motors.

Example 3 presents a condition of deposit on the exterior surfaces of the wall. The heat wave W3 starts at A2, reaches maximum at H2, which is the pre-ignition point, and the motor quickly shows distress.

Example 4 presents a state of deposit on the exterior and scale on the flame-swept surfaces of the cylinder wall. The heat wave 2A and 2B is almost flat; pre-ignition is due to glowing of the inner scale at H1.

Referring to Fig. 4, the cylinder wall is represented as thin—good automobile practice.

Example 1—The scale is within the cylinder. The heat wave A to B is but slight. Trouble follows at high speeds or under heavy loading of the motor and reduced speeds, due to glowing of the scale at H1.

Example 2—The walls are shown devoid of scale or deposit. The heat wave entering at a raiser to maximum just before the exit takes place at B. The performance of the motor should be good.

Example 3—Deposit is shown outside—over the water-swept surfaces. Pre-ignition follows high speed or heavy loading at reduced speeds taking place at H2 in the curve. Reaction of heat stored in the metal, as shown by the upward sweep of the curve A, B, is responsible for the trouble.

Referring to Fig. 5, this is a case showing thin cylinder walls, but there is a marked difference in heat conductivity of the metal in the respective walls to consider.

Example 1—This is representative of metal of high conductivity. The heat wave A to B, even at very high speeds, shows but a slight hump. Pre-ignition is not eminent in this example.

Example 2—The metal is of low heat-conducting ability. The heat wave A, B sweeps upward, bringing pre-ignition at H1. Increasing speed or heavy loading at reduced speeds aggravates this type of trouble.

The automobile engineer requires strong, pure gray iron for cylinders. The walls must be thin in order that heat may not be stored up in the section or body of the metal. The mixture must be strong in order that thin walls will sustain under the forces offered in service. The heat conductivity of the metal must be high. To realize high-heat conductivity, it is necessary to use pure (as nearly as possible) metal, it being true of iron, and steel also, that the purer it is the greater is the heat conductivity. But it is feared that the average foundry is ill fitted to cope with this considerable problem, and yet, in Europe, just this phase of the cylinder-casting problem gets its measure of laboratory attention. But this is not to say that all of the countries in Europe are doing so well; indeed, not a few of them are content to just turn out castings.

American Castings Are Strongest

Analysis on numerous occasions discloses a big difference in the chemical composition of cylinder castings from the several sources of supply. As a rule American-made cylinders are stronger than the imported products. When the American foundryman discovers that his castings are the strongest, he puffs up. Were he told that the heat conductivity of his metal is too low to use, his state of mind would become so dazed that no amount of persuasion would have any further effect upon him. Referring to the average American foundryman, to be sure, it may not be out of place to say that foreign foundries deliberately sacrifice tensile strength to get heat conductivity of metal. It may come as an incident, but these purer castings are free from internal strains to a marked degree.

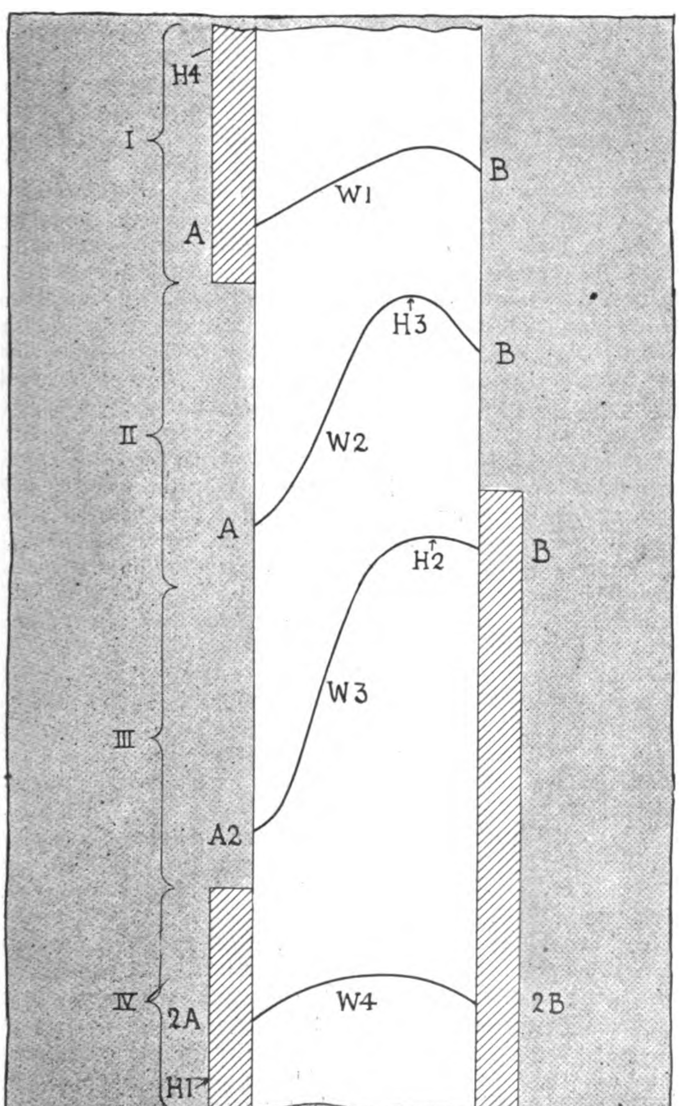

Fig. 5—Offering two conditions of a thick cylinder wall, showing the heating effect with metal of both good and bad heat conductivity

so that the actual available strength of the finished product is greater than in the other case of castings showing maximum tensile strength.

Reverting to Fig. 1, remembering that the walls of the parts and jacketing are flared and bulged in the manner before alluded to, it is the purpose now to point out wherein this practice helps the foundryman. The fact that a test proof of cast iron shows a tensile strength of 25,000 pounds per square inch, or even 28,000 pounds, is no assurance at all that the iron lodging in an actual cylinder will have the same available tensile strength. If the internal residual strains amount to, say, 10,000 pounds per square inch, this value must be deducted from the initial strength to derive the available strength. In order to coax the internal strains to subside, it is the idea of the German designer to avoid parallelism of walls in juxtaposition and to substitute a series of curves, bulges and flares, so interrelated as to afford a sufficient give to the metal as to relieve the internal strains. It is not unreasonable to expect that this plan affords compensations greatly in excess of the equivalent of 10,000 pounds per square inch of initial tensile strength of metal. Under these circumstances, if purer iron offering a higher heat conductivity, even with a considerably lowered initial tensile strength, is actually used, the gain will be two-fold: First, the available tensile strength will be higher, and, second, the motor will not overheat.

—

A CORRESPONDENT to *The Motor,* England, states that during the last few years when automobile racing has demanded the necessity of an engine that will give an extraordinary power relative to its size, designers have been faced with the question, "Are we, in designing an engine for general use to be influenced by the results of freak machine performances?"

There are cars on the market today, the correspondent goes on to state, with the stroke of the engine the same as the bore, and also with the stroke double the bore. The makers of each car state why their machine is superior to those of their competitors. Each is satisfied and each sells cars.

Let us look at it from the theoretical point of view.

Two cases must be considered, namely, the best diameter of the cylinder and the best length of stroke corresponding, taking into account the minimum weight per horsepower and high efficiency.

We know the power of a cylinder increases with the square of the diameter, and that, approximately, the weight increases with the cube. Therefore, the smaller the cylinder, the greater the indicated horsepower per pound. Considering then the small weight of a small cylinder, the necessary power must be derived from other sources than the bore-size if the engine is to be compact. The only possible means available is to increase the compression by employing a long stroke. And this not only increases the power, but increases the efficiency. These two, by the way, are not the same thing, for an engine may be powerful yet not efficient. The thermal efficiency of an engine is:

$$\frac{\text{Heat converted into work}}{\text{Heat available}} \times 100$$

or the ratio of the heat converted into work to the heat available.

The increase of compression naturally brings about a higher temperature of the compressed gas, which in turn naturally aids the efficiency of the engine by rendering itself more easily ignited. If then all this is true, the longer stroke we get, the more efficient and powerful engine will be the result.

Now, take the other side of the practical point of view. Two engines of 3-inch bore are made, but whereas one has a stroke of 3 1-2 inches, the other has a stroke of 5 inches. Run them both at 2,500 revolutions per minute and see which runs the smoother and more evenly of the two. And after constant use see which one has worn its big end crankshaft bearing away most.

As far as one can gather, the car that is required nowadays is one that will run from 5 to 50 miles an hour on high gear, and be efficient as a good car should be.

Tire Repairing Shop Cost Keeping Systems

Used Labor and Material Records Are Beginning to Enter Establishments Where Casings and Tubes Are Overhauled for Service

FEW tire repairmen recognize the value of cost-keeping systems at this day. This accounts for the fact that only a small percentage of them have adopted them and that, where systems have been introduced, they are very simple, though sufficient for the needs. Most shops do not keep records continually of the cost of every individual job, but the progressive among them do so until they arrive at a fair standard cost of a repair job, or, rather, of the various kinds of jobs handled in the shop. After this, the detailed cost-keeping system on every job is reduced to a more lenient process, consisting but in the time-checking of the men, this being carried on for reasons of policy, as one of the most successful tire repairmen of New York remarked.

Repair systems in tire shops are somewhat similar to those used in recording costs in an automobile repair department. They comprise two or three blanks, a receipt to the customer who brings in a tire to be repaired, an order specifying the work to be done on the tire accompanying the same to the shop and a time card, on which the men doing the work enter the time spent on each job. Clock cards for stamping time in and out of the workmen are also used in many shops. Furthermore, some companies keep a record of the materials used every day, itemizing it by the numbers of the jobs on which they are used. An inspection of a number of shops, however, indicates that records of material are kept by few of the shop managements. The reason therefore is that it is rather a difficult matter to measure and note the small quantities of vulcanized and unvulcanized Para rubber, cotton strips, cement, etc. The opinion seems to be that the continued recording of every small quantity of material used in the shop is too formidable to be carried on. Despite this, modern shop managers who recognize the value of cost standards, do conduct such records, at least for some time, when it is possible to formulate standards of actual material costs. The unit cost of material of each particular type of repair having been fixed, it is an easy matter to find out at the end of the week whether these standards have been kept up or not, or if they have been raised, without continuing individual material-cost records for every job done in the shop.

The records are in all cases kept by shop workers and office force combined. The adjuster or his clerk fills out the first card or slip which serves as receipt to the customer and as a work order, while the records of labor spent on each job are filled in on the cards by the men doing the work. The correctness of these records is checked by continued inspection of the shop work, this supervision being carried out by the foreman of the shop. In this way, as well as by the sparse use of used materials records, the personal equation is permitted to enter into tire repair work to an extent far exceeding that influencing ordinary automobile repairs. It is a simple fact, easily reasoned out and easily proven, that the lack of system due to the discomforts arising from its use in this particular field is a detriment to the commercial success of a tire repair enterprise. There is no doubt that where complete all-around records are inforced, the economy of the shop operations may be increased to no small extent.

Fig. 1—Time distribution card used by the repair workers in Schoonmaker Company's shop

The leading tire repair establishments of New York City have used cost-keeping systems for a number of months, and, after some experimenting with the types of forms put to use in this connection, a good many have arrived at what they consider to be final standards of system blanks. At any rate, the forms now in use are almost without exception very simple and well adapted to their purpose, being as few as possible and yet giving the office and the shop workers a chance to record all essential data on tire repairing.

Description of Firestone System

TWO representative systems which contain every feature of cost-keeping and repair recording used in New York tire overhauling shops are described below. They are used by the Firestone company's metropolitan branch and by the E. Schoonmaker Company, one of the leading tire repair shop operators of the city. The Firestone concern uses one card, Fig. 2. printed black on yellow cardboard. The card is 3 1-3 by 8 1-2 inches and consists of three sections which serve as work order, customer's receipt and receiving slip. When the tire is received by the adjuster who is in charge of the firm's repair department, the card, Fig. 2, is filled out. The date of receipt, name of customer, size of tire and the work to be done on it, and what other particulars are essential and may be seen by referring to the illustration, are entered on the card, which is then separated in its three sections by tearing the perforations. The middle section, the so-called claim check, goes to the customer and is later exchanged against the repaired tire, casing or tube. The receiving slip is kept by the adjuster until the repair has been completed, after which it is filed away under the name of the customer, names being, of course, arranged alphabetically. The bottom section goes to the repair shop with the casing or tube. There the time spent by the men is recorded on the form, specifying the periods spent on cutting, buffing, cementing, vulcanizing, etc. The Firestone company does not specify the names of the men who do these operations, as the shop has been so organized that each man does but one class of work. It is for the same reason that no time-distribution cards are used in this shop, for, while the men stamp their time in and out, the way it is used is obvious upon examining the repair cards. Furthermore, the company relies to a great extent on the foreman to keep his men busy at all times.

The repair being completed, the tire and the disposition records, as the company calls the bottom section of the card, are returned to the adjuster's office, who directs the bookkeeper to make out a bill which, together with the tire, is given to the customer in exchange for the claim check. Naturally, some customers are required to pay cash for their jobs. The bookkeeper enters the work in the ledger, whose records serve as the basis for monthly statements, so that the three sections of the cards are not required by the company after the tire has been delivered to the owner. But to avoid any possible complication, which might arise in the future, the three sections are filed away together under the name of the customer.

A system different in its details is the one used by the Schoonmaker company. It consists of three forms, one of which is designed similar to the one of the Firestone company, the second as a worker's time-distribution card and the third as a material record. The clock card is also used in this shop.

Fig. 3 shows the first-mentioned blank which also consists of three sections, with perforations between them, representing customer's receipt, shop order and office record. The process of using these blanks is identical with the one prevalent in the Firestone repair department. The worker's time-distribution card, Fig. 1, is a simple but efficient design and gives the office of the company all the information which may be desired with reference to the repair work done by each man employed in the shop. Every time-distribution order is marked with the number of the workman, his name and the date on which the card is used. In the lower portion of the form he enters the number of the repair job which appears printed on the work order, the name of the customer for whom the work is done, the make of tire upon which he works and, finally, the nature and quantity of the material used in connection with every repair job. The material records are kept in the form of a large book or ledger, and every workman is required to enter all the material in this book, which is kept in the office of the shop foreman. Exactness of the material records is a condition, the importance of which is impressed on all the men, while the distribution of their time is not checked except by the general inspection work of the foreman, no time-clock mechanism being employed. The reason for this course is stated to be due to the many small jobs done in the shop and the consequent loss of time which would be incurred by the men running to a time-clock every few minutes. The superintendent of the Schoonmaker company, however, was emphatic in stating that, in his establishment, standard costs of repair operations have been arrived at long ago, so that from the workman's time-distribution card it becomes fairly clear whether the man wasted any time or not.

Practical Value of a System

It should be remembered that the arrival of standards of cost for all operations done in a shop are the purpose of all cost-keeping systems. These records again form a basis for many improvements, as, if it is once found that the men use on the average, say, 1 hour for a job which could be done in 45 minutes, the course which should be taken can be made clear to the foreman. It is his business to see that the time consumed on a given job should be reduced from the actual, present standard to the ideal one; it is, furthermore, his business to devise ways and means as to how to do this. The effect of such a course is that the unit cost of the work done in the shop is reduced in proportion to the time consumed, so that with the same force a larger volume of business may be handled, which will naturally flow to the establishment if a little of the saving in labor cost is used for reducing the retail price of the repair jobs. This being essentially equal to an *increased supply of repair work* caters to an increased demand, if the price is slightly lowered to invite a larger number of customers.

It has been the curse of the repair business, automobile and tire trade as well, that the operators have either thought that there is no chance to make money in their business or that they used it to exploit their customers without any remorse. Only lately these branches of the automobile business have been put upon a saner and, in the long run, more profitable basis. By and by repairmen began to see that their business is like others and that the same principles of work and trade policy must, as elsewhere, be applied if a lasting success is preferred to a spontaneous inflow of cash.

Accelerometer—Its Use and Value

Rate of Speed Increase Depends Upon Torque Continuity and Reduction Between Motor and Driving Wheels

Graphic Form Valuable in Examination of the Automobile's Accelerative Powers on a Time Basis

THE acceleration of any given motor car at any moment depends primarily upon two factors—1, the engine torque; 2, the gear ratio in use. The former is governed by the total cubic capacity of the cylinders of the engine, and the latter by the gear-box ratio corresponding to the gear in use at the moment. The proportionality of torque to cylinder volume is based upon the experimentally ascertained fact that the mean pressure is not appreciably affected by cylinder dimensions in any four-stroke petrol engine as usually built. Given this constancy of mean pressure, it follows that the mean torque must depend upon the product of cylinder area by crank throw, that is upon D^2L, the cylinder displacement. An interesting corollary to this is the deduction that for any given gear ratio on a given car the car speed and the brake horsepower will be identical for all engines of equal volume which may be fitted to the car.

A graphical construction affords the readiest way of tracing the relationship between acceleration, torque and gear ratio. Thus in Fig. 1, A B is the torque curve on top gear, C D the torque curve on second gear, and E F that on bottom gear (taking the case of a three-gear car). These torque curves are plotted with car speed horizontally and pounds per ton of equivalent tractive effort vertically. A definition of the vertical co-ordinate would be that it is the number of pounds of tractive effort per ton weight of vehicle at the road wheels equivalent to the engine torque at that speed. On the same diagram, and to precisely the same scale, it is possible to plot the curve G H, representing at each speed the total resistance to motion, including the friction of any internal gearing between the clutch and the road wheels.

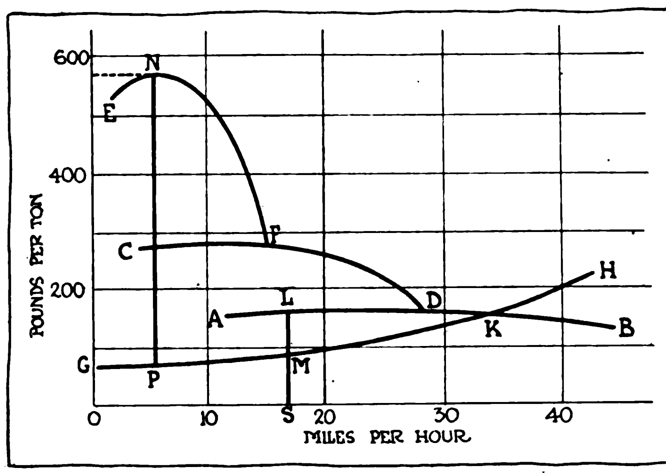

Fig. 1—Diagram of automobile torque and resistance curves

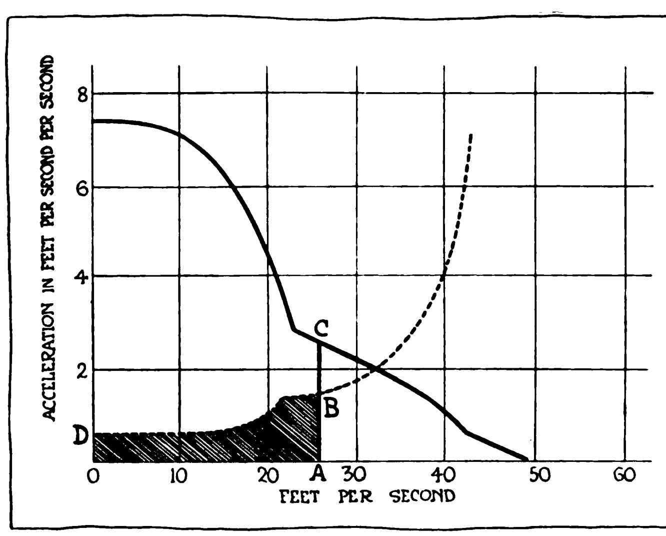

Fig. 2—Method of predicting the acceleration-time graph

Now, at the point K two of these curves cross, showing that at that point the tractive effort due to the engine is exactly balanced by the resistance to motion. This point therefore gives the speed—some 32 miles per hour—at which the car would travel with throttle open on a level road. The effect of climbing a gradient is to increase the resistance to motion by an amount proportional to the gradient, and the resistance curve G H rises, keeping parallel to itself, by this amount, so that the point K moves in to the left, showing that the steady speed will be less. At the speed O S the resistance is only M S, whereas the engine effort is equal to L S; the excess force L M produces acceleration if the road be level, or a combination of accelerations and hill-climbing ability if the road be rising. When the road is level the whole of M produces acceleration, and the amount of that acceleration can be directly scaled off by the length of L M (1 foot per second is very nearly equivalent to 70 pounds per ton).

The relationship between the three torque curves shown in Fig. 1 is very simple. A B is the torque curve on top gear plotted directly from a bench test diagram. C D is the same curve compressed horizontally and expanded vertically. The ratio of this compression and expansion is the ratio of the engine revolutions per minute at any given car speed when on top gear to the engine revolutions per minute at the same car speed when on second gear. It will be readily seen that coresponding points on the torque curves will lie on the same rectangular hyperbola, and this gives an easy graphical construction for drawing the curves E F and C D when A B is given and the gear ratios of each gear are known. The rectangular hyperbola which just touches each of these curves touches them at the points of maximum horsepower.

Each of the torque curves thus obtained requires, properly, its own resistance curve, since the frictional loss between clutch and road wheels will depend upon which of the gear wheel combinations in the gearbox is in use—most of the gearbox friction arises from the churning up of the grease or oil in use, is not sensitive to the amount of torque transmitted, but rises rapidly with speed. There should, therefore, be three resistance curves, each a little higher than the last. But it is found to be far simpler to keep to the one resistance curve and to lower the curves E F and C D by the amount of this extra friction. This convention greatly simplifies the diagram. Thus, on bottom gear the maximum possible acceleration can be directly scaled from the length N P. In this manner it is possible to predict the acceleration on each gear at any car speed, and from the figures so obtained to make a graph of predicted acceleration on a car speed base.

When such a graph has been obtained it is sometimes desired to convert it into one based on time instead of on car speed. To do this we must plot on the car speed base the reciprocal of the acceleration and measure the area between this curve and the horizontal axis; these areas will give the time in seconds corresponding to each acceleration value, and the acceleration and time graph can then be constructed. The exactitude of this procedure follows from the relationships

$$\int \frac{1}{a} \, . \, dv = \int \frac{dv}{\frac{dv}{dt}} = \int dt$$

The curves in Fig. 1 have been drawn to represent to scale the case of a 15-horse-

*Paper read before the British Association at Dundee by Mr. H. E. Wimperis, M.A., inventor of the Wimperis accelerometer.

power (R. A. C. rating) touring car with hood and screen in use. From this we will proceed to predict the acceleration-time graph. The first difficulty that arises lies in the fact that the car does not start with the engine in gear and the curve E N F does not meet the vertical axis. For reasons explained later this is met by drawing the dotted line T N and treating it as a part of the bottom gear torque curve. The acceleration speed graph shown by the firm line in Fig. 2 is obtained from Fig. 1 by direct scaling, as already explained. The dotted curve gives the reciprocal of the acceleration, and the shaded area measures the time taken from rest to attain an acceleration equal to A C. The acceleration-time graph thus predicted is shown in Figs. 3 and 4, allowing an interval of one second to effect the gear changes from bottom to second and from second to top. The distinction between Figs. 3 and 4 is that in the former the driver is assumed to change gear at 2,000 revolutions per minute and in the latter at 1,600 revolutions per minute; also that in the former the gearbox friction has not been allowed for, while in the second it has. It will be seen from Fig. 2 that the maximum possible acceleration is about 1.1 foot per second per second on top gear, 3.0 feet per second per second on second gear, and 7.0 feet per second per second on bottom gear.

Experimental Measurements—The above is a simple method of predicting the acceleration of a motor car; it remains to describe how this acceleration can be experimentally measured, and then to compare the curves given by experiment with Figs. 3 and 4.

Two methods are in use for the measurement of the car acceleration: 1, by deduction for a space-time graph; 2, by the direct indications of an accelerometer. Of these two methods the former has the attraction that none of the measuring apparatus is carried on the moving vehicle. It is, moreover, a simple matter to measure the distance traveled at the end of equal time intervals; the slope of this space-time graph at any point measures the velocity, and a velocity-time curve can then be constructed. And the slope at any point of this velocity-time curve measures the acceleration. This process is, however, both long and inaccurate, particularly at the gear change points. The same data could have been treated equally well by an analytical process based on the calculus of finite differences; such a method has been used at Brooklands, but it suffers from the alternative disadvantages that, if a large number of terms in the infinite series (given by the method of the calculus) be taken, the process is exceedingly laborious, and that if few are taken the method fails in accuracy, particularly when the acceleration is changing rapidly. It is far more difficult to measure the acceleration of a car than of any other vehicle, owing to the discontinuity of motion in the gear changing.

The use of an accelerometer avoids these lengthy and troublesome calculations, but has certain disadvantages peculiar to itself. It is open to the objection that the measuring instrument is carried on the moving vehicle, and is therefore subjected to a good deal of vibration, and possibly to zero-error should the floor of the car change appreciably in its upward or downward tilt relative to the road. Vibration gives little trouble in a suitably designed instrument, and is actually useful in that it helps to overcome any statical friction there may be in the mechanism. The difficulty due to change of tilt cannot, however, be avoided by any attention to the mechanism of the accelerometer. But its amount has been the subject of careful study on a variety of cars, and been found to be less than can be measured in practice; were it otherwise, it would be necessary to take the precaution of first blocking the car springs.

Acceleration tests were made with one of the recording accelerometers above mentioned on the car for which Figs. 3 and 4 were predicted. The results are shown in Figs. 5 and 6. The former was taken on Brooklands track, when the driver was instructed to accelerate as rapidly as possible, and the latter on the road on the way to Brooklands without the driver knowing that any test was in progress. In both cases the road was pretty nearly level, rising about 1 in 80 in the case of Fig. 5, and falling about 1 in 100 in the case of Fig. 6. There is a striking difference between the test and non-test starts, and the latter was, of course, much the more comfortable for the passengers, the rate of change of acceleration being far less.

It is interesting to compare the prediction and the reality. On second and on top gears the predicted acceleration agrees very nearly with the actual figures, but on bottom gear the reality is some 2 feet per second per second, or about 30 per cent. below the prediction. Now, the following are factors which all influence acceleration, particularly when on bottom gear as the car starts from rest.

a—The momentum stored in the rapidly rotating flywheel is suddenly liberated when the clutch is let in.

b—The carbureter is liable to choke with the rapid change in engine output.

c—during the engagement of the clutch the engine is exerting torque.

d—The road wheels are liable to slip.

e—The momentum given to the car is partly absorbed in giving momentum to the rotating parts.

As regards *a*, the momentum stored in the flywheel of this car was 1 1-2 per cent. of that stored in the car when the top gear was in. Before starting the driver may spin his engine and flywheel at a rate—say, 2,000 revolutions per minute—equal to that equivalent to running 40 miles per hour on top gear. And if this momentum be given to the car, it will produce in it a speed of 1 1-2 per cent. of 40 miles per hour—or 0.6 miles per hour—corresponding to about 1 foot per second per second if the operation were completed in just 1 second. During the same time interval, whatever it may be, the engine is also exerting torque and this *c* is a further reason why the starting acceleration should exceed the predicted value. It is difficult to assess the engine torque during the clutch engagement when the engine speed falls rapidly from 2,000 revolutions per minute to only a few hundreds. In the limiting case we may take the torque during this brief interval as equal to the maximum torque on that speed, and draw the dotted line T N shown in Fig. 1. Cause *b* has probably—with *d*—much the most important influence on the acceleration—enough influence, in fact, to neutralize the factors tending to make the predicted acceleration higher than the true and to reduce the actual substantially below the prediction, for it is not to be expected that when the load on the engine is changing so rapidly as it does during the starting of the car that the carbureter will be able to supply fuel exactly proportional to the load, as it undoubtedly does in a good engine when running on

Electric Lighting System Requirements

Dynamo Should Be Geared to Give Full Output at a Speed of 15 to 18 Miles Per Hour

Design of Lamp Reflector a Potent Factor in Determining Illuminating Efficiency

IN determining the necessary qualifications for a dynamo lighting system for any particular use, the following points immediately become of importance:

1—The lamps to be used.

2—The dynamo output needed.

3—The dynamo speed and the method of driving the dynamo.

4—The proper size storage battery to be used with the dynamo selected.

5—The type of wiring.

The most important of these is the first, that is, "What lamps to use." After determining the lamps to be used we immediately become of importance:
from this the other points can be readily deduced. There are only three size bulbs now in general use for headlight work, these being respectively 16, 21 and 25 candlepower.

For small motor cars, which travel at comparatively slow speed, and where the owner would be satisfied with light that while better than acetylene lights usually supplied with these small cars, is still not the most powerful, and where he will not be likely to compare his lights with those of friends who have higher power, to the detriment of the 16-candlepower lamps, 16 candlepower is undoubtedly ample.

On the higher-powered cars the 21-candlepower bulbs are in almost universal use to-day. These will give ample light for driving up to a speed of, say, 40 miles an hour at night, illuminating the road far enough ahead that any object may be observed in time to stop almost as well as in daylight; in fact, give all the light that is needed.

Such lamps when used with a shallow parabolic reflector will light a road 50 feet wide for the full width of the road from the front of the car to a point over a quarter of a mile away. A deep parabola of the same focus will light the road even further, but will not give as much light at the sides close to the car. Where extremely high-powered cars running at very high speed are used and where very large reflectors can be used, 25-candlepower bulbs are sometimes used.

It must be realized that with small reflectors built to take a 16-candlepower bulb the insertion of a 21-candlepower bulb will not give a proportionately larger amount of light on the road, and similarly a 25-candlepower bulb in a reflector built for 21 candlepower will not give sufficient additional light to warrant its use. **The reflector should be adapted to the particular size bulb used; for this reason there is little benefit in using large candlepower bulbs in small reflectors.** With a commercial reflector having the greatest diameter of 8 inches a 16-candlepower bulb is about all that can be focused economically. With one of 10 inches diameter a 21-candlepower bulb should be used, and there is little use in using a bulb larger than 21 candlepower except with a 12-inch reflector, which is very seldom seen on account of the large size.

We can therefore safely assume that the bulbs to be chosen for the headlights will be of 21 candlepower, these being almost universal for cars of over 25 horsepower to-day. The side lamps and rear lamps are for signaling only, and bulbs of small candlepower can be used. Four-candlepower or 2-candlepower bulbs are adequate. It is customary to use 4-candlepower side lights and 2-candlepower rear lights. The amount of current taken by these side and rear lights is so small that there is no objection to using 4-candlepower bulbs for all three or 2 candlepower for all three, but the desirability of having a brilliant light at the side, for appearance's sake, has led to the use of 4-candlepower bulbs. Frosting the bulbs in the side lights gives a very pleasing appearance, and I think will be very largely adopted in the near future.

In addition to the head, sides and rear, the car will probably be equipped with such current-consuming devices as a speedometer light and electric horn, very possibly a cigar lighter, a light in the tonneau or limousine, and similar lights. None of these lights, however, is used for a very long period of time, and in designing the balance of the system after having decided on the five main lamps it may be safely assumed that the overload capacity of the outfit will take care of these additional loads, which are run for a short time only.

We have therefore assumed that the lamp load on an ordinary car should be two 21-candlepower headlights, two 4-candlepower sidelights and a 2-candlepower rear light. The two headlights will take 7 amperes, the two side lights 1.7 amperes, the rear light .6 ampere, making a total lighting load of 9.3 amperes.

The second point we have to determine is the dynamo output needed. We have already assumed the light load to be 9.3 amperes. In order to make sure that we have ample overload capacity to take care of the many short loads made by the horn, speedometer light, etc., the dynamo should be capable of delivering to the storage batterly slightly more amperes than required by the lamp load. For this reason **an output of 10 amperes of the dynamo has been accepted almost universally as the proper amount when such a lighting equipment is used.** This will keep the storage battery always up to the best efficiency and at the same time it is small enough that the storage battery will not have to have too large plates in order to run without undue deterioration.

Dynamo Speed Needed

The dynamo should be so geared to the car as to give its full output at from 15 to 18 miles an hour, and any speed above this. At a speed lower than 15 to 18 miles an hour the car will not be driven for more than a very few miles with all the lights lighted, and the reserve capacity of the storage battery will more than make up for this short time. Of course, when the car is being driven in the city where the headlights are not being used, it often runs more slowly than this, but at these lower speeds the dynamo is generating a proportionately smaller amount and will give ample current to take care of the two side and rear lamp, which take only a total of about 2.3 amperes. A shunt-wound dynamo which will deliver 10 amperes at, say, 15 miles an hour will deliver 2.3 amperes at 8 to 9 miles an hour, so that whenever the car is running it will supply ample current for the side and rear lamps.

What shall be the ratio of speed between the dynamo and the engine, and what shall be the method of driving the dynamo? These two points are so interrelated that logically they should be considered together. The size, weight, and consequently, the cost of the dynamo, are determined not only by the ampere capacity, but also the speed at which the dynamo will deliver the stated ampere capacity into a 6-volt three-cell lead battery. I will not treat of the relative size, weight and cost of shunt, series, compound or magneto type of dynamos, but limit my statement to the fact that in dynamos of any one type the size, weight and cost are determined by the ampere capacity and the speed at which this number of amperes can be put into a three-cell lead battery.

The cost of a dynamo which will deliver 6 volts and 10 amperes at 1,500 revolutions per minute is 30 per cent less than of one which gives the same output at 1,000 revolutions per minute, and less than half the cost and of about half the weight of one designed for the same output at 500 revolutions per minute.

A shunt-wound dynamo designed to put 10 amperes into a three-cell battery at about 1,000 revolutions weighs approximately 21 pounds and can be made approximately 8 inches long by 5⅝ inches high by 4¾ inches wide. If we reduce the speed to 500 revolutions the weight becomes approximately 33 pounds and the dimensions approximately 9¼ inches by 7½ inches by 4¾ inches. This 1,000-revolution dynamo should be run at engine speed for the best results.

The question immediately comes up whether, as a matter of judgment, there is sufficient advantage in running at the lower speed to make up for the added weight and the added cost. It will be found in general that where a shaft is provided on the engine to which the dynamo can be coupled, and this shaft runs at engine speed, the added weight and cost of the engine-speed dynamo are warranted, because the cost and complication of sprockets and chain for driving are eliminated. But where such a shaft would have to be put in the engine specially and driven by gears, or when some shaft already projecting runs at engine speed but is not so located that the dynamo could be directly coupled to it, and consequently either gears or sprockets and chain have to be used, there is little question but that a dynamo delivering its full

NOTE—From a paper by Leonard Kebler in the S. A. E. Bulletin for September.

output at 1,000 revolutions per minute and running at about twice engine speed is the happy mean in weight, cost and size.

A dynamo which will put 10 amperes into a three-cell battery at 1,000 revolutions, driven at twice engine speed on a car with 36-inch wheels, geared 3¼ to 1 on the back axle, will start to charge the battery at from 6 to 7 miles an hour, and will give enough current to supply all the lamps, that is, about 10 amperes, at 15 miles per hour.

The same dynamo on a car geared 3 to 1 with 36-inch wheels, starts to charge the battery at 9 miles per hour, and will deliver enough current to take care of all the lamps at 18 miles per hour.

Such a dynamo I believe to be the ideal one where there is no provision made for driving directly at engine speed. A machine running at higher speed than this has not sufficient advantage in weight and cost to warrant the higher speed of the chain and the higher speed in revolutions per minute of the armature and the additional wear on the bearings and additional chance for noise. At the same time the use of a dynamo at less than twice engine speed to get a reduction in chain speed and wear on the bearings has not sufficient advantage to warrant the use of a larger, heavier dynamo running at, say, engine speed and driven by chain gears.

On a dynamo driven by ⅜-inch pitch silent chain at twice engine speed, sprockets of 30 and 15 teeth would be used. At 45 miles per hour this chain would run 1,500 feet per minute and at 60 miles per hour 2,000 feet per minute. These speeds are not excessive, but if a dynamo giving its output at 1,500 revolutions per minute were used running at three times engine speed, we would use 45 and 15-tooth sprockets and the chain speed would become 2,250 feet per minute at 45 miles per hour, and 3,000 at 60 miles per hour, which is too high for efficiency or long life. We may therefore decide not to run our dynamo at over two times engine speed.

On the other hand, where it is possible to drive at engine speed through an Oldham coupling the ideal case is undoubtedly reached, and in this case the additional weight and cost of the dynamo are warranted, as we save the cost of sprockets and chain and eliminate the necessity of oiling them, etc.

Method of Dynamo Driving

Having determined the lights to be used, the dynamo output, and the relative speed of the dynamo to the car, the next point to determine is the method of driving the dynamo. **A very useful method of driving the dynamo is to extend the pump-shaft through the pump, leaving an extension back of the pump to which the dynamo can be coupled directly by means of an Oldham coupling.**

In other cases it is possible to have the armature shaft of the dynamo extend through both ends and drive from the timing gears through the dynamo armature to the magneto, having the magneto and the dynamo lined up in tandem.

In each of these cases a dynamo running at engine speed is used for a four-cylinder car and one and one-half times engine speed for a six-cylinder machine.

When neither of these methods is possible, and it becomes necessary to drive the dynamo by gears or silent chains, we will then use the higher speed machine, running at about twice engine speed, and this can be driven in a number of different ways. Where the pump is driven separately from the magneto, it may be driven at twice engine speed and the dynamo can be run directly from the pump-shaft through an Oldham coupling. **Where a shaft running at twice engine speed can be installed projecting from the timing gear case or from the gearbox it can be driven by gears or chain running in oil, and then the dynamo can be directly coupled to the shaft. This gives a noiseless and almost wearless drive.**

A sprocket on the pumpshaft or magnetoshaft driving a sprocket on the dynamo by silent chain at twice engine speed is quiet, efficient and satisfactory. It is, of course, better if the chain can be enclosed and run in oil. Any one of these methods has been proven to be entirely satisfactory in practice, to have long life and to be quiet.

Size of Battery Needed

Having determined all the necessary features of the dynamo regarding output, speed and method of drive, we turn to the storage battery. The first thing to determine is the proper size to use with the dynamo selected. It must fulfill two conditions:

A. If the car owner runs entirely in the daytime the battery must have sufficient square inches of plate surface to be charged, whenever the engine is running, at the maximum dynamo amperes without injury to the battery.

B. If the car is standing still with all lights lighted, the battery capacity should be sufficient to keep all the lights burning for 6 hours; and when only the side and rear lights are on, it should be capable of keeping these lighted for, say, two nights, or 24 hours.

Considering A, experiment shows that a battery having 160 square inches of positive plate surface and 200 square inches of negative plate surface will not be injured by use with a dynamo giving 10 amperes output on an engine. Such a battery would undoubtedly be ruined if 10 amperes were put into it continually on the test bench, but the conditions in motor car service are so different as to require some comment.

There are two things that cause rapid deterioration of storage batteries when they are charged continuously at a high rate: The first is that the heating of the battery due to continuous charging softens the plates so that they become readily disintegrated. The second is that large bubbles of gas form on the negative plates, and when these bubbles break away from the plates they take particles of the active material, especially when this has become softened due to heating.

In motor car work, in the first place, it is very seldom that a battery is charged continuously at the maximum rate for more than two hours at a time. There are always stretches of a few minutes when the engine is slowed down, so that the dynamo does not deliver its full output, or when the engine is stopped entirely, and the battery has a chance to cool off. As a result the service is not at all analogous to tests made on a bench where the current is put into the battery continuously. On a test bench the battery would get hot, but on a car it will not. In fact, in a battery with the plate surface already decided upon there is little or no heating in ordinary service and no excessive heating in the most severe service. In the second place, the large air bubbles do not have a chance to form on motor car batteries, due to the jarring and jolting that a motor car gets in going over the road. Before the bubbles have time to become large enough for them to take off a serious amount of active material they are jolted loose and do not injure the plates to any material degree. As a result it will be found that storage batteries can be run at almost double the charging rate without undue deterioration on a motor car that they can when standing still on a bench. The mechanical agitator, now often used for large stationary batteries to keep bubbles from forming, is replaced by the jolting of a motor car, and the various methods of cooling often adopted for large stationary plants is taken care of in this case by the occasional slowing down and stopping of the engine.

On a motor car a battery is run under ideal conditions, because it is being constantly charged and discharged under ideal conditions as regards agitation and coolness. A battery having the plate surface mentioned above will light all the lamps, that is, discharge at a 9½ to 10-ampere rate for about 3¼ hours, and will light the side and rear lamps for 24 hours. Such a battery does not light all the lamps long enough, so that if batteries of this size are used there should be two of them, or a larger capacity battery, having at least 80 ampere-hour capacity at a 10-hour rate, can be used.

Any battery made by a reputable maker and having 80 ampere-hour capacity at a 10-hour discharge rate will fulfill all requirements. This latter battery will fulfill all the specifications and has ample plate surface, ample capacity to run all lamps for at least 6 hours and the side and rear lamps for 24 hours.

Method of Wiring System

The use of a bayonet lock socket has now become universal for practically all connection plugs and all lamp plugs, so that there is little need of discussing this. One point, however, that is not entirely cleared up is the type of wire which should be used for motor car work.

The cable to be used for motor cars must stand a test of 12 hours immersion in oil, 12 hours immersion in gasoline and 12 hours immersion in water, and then stand 500 volts applied between the two conductors without breakdown.

Such a wire has ample insulating capacity and will take care of any oil, gasoline or water that it may get in motor car use. Wherever there is any abrasion the cable should be armored either by a light woven metallic armor or by conduit, loom or some similar material. There is no use armoring against heavy abrasion such as might be had by the wire rubbing against the flywheel, as any armor will wear through rapidly in this case, but the armor should take care of the abrasion that occurs on the leads of the lamps as they swing against the frame or some similar part, and almost any of the woven metallic armors will do for this purpose.

Wherever rubber or material that would be dissolved by gasoline or oil is used for insulation it should be protected by another covering impervious to oil or gasoline so as to render it impossible for the insulation to be ruined.

Hardening Difficult With the Facilities of the Small Shop; Vibration Changes Position of Carbureter Stop Screw; American Progress of 10 Years; Peugeot Car Has No Torque Rods; Use of Plastic

Case-Hardening in the Shop

EDITOR THE AUTOMOBILE:—Please tell me how to case-harden with crushed bone, using the tools to do the work that may be found around a machine and blacksmith shop.

Rochester, N. Y. SUBSCRIBER.

—None but very small parts could be treated with the facilities to be found about the ordinary machine or blacksmith shop. The parts to be case-hardened are packed in the bone meal and inclosed in a cast-iron box. The entire box has to be heated.

With iron or soft steel the heating of the box is then carried on until an intense red heat has been reached. This will be close to the melting temperature of the box. The part to be hardened is then chilled in cold water. After carbonizing, as the case-hardening process really is, the metal if it is to be carefully prepared should be annealed at 1,625 degrees Fahrenheit and allowed to cool slowly. It is then reheated to about 1,400 degrees and quenched in water. The temperature to which the box and its contents are raised should be about 1,500 degrees with ordinary steels. Nickel-chrome steels carbonize at 2,000. degrees and tungsten steels at 2,200 degrees. Good work cannot be expected without the facilities of the hardening room.

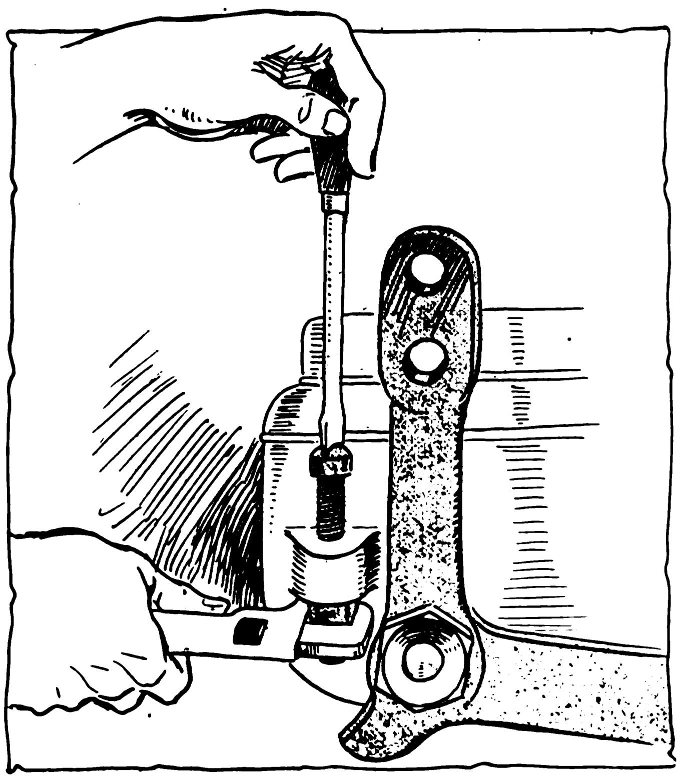

Fig. 1—This screw to be adjusted so motor will run with throttle closed

Motor Won't Throttle Down

Editor THE AUTOMOBILE:—I have just returned from a 400-mile run. During the latter part of the tour, I noticed that I could not get my motor to throttle down in spite of the fact that I had the lever turned as far back as it would go. I thought at the time that the trouble was due to the fact that the motor was somewhat overheated, having run continuously for a great length of time and having passed through some very hilly country. After returning to the car yesterday, however, I found that the motor went so fast when I started it that it could almost be said to be racing. This showed me that it could not be overheated and I am at a loss to account for it. I have not had occasion to run the car since and would like to know what the trouble can be before I start out again.

Worcester, Mass. CHAS. JENKINS.

—The carbureter throttle stop screw has been vibrated out of position. On your carbureter at the point where the control linkage is attached, you will notice a small screw similar to that shown in Fig. 1 which permits the throttle to go back just so far that it will be impossible to stop the motor by means of the throttle alone but which will permit it to run idle at very slow speed without choking up and stopping. This screw should have a lock nut upon it as shown in the illustration which will prevent its working loose and doing the very thing that has happened on your car. On account of the close proximity of the carbureter stop screw to the motor, the vibrations are severer at this point and no doubt you will find that the lock nut has become loosened and permitted the stop screw to turn in so far that the motor cannot be throttled down. In fixing the screw in its proper position its purpose must be kept in sight. Start the motor and slowly turn the stop screw keeping the throttle valve lever close up against it until the motor turns over regularly as slowly as possible. The lock nut is then tightened being sure that the position of the stop screw is not changed when turning the nut.

How We Stood Ten Years Ago

Editor THE AUTOMOBILE:—On page 479-80 of THE AUTOMOBILE for September 5, you have published a selection from a French magazine, which probably represents French conditions of 10 years ago, but it does not do justice to American conditions of that date. I, therefore, wish to call attention to a few things wherein we were much in advance of the French at that time. The writer of that article is wrong about engine speeds, for Duryea three-cylinder engines designed in 1897, 15 years ago, had speeds up to about 2,000 and developed maximum power at about 1,200 r.p.m. This engine was also a monobloc having the three cylinders in a single casting. Prior to this for some 4 years, the two-cylinder casting was used on American vehicles. The throttle control was used in 1895-96, and regularly thereafter; the last governors being applied in the winter of 1895, and although made up and on the engines, were taken off because the throttle control gave such perfect results.

Lubrication by large reservoir cups, which fed by the pressure in the cylinder, was applied about 1889, and was used in conjunction with splash. The automatic air valve was applied to American engines in 1899, and American patents taken out about that time. Low tension dynamos were designed as early as 1893, and made and fitted to vehicles in 1896-97. They not only gave current for ignition, but provided an electric headlight. Tie rods were always behind the axle on Duryea vehicles, even as early as 1892, and one company I was connected with in 1898, owned what seemed to be a basic patent on a worm drive for electric motor vehicles which patent has since expired, and which drive is gaining in popularity. In many other features America was not behind, but instead led foreign inventors; but American capitalists were not willing to take up the new business, and American buyers too busy while at home to see anything but dollars, had to go abroad to be convinced of the merits of the new transportation, in which matter they were greatly assisted by the better qualtiy roads in foreign countries.

In the same issue Mr. Heffly, page 484, hits the nail on the head when he gives as a reason for using the metric system in their American factory, "that our parts could be interchanged with the parts made by European factories." In short, although the American market is almost wholly dominated by supplies made to inch measurements, he would not change, because of the bother of doing so; and this is the meat of the cocoanut. It will never pay American makers to change their sizes simply to conform to a theoretical standard. Foreign buyers have no care whether their goods are measured by inches or some other way, so long as they do the work required of them at the proper price, and American makers must avoid any changes which add to the expense of production, for this would lessen, instead of increase, foreign sales, and do no good at home.

Saginaw, Mich. CHAS. E. DURYEA.

Regarding Peugeot Suspension

Editor THE AUTOMOBILE:—In your interesting description of the Peugeot racer, which THE AUTOMOBILE published recently, it was stated that this remarkable car has neither radius nor torsion rods, all the propulsive effort being transmitted through the rear springs. This being the case, please explain why the above devices are used in practically all pleasure cars, if it is possible to construct a shaft-drive system which will successfully transmit the 175 horsepower of this racer without them.

2—In the same issue mention is made of a governor that will not permit the speed of a vehicle to run above what the owner deems is safe. Has any such governor ever been perfected and if so, where can one be purchased?

East Canaan, Conn. DEWEY C. CANFIELD.

—In the first place, it must be remembered that the suspension of a racing car must be considerably stiffer than of the ordinary touring car. The Peugeot is a pure racer. It has been built for speed, not for comfort. Every bit of extra weight that could be removed without weakening the car has been taken off. With this in view, the attachment of the springs to the frame may be noted Fig. 2. It will be seen that the joint is not a shackle, but merely a rigid connection to the frame by a pivot which permits of motion in but one direction. The torque strains fall entirely on these pivots, which are made heavy enough to stand the stresses imposed. In addition to the rigid support at the frame it will be noticed that two extremely heavy straps are placed one on each side of the differential case, which is also heavily braced by the steel housing not shown in the illustration. The straps are capable of absorbing the entire torque strain if necessary and with the differential housing and heavy spring connection besides, the support is ample. In the case of an ordinary touring car, the springs are made as light as is consistent with strength, to make the riding as easy as possible. The added duties of torque strains would compel the spring designer to make the springs to meet both the strains of suspension and torque and the easy riding qualities would suffer in consequence. The springs in a light touring car are thus made

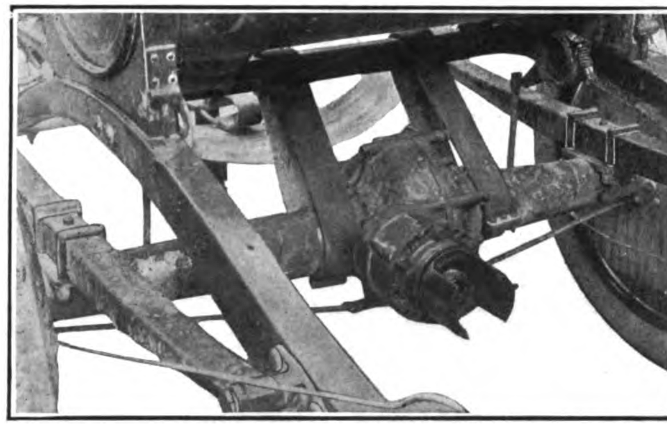

Fig. 2—Rear suspension of the Peugeot. Note heavy straps in place of torque rods

with as flexible a connection as possible and the torque strains are taken up by independent members.

2—A large number of highly satisfactory governors of this type are on the market. Indeed, it is not too much to say that any manufacturer of commercial vehicles in the United States will apply such a governor to his output and will guarantee the correct action of the same within reasonable limits of speed. Any large supply house will carry such a device or will secure one for you at any time.

Using Plastic Tire Mender

Editor THE AUTOMOBILE:—I have purchased a small outfit put up by one of the leading tire concerns, consisting of a can of cement and another can of a stiff plastic preparation which is used to fill cuts in the casing. I would like to know if such a preparation is good to use on tires, if it really does the work and what is the best method of using it. I am sure many others have bought preparations of this kind and then hesitated to use them in the thought that perhaps they were doing the tire more harm than good by their use.

New Rochelle, N. Y. OWNER.

—The preparation you speak of is in common use and it is a very meritorious product. The repairs made with its use are second only to the jobs done by the use of a vulcanizer as far as efficiency goes. If you will carefully go over the tire every little while, seeing that every cut is filled you will get a much greater mileage from a shoe than you would were you to neglect

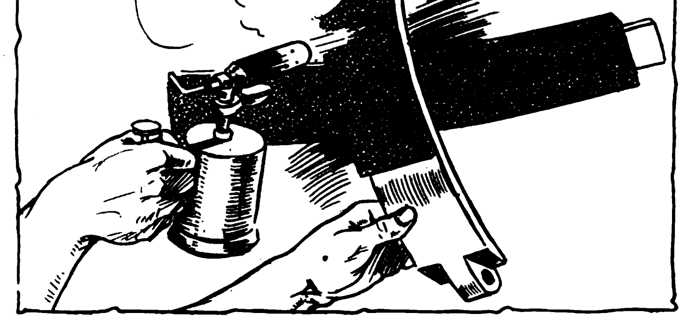

Fig. 3—A very gentle flame applied to the brake will fry out the grease

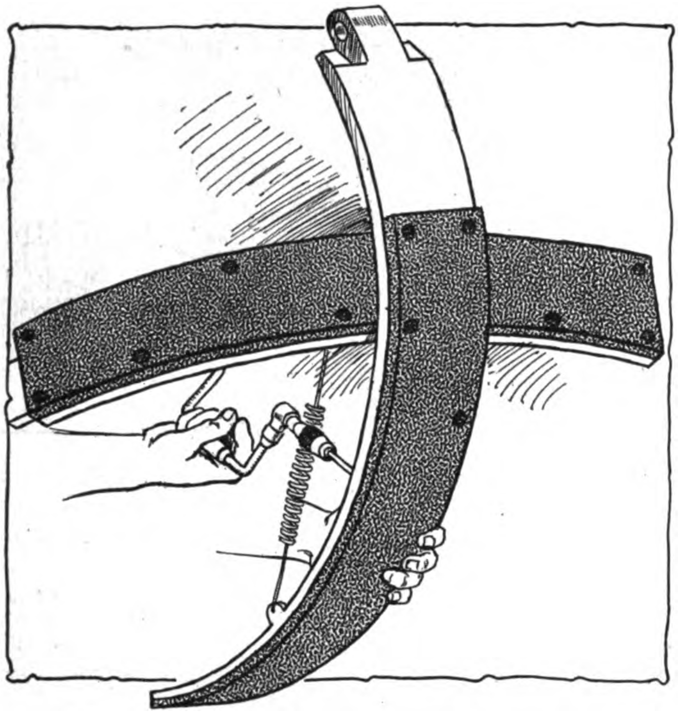

Fig. 4—Holes in the shoe can be used as a guide in drilling the lining

it. The method of using these preparations is practically the same in all of them. The first step is to see that the cut is scrupulously clean. A little gasoline which is applied by soaking a small piece of cloth in the liquid and winding it about a match and then inserting the latter in the cut, rubbing it around the walls, will take out the dirt which will have been forced in by traveling with the tire in that condition. After the cut has been thoroughly cleaned out a coating of the fine cement is applied and allowed to become thoroughly dry. A piece of the plastic, a little larger than the cut, is then taken and kneaded between the fingers. Now apply a second coat of the cemnet to the cut and when this becomes tacky, press in the plastic which has been kneaded until very sticky. Press the plastic firmly into the cut, being sure that it fills it completely. It will attach itself to the tread and will effectually prevent the entrance of water or grit which would end to destroy the fabric and body of the tire. It would be well to make a rule to go over the tire thoroughly every week looking for cuts in the side or face of the tread which would prove a source of weakness and cut down the tire mileage.

Putting Brakes in Condition

Editor The Automobile:—I am about to make a trip through somewhat mountainous country and I wish to put my brakes in the best possible condition; will you kindly tell me through The Automobile exactly what I should do?

Goshen, N. Y. Tourist.

—There are three things which must be particularly noticed in taking care of the brakes and in putting them in condition for a trip such as you mention. These items are as follows:

1—There must be no grease on the shoes.

2—The fabric must be in the best of condition.

3—The brake linkage must apply the brakes when the pedal is depressed.

These will be taken in order and the method of procedure in fulfilling the three requirements will be shown.

1—The grease which penetrates to the brake shoes works through from the differential. In some cases the grease applied to the bearings in the neighborhood of the brakes will get through to the fabric. Regardless of how the grease has worked its way into the bands, the damage resulting will be the same The coefficient of friction of the material will be so cut down that the brakes will not hold as they should and for a tour in a mountainous country will be very dangerous. To treat this trouble, the rear wheel should be removed and the brakes taken off. This will be a simple operation regardless of what car you are driving, consisting merely in the removal of the nuts which will be in plain view when the rear wheel is taken off. The next step is to inspect the material with which the brakes are lined and see if the treatment will fall under the head of number 1 or 2, in the list above. Should the trouble be that there is a coating of grease over the surface of the fabric, there will be two methods of procedure. The first is the removal of the grease by the application of gasoline. The gasoline will cut the grease and remove it from the surface very well. The method has one drawback, however, and that is that it does not take the grease from below the surface of the fabric. An inspection of Fig. 3 will show the method employed in some of the large New York repair shops for taking the grease from below the surface of the fabric. The flame of the torch must

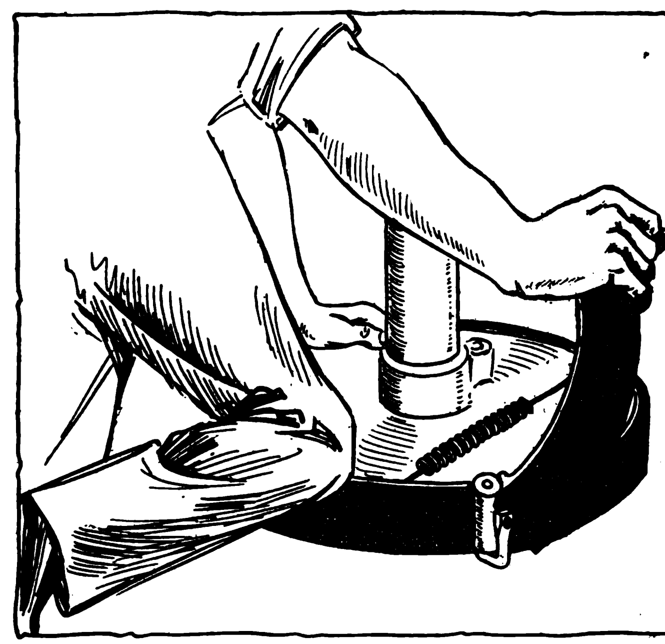

Fig. 5—Step in the assembly of an expanding brake. Spring put on first

be very gently applied so as not to char the fabric itself. After the heat has been directed against the surface of the brake for a short length of time it will be noted that the grease will literally fly out of the fabric leaving it upon the surface in the form of a black carbonaceous deposit. In this state it is readily removed by a cloth steeped in gasoline. The surface of the brake will now be in good condition if the lining has not been worn out. A careful inspection should be made to determine the cause of the leakage of oil or grease to the brakes if it is noted that such leakage is excessive. The differential housing, when the car is in motion is literally filled with flying grease and oil a large part of which works its way along the drive axle. In order to prevent it from working its way out to the end of the axle housing and then into the brakes, a thick wadding of felt is placed around the drive axle and acts in the nature of a stuffing box. In time, the felt will become worn away in some cars where the installation has not been as carefully made as in others. It can readily be replaced and should be, if the driver of the car notices that the brakes exhibit a tendency to slip after a short space of time and examination shows that this is due to the continual passage of grease into the brakes. A slight coating of oil will cause a remarkable falling off in the coefficient of friction and will reduce the efficiency of the brake materially.

2—Assuming that the brake material has been found badly worn. The material may not be torn, but merely worn until it is flush with the rivet heads. This may be due in a certain number of cases to the fact that the rivet is not sufficiently countersunk and this can be cured by flattening it out further by means of a hammer and riveting iron. In lieu of a regular riveting iron, a nail punch or small chisel will serve excellently. Where the brake lining is torn or worn down so far that it is evidently useless and cannot be restored by cleaning to good condition, it must be replaced. To do this, the fabric is first pried away from the shoe as shown in Fig. 6. The rivet is then cut off by means of a cold chisel and hammer as shown in the same illustration and the rivet then punched out. It will be often very difficult to get the rivet out after the head is cut off, owing to the burr which is placed on the end of the rivet in cutting it. If the brake is placed across the jaws of a vise which is opened just sufficiently to allow the rivet to be punched through, the rivet can be readily removed with a small punch assisted by light blows of a small hammer. Care must be taken in the operation not to spring the shoe out of shape, for to do this would cause the brake to drag later and this would mean an immense loss of power and at the same time the rapid wear of the new fabric. In ordering a new piece of fabric from the factory, it will only be necessary to state the model and year of your car, giving the serial number as additional information. The brake lining will be sent you already punched so that it is only necessary to rivet it in place again and the repair will be made. In some cases, the fabric will be purchased from another dealer and in this instance it is necessary to give the length of the piece of fabric required. This is done by measuring with a tape measure around the periphery of the band to which it is to be applied, or, if the old fabric be carefully removed, this can be measured and will serve admirably as a pattern. When the right length of fabric has been secured, lay it around the drum and, with a drill

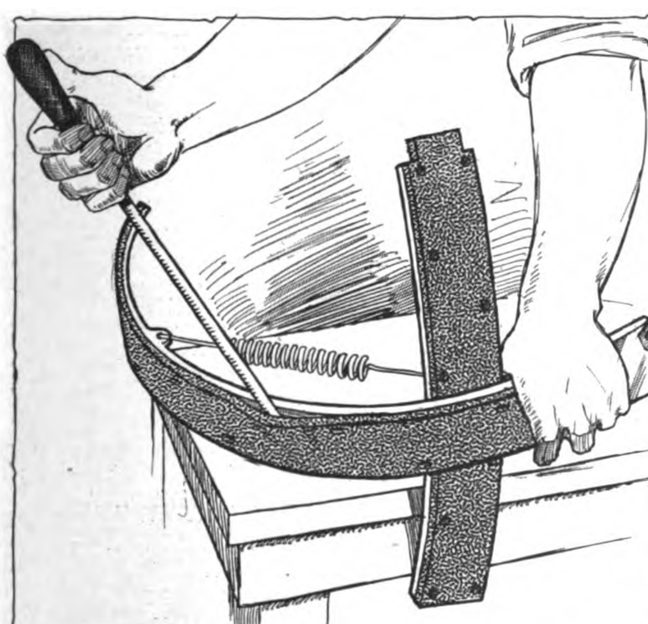

Fig. 6—Before cutting off rivets, pry fabric away from the metal shoe

as in Fig. 4, pierce the holes for the rivets through the new lining. The holes which are already through the metal will serve as a template in marking out the new holes. The holes drilled through the fabric are then countersunk to allow of the head of the rivet being below the surface of the material so there will be no possibility of a metal-to-metal contact between the rivets and the brake drum. The rivets are put through from the fabric side, leaving the head on this side. and riveting them over from the other side. The head of the rivet will be at least 1-16 inch below the surface of the fabric when the work is done.

Replacing the brake upon the drum, if it is of the internal expanding type, will not be an easy matter if the knack is not understood. The drag spring should be first placed on the brake shoe. It can then be sprung over the drum as illustrated in Fig. 5. If the operator tries to place the spring in position after the shoes are in position over the drum, he will have to work entirely against the tension of this spring which amounts to about 20 pounds ordinarily and sometimes more. The best method is to carry the assembly as far as possible without putting the shoes over the drum. One shoe is then placed in position and the other sprung over and immediately fastened. The aid of a second person in slipping the bolt or pin which holds the second drum in place will be a great convenience to one who has not had much experience in the assembling line.

3—The adjustment of the brake links is easily understood and, although the details will vary on every car, any American-made car will use the same method for regulating this part of the brake mechanism so that the brakes will be applied when pressure is placed upon the pedal or pull upon the emergency brake lever. Should the examination of the brakes fail to disclose either wear or grease upon the surface of the shoe, the linkage can be called upon to cure the slip. At each joint in the brake control rods, as they are traced from the pedal or lever to the brake itself, will be found a Y-shaped piece called a clevis. These clevises are capable of being turned to left or right, screwing them off or on the rod which carries them. Screwing the clevis off the rod tends to lengthen the rod while screwing it further on the rod will shorten the total length. When one of the rods is shortened the bell crank lever which applies the brake will be pulled back and the drum pulled closer to the shoe. As a result, when the pedal is all the way down or the lever all the way back the brake is applied with greater force. In some cars a turnbuckle takes the place of the clevis adjustment.

Oakland Uses Northway Motor

Editor The Automobile:—Will you kindly give me the following information: Is the Oakland car an assembled car, and does that company build motors for any other firms?

I have been told that they build the motors for the Cartercar and Cole, and would like to know if they are connected in any way with the Buick Motor Car Company?

Gatesfield, Neb. H. Blanchard.

—The Oakland motor car is an assembled car in that it employs the work done by specialists in each line. The motor is a Northway, the rear axle is a Weston-Mott, etc. The Oakland Motor Car Company does not build motors for themselves or for any other concern. The same power plant is used in other cars of which the Cole is an instance. The Northway concern is a constituent company of the General Motors merger which also includes the Buick company and the Oakland, and the two latter companies are thus constituents of the same merger.

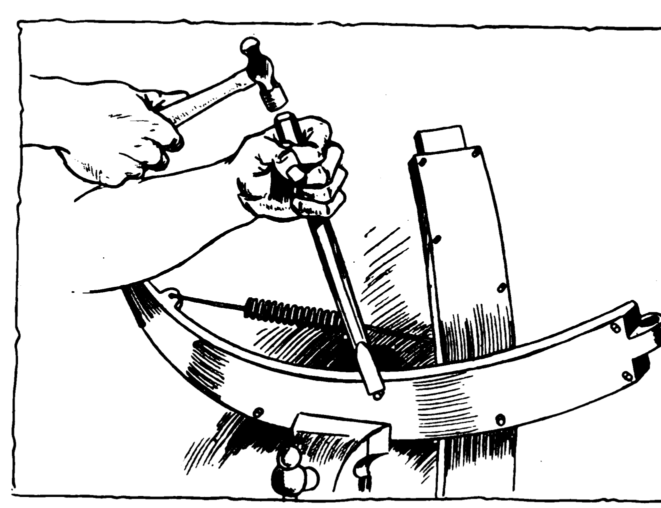

Fig. 7—Be careful in chipping off rivet heads that shoe is not bent

New York, Chicago and Boston Show Space Allotted

Lists Show Big Increases in Representation Over Those of Last Year, Including 405 Exhibitors Comprising All Branches of the Automobile Industry

ALLOTMENTS of space for both weeks of each of the national automobile shows and also for the Boston show have been made by the Motor and Accessory Manufacturers. The lists show a large increase in representation as compared with those of last year and include all told 405 exhibits.

The allotments for each of the shows appear below:

MADISON SQUARE GARDEN, NEW YORK, FIRST AND SECOND WEEKS

Ajax-Grieb Rubber Co..........New York, N. Y.
Automobile Supply Mfg. Co........Brooklyn, N. Y.
Badger Brass Mfg. Co..............Kenosha, Wis.
Baldwin Chain & Mfg. Co........Worcester, Mass.
Bijur Motor Lighting Co.........New York, N. Y.
Bosch Magneto Co............New York, N. Y.
Bower Roller Bearing Co..........Detroit, Mich.
Bowser & Co., S. F............Fort Wayne, Ind.
Briggs Magneto Co....................Elkhart, Ind.
Brown-Lipe Gear Co...........Syracuse, N. Y.
Buda Co., The.......................Harvey, Ill.
Budd Mfg. Co., Edward G.. ....Philadelphia, Pa.
Byrne, Kingston & Co..............Kokomo, Ind.
Carnegie Steel Co.....................Pittsburg, Pa.
Champion Ignition Co...................Flint, Mich.
Chicago Drop Forge & Fdry. Co.......Chicago, Ill.
Coes Wrench Co...............Worcester, Mass.
Columbia Nut & Bolt Co........Bridgeport, Conn.
Connecticut Telephone & Electric Co..Meriden, Conn.
Consolidated Rubber Tire Co......New York, N. Y.
Continental Caoutchouc Co.........New York, N. Y.
Cook's Sons, Adam.............New York, N. Y.
Cotta Transmission Co...............Rockford, Ill.
Cramp & Sons, Wm., Ship & Engine Bldg. Co., Phila.
Diamond Chain & Mfg. Co......Indianapolis, Ind.
Diamond Rubber Co....................Akron, O.
Dixon Crucible Co., Jos.........Jersey City, N. J.
Edison Storage Battery Co....West Orange, N. J.
Edmunds & Jones Mfg. Co..........Detroit, Mich.
Eisemann Magneto Co..........New York, N. Y.
Electric Storage Battery Co......Philadelphia, Pa.
Empire Tire Co.................Trenton, N. J.
Findeisen & Kropf Mfg. Co..........Chicago, Ill.
Firestone Tire & Rubber Co..........Akron, O.
Fisk Rubber Co............Chicopee Falls, Mass.
G & J Tire Co...............Indianapolis, Ind.
Gabriel Horn Mfg. Co.............Cleveland, O.
Garage Equipment Mfg. Co.......Milwaukee, Wis.
Gemmer Mfg. Co...................Detroit, Mich.
Globe Machine & Stamping Co......Cleveland, O.
Goodrich Co., B. F....................Akron, O.
Goodyear Tire & Rubber Co............Akron, O.
Gray & Davis....................Amesbury, Mass.
Harris Oil Co., A. W..........Providence, R. I.
Hartford Rubber Works Co......Hartford, Conn.
Hartford Suspension Co.......Jersey City, N. J.
Havoline Oil Co..............New York, N. Y.
Heinze Electric Co..................Lowell, Mass.
Hess-Bright Mfg. Co...........Philadelphia, Pa.
Hess Steel Castings Co...........Bridgeton, N. J.
Hyatt Roller Bearing Co............Newark, N. J.
Janney-Steinmetz & Co...........Philadelphia, Pa.
Johnson & Co., Isaac G............New York, N. Y.
Jones & Co., Phineas..............Newark, N. J.
Kent Mfg. Works, Atwater......Philadelphia, Pa.
Kokomo Electric Co..................Kokomo, Ind.
Lefever Arms Co...................Syracuse, N. Y.
Light Mfg. & Fdry. Co............Pottstown, Pa.
Link-Belt Co...................Philadelphia, Pa.
McCord Mfg. Co....................Detroit, Mich.
Manufacturers Foundry Co.......Waterbury, Conn.
Michelin Tire Co...................Milltown, N. J.
Morgan & Wright...................Detroit, Mich.
Mosler & Co., A. R. ....Mt. Vernon, N. Y.
Motsinger Device Mfg. Co..........Pendleton, Ind.
Motz Tire & Rubber Co...................Akron, O.
Muncie Gear Works...................Muncie, Ind.
National Tube Co...................Pittsburg, Pa.
New Departure Mfg. Co.............Bristol, Conn.
New Miller Carburetor Co.......Indianapolis, Ind.
N. Y. & N. J. Lubricant Co.......New York, N. Y.
Oliver Mfg. Co......................Chicago, Ill.
Pennsylvania Rubber Co............Jeannette, Pa.
Pittsburg Model Engine Co.............Peru, Ind.
Remy Electric Co................Anderson, Ind.
Republic Rubber Co...............Youngstown, O.
Rose Mfg. Co...................Philadelphia, Pa.
Ross Gear & Tool Co...............Lafayette, Ind.
Royal Equipment Co..........Bridgeport, Conn.
Schrader's Son, Inc., A..........New York, N. Y.
Schwarz Wheel Co...............Philadelphia, Pa.
Sheldon Axle Co.................Wilkes-Barre, Pa.
Smith Co., A. O..................Milwaukee, Wis.
Spicer Mfg. Co....................Plainfield, N. J.
Splitdorf Co., C. F..................Newark, N. J.
Standard Roller Bearing Co......Philadelphia, Pa.
Standard Welding Co..................Cleveland, O.
Stewart & Clark Mfg. Co..............Chicago, Ill.
Stromberg Motor Devices Co..........Chicago, Ill.
Stutz Auto Parts Co..............Indianapolis, Ind.
Swinehart Tire & Rubber Co............Akron, O.
Texas Co., The.................New York, N. Y.
Timken-Detroit Axle Co..............Detroit, Mich.
Timken Roller Bearing Co., The.......Canton, O.
Turner Brass Works, The..........Sycamore, Ill.
United Rim Co.......................Akron, O.
U. S. Light & Heating Co.......New York, N. Y.
Vacuum Oil Co................New York, N. Y.
Valentine & Co................New York, N. Y.
Veeder Mfg. Co., The............Hartford, Conn.
Vesta Accumulator Co.............Chicago, Ill.
Warner Gear Co......................Muncie, Ind.
Warner Mfg. Co........................Toledo, O.
Weed Chain Tire Grip Co.........New York, N. Y.
Weston-Mott Co.......................Flint, Mich.
Wheeler & Schebler............Indianapolis, Ind.
Whitney Mfg. Co...............Hartford, Conn.
Willard Storage Battery Co.........Cleveland, O.
Williams Co., J. H...............Brooklyn, N. Y.
Wolverine Lubricants Co.........New York, N. Y.
Young, O. W.....................Newark, N. J.

MADISON SQUARE GARDEN, FIRST WEEK ONLY

American Ball Bearing Co..........Cleveland, O.
American Bronze Co..................Berwyn, Pa.
American Hardware Corp......New Britain, Conn.
Auburn Auto Pump Co............Boston, Mass.

New York Show Spaces

Car Allotments at Madison Square Garden and Grand Central Palace Made

ALLOTMENTS of space for the automobile show in 1913, which will be held at Madison Square Garden and Grand Central Palace under the auspices of the Automobile Board of Trade during the week commencing January 11, were made Thursday. The members of the Automobile Board of Trade will be housed at the Garden and the other manufacturers will be represented at the Palace.

There will be eighty-seven different makes of automobiles shown, including forty-six at the Garden and forty-one at the Palace. Those who drew space at the Garden are as follows:

Olds, Lozier, Stoddard-Dayton, Oakland, Flanders, Franklin, Stearns, Pope, Stevens-Duryea, Peerless, Locomobile, Mitchell, Winton, Cadillac, Buick, Packard, Hudson, Maxwell, Overland, Pierce-Arrow, Chalmers, Reo, White, Cartercar, Warren, Marmon, Garford, Columbia, Moline, Thomas, Premier, Pullman, Alco, Jackson, Mercer, Auburn, Haynes, S. G. V., Cunningham, Knox, Moon, Matheson, Selden, National, Abbott-Detroit, and Velie.

It will be noted in the list above that the Alco, Auburn and Abbott are listed as members of the Automobile Board of Trade as they were elected to membership recently and have qualified. A number of additional applications for membership have been made and acted upon, but no announcement has yet been made as to who are included in the new list.

The companies that will show at the Palace are as follows: Imperial, Cole, Inter-State, Case, Herreshoff, Krit, Cutting, Kissel, Paige-Detroit, Speedwell, Pathfinder, Austin, Regal, Buffalo Electric, Flanders Electric, Columbus, Metz, Studebaker, Fiat, Hupmobile, Kline, Henderson, Michigan, Benz, R. C. H., Bergdoll, Stutz, American, Rambler, Ohio, Crow, Edwards, Atlas, Lenox, Davis, Paterson, Marathon, Havers, Westcott, Only Car and Marion.

Salon Dates January 2-11

As has been the case for several years past the 1913 automobile show season in this country will be inaugurated by the Annual Salon of Imported Cars, held in New York. The dates for the coming salon are January 2-11 and it will again be staged in the grand ball room of the Hotel Astor. Among those who have already arranged to have Paris exhibits shipped to this country are, De Dion Bouton, Isotta, Fraschini, Lancia, Mercedes, Metallurgique, Minerva, Panhard and Renault. This list represents five nations, France, Germany, England, Italy and Belgium.

Motor Trucks Cause Strike

Chicago Company's Teamsters Quit When Motor Trucks Are Used With Them

FOR the first time since the introduction of the motor truck in the Chicago commercial field teamsters struck during the day because the trucks had been used in part to replace team service by the Consolidated Bottling Company. The company installed six motor trucks, each of which will do the work of two teams. Thirty regular teamsters walked out. The teamsters wanted each motor truck restricted to do the work of only one team.

"The company called for the police to guard its property and threatened to shut the teamsters out for good unless they return to work. George Lomax, president of the concern, said the men violated their agreement."

The above, from the Chicago *Tribune*, October 4, shows something of the attitude assumed by certain branches of the teamsters' unions toward motor transportation, and shows also how, through ignorance, a man or bunch of men may stand in their own way.

The trouble arose over the fact that a motor driver made a delivery and collection at a point on another man's route. Since drivers are paid for the amount they sell off the wagon, the man whose territory was invaded made objection and was upheld by his mates.

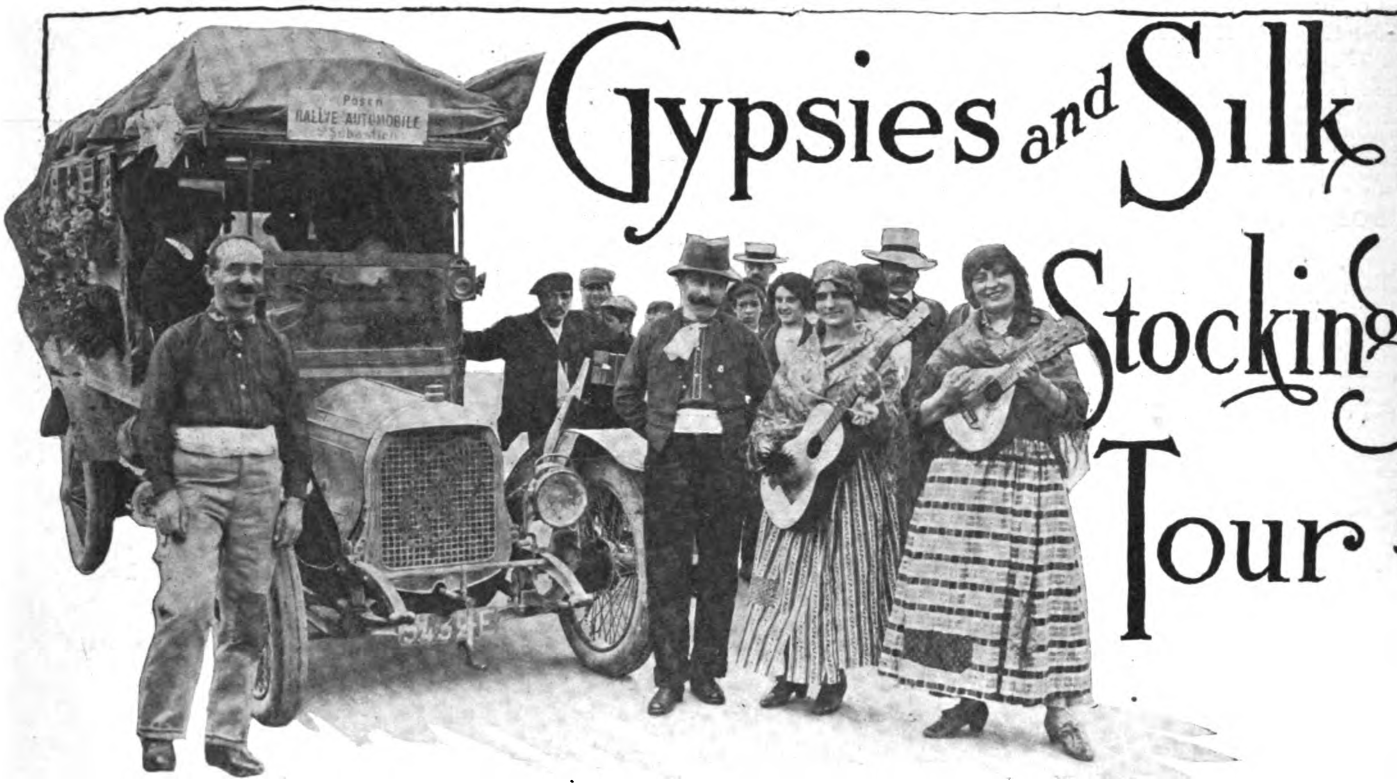
Their general attitude toward their work in this district is shown by an incident on visiting the bottling works in question. To reach the works one must pass under a railway bridge about a block long, dark and damp. Under this bridge, on the trip in, a team and wagon was noticed standing on the far side of the wide roadway, the horses with heads drooped and the driver sound asleep on the seat.

On account of the teamsters' attitude, according to Mr. George Lomax, president of the bottling works, it has been necessary to have three men on some of the trucks. In hiring a driver the teamster refuses to give up his wagon and, upheld by the union, must ride on the motor truck, make the sales and receipt, while a boy is taken along to help in the unloading. This is only on heavy routes.

The motor trucks make as high as 80 miles a day, the longest run made daily being 38 miles out and back to Joliet, Ill. Several of the machines make two runs a day of 40 miles each. Thirty-five stops are made per trip of 10 to 15 minutes each. Drivers take back empty cases.

One hundred cases are carried to a load, weighing 40 pounds each. The trucks are of 2-ton capacity and are built by the Consolidated Company for their own use. Trucks run full both ways.

Gypsies and Silk Stocking Tour



The Gregoire car of Monsieur Picard, first of the general classification A, showing the passengers costumed as Gypsies

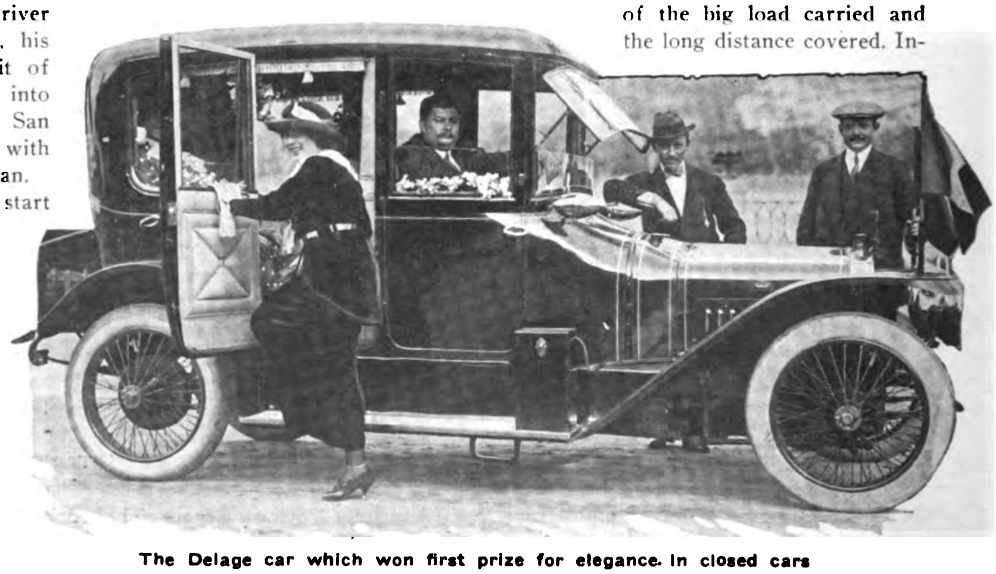
SAN SEBASTIAN, Sept. 27—Out of about 100 competitors a Gregoire caravan won first place in the European rally ending at San Sebastian. The Gregoire people were wise enough to see that in order to win this competition they must carry the greatest possible number of passengers, travel the greatest distance and have the smallest possible motor. They therefore selected one of their semi-racing types of chassis, having a high-efficiency grand prix type of motor and sent it to Posen, in Poland, to make a run of 1,470 miles ending at the Spanish holiday resort. The chassis was specially trussed with a view to carrying eleven persons, representing with their baggage, accessories and bodywork a load of about 3 tons.

With a keen eye to business the Gregoire company equipped this chassis with a caravan body bought for a few dollars from a band of wandering gypsies. With all the accessories, such as chimney, flower pots, bird cages, sweeping brushes, bundles of rags, etc., the combination was so strange that the police were required to keep the spectators back in nearly every town passed through. The crew, consisting of race driver Porporato, the Gregoire agent in Berlin, his wife and relatives, entered into the spirit of the movement, transforming themselves into wandering gypsies, and on arrival at San Sebastian driving through the town with banjoists seated on the roof of their caravan.

The rally regulations provided that a start should be made from various European cities on given dates, the competitors uniting at Bordeaux, then proceeding in a group to San Sebastian. They had to maintain a commercial average of 19 miles an hour and about 240 miles a day. For every 100 kilometers (62.5 miles) they received 4 points; for every passenger, 5 points; for every 100 kilograms (220 pounds) in weight, 1 point; for a closed body, 8 points, and for an open body, 3 points. To equalize chances deductions were made as follows: for every liter cylinder area, 10 points; for every kilometer less than the average imposed, 2 points.

To get advantage of the mileage points nearly all the competitors sought to start as far away from San Sebastian as possible. Results showed that the rules were such that the short-distance tourists had little chance of being well placed. The necessity of running out to a distant starting point necessarily increased the mileage, many of the cars covering 1,000 miles before officially beginning the run. There were exceptionally few failures to meet the minimum requirements, for over sixty cars made the trip from such points as St. Petersburg, Warsaw, Berlin, Amsterdam, Vienna, Milan, Brussels, etc., without a loss of points, and their final position could only be determined after careful weighing and calculation. The Gregoire, heading the list with 144.9 points, was followed by a Hispano-Suiza with 116.6 points, a Berliet with 108.7, a Laurent-Klement with 104.5, an Apollo with 101.1 and sixty others in decreasing value.

The feature of the tour was the small size of the motors in view of the big load carried and the long distance covered. In-



The Delage car which won first prize for elegance in closed cars

A closed car with inside drive ascending one of the mountain traversed

tended primarily as an advertising scheme for the town of San Sebastian, the rally had the valuable quality of showing up the regularity of cars under long-distance touring conditions and of revealing what can be done with motors of really very small dimensions. The accompanying table, giving the particulars of the first ten cars only, shows the distance covered.

In addition to these, fifty-two others were classed, among them being a Ford car, the only American competitor in the rally. A few days before the start of the event some changes were made in the rules; as notification of these could not reach Russia before the departure of the competitors from St. Petersburg a separate list of awards was made for all those having started the run from Russian territory. Under this heading the winner was a Metallurgique car of 3.5 by 5.5 inches bore and stroke, covering a distance of 2,225 miles in its run from St. Petersburg, and securing 163 points, the highest number given to any competitor. The car had a torpedo touring body with five persons aboard. The second under the heading was a Russo-Baltique, of 4 by 5.1 inches bore and stroke, with seven persons aboard, also coming from St. Petersburg, and winning 152 points. The third was a similar car with only two passengers, also from St. Petersburg, and winning 96 points.

On arrival at San Sebastian an elegance competition was held, when the inside steering Delage, having won eighth place on the general list, was awarded the first prize for elegant appearance being followed by the Metallurgique coupé hailing from Brussels, a similar car from Berlin, a Scap, a Gregoire inside steering, and a Scar. In the open-car section the first prize winner was M. Aschoff's Metallurgique torpedo, followed by two other Metallurgique torpedoes, Paul Garnier's La Buire torpedo, a Mercedes torpedo, a La Buire, a Berliet, and an Anasagasti.

A hill-climbing competition was also open to all the rally competitors divided into three classes, two of them being for open cars, two for closed cars and one for cars without any limitation. In the small section of the open cars the fastest was Porporato's Gregoire, which with its caravan body had carried eleven persons across Europe. It covered the 3 kilometers of winding gradient averaging 10 per cent., and having a number of difficult turns, in 4 minutes 31 1-5 seconds. Second was a Scar in 4 minutes 47 seconds; third, a Gobron in 5 minutes 17 seconds; fourth, a Rolland-Pilain in 5 minutes 17 2-5 seconds; fifth, a Gobron in 5 minutes 20 3-5 seconds, and, sixth, inside steering Delage in 5 minutes 33 3-5 seconds.

In the big touring car class the first prize winner was a Rolls-Royce in 4 minutes 33 4-5 seconds, second being a Delaunay-Belleville, followed by a Turcat-Mery, a Scap and a Renault.

In the touring car section the first four were Mathis, 4:24 2-5; Ford, 4:32; Crespelle, 4:32 3-5; Sava, 4:47. The fastest big touring car was a Benz in 4:06 1-5, followed by Rolls-Royce, 4:07; Graft & Stift, 4:17 2-5; Metallurgique, 4:47 1-5; Lorrain-Dietrich, 4:53 3-5.

—

Gaillon Climb

PARIS, FRANCE, Oct. 6—Cable—This year's Gaillon hill-climb was won by Fritz Erle's Benz in 22 seconds, 1 second less than last year. His performance means a speed of 101.5 miles per hour up the 1 kilometer with 9 per cent. gradient. The other times were:

Car	Driver	Time	Car	Driver	Time
	Crespelle	:36	Alcyon	Barriaux	:41

Harking Back a Decade

Alexander Winton Set New Track Marks at Providence—73 Entered in New York-Boston Run

FROM *The Automobile and Motor Review,* October 4, 1902: The Right Honorable Arthur J. Balfour, M.P., is considered one of the most enthusiastic users of the automobile in England. The British premier uses his cars for business and relaxation.

The rules for the hill trials and tire tests recently held under the auspices of the Automobile Club of Great Britain and Ireland were entirely different from those in effect during the New York-Buffalo run of last year. As far as the entered cars were concerned they were classified according to their listed prices and their manufacturers guaranteed to supply duplicates of the entered cars to customers who place orders before a specific date.

The Detroit Automobile Club, which was organized last June, now has a membership of sixty. F. H. Newberry is president.

Alexander Winton, in his Bullet, set new gasoline automobile marks from 2 to 5 miles at the race meeting held in Providence, September 24. The turns were not banked and the rear wheels of the car slewed around with such abandon that after Mr. Winton had made 5 miles of the scheduled assault on the 10-mile record held by Fournier, he slowed down and abandoned the attempt. Up to 5 miles his time was faster than ever before made on a circular dirt track. The 2 miles were covered in 2:12 1-4; 3 miles, 3:18 3-4; 4 miles, 4:25, and 5 miles, 5:30 3-5. This ranges from 1 to 2 seconds faster for each of the distances. The Cannon steam racer established a new mark for steamers when it covered the mile in 1:05 1-4.

The German Emperor used his automobile frequently during the field maneuvers of the army, just concluded. The Crown Prince acted as driver on more than one occasion.

Exports of automobiles and parts for the week ending September 27 were valued at $13,435.

The New York aldermen are considering the enactment of an ordinance to tax hacks and public conveyances from $2 to $5 for license to operate, including automobiles in its terms. Private conveyances are to be taxed $10 a year. The automobile fraternity is solidly arrayed against the proposed measure.

Entries have closed for the New York to Boston and return reliability run and seventy-three contestants are indicated. The original rules drafted called for an average speed of 15 miles an hour, but the Automobile Club of America has amended them so that the average speed limit must be 14 miles an hour. First-class certificates will be issued to those contestants who maintain an average of from 12 to 14 miles an hour. The entries consist of fifty-five gasoline automobiles, seventeen steam vehicles and one electric. The cars range in rated horsepower from 4 to 24, the latter being an Ohio and a Pope.

Accelerometer—Its Use and Value

(Continued from page 729.)

the bench test from which the torque curves in Fig. 1 are derived. In short, the carbureter is likely to choke and so cause loss of torque. This explanation is borne out by the fact that when grade climbing on bottom gear the carbureter has time to act, and it was found that the car in question was capable of climbing a grade steeper than 1 in 5, equivalent to an acceleration reading exceeding 6 1-2 feet per second per second. Some carbureters have better starting qualities than others and curves such as these bring out the differences. As regards *d*, an initial starting acceleration of about 7 would, with, say, two-thirds of the car weight on the rear axle, correspond to a ratio of tractive effort to axle load of about one-third; this should not cause slipping if the clutch is let in gently, but with suddent starting the momentary acceleration may rise enough to cause slipping to begin, and once begun it is liable to continue.

Ideal acceleration would require to conform to the following conditions: It should at any moment absorb the full output of which the engine is capable, that is, the horsepower exerted should be constant, and it should be graduated so that the acceleration does not increase or decrease faster than a certain rate.

It may be said at once that neither of these conditions can be fulfilled by the motor car as at present made. Material alterations would be necessary. To yield a constant horsepower throughout the starting period—and when hill-climbing—it would require to be fitted with an infinitely variable gearbox; instead of there being three torque curves, as in Fig. 1, there would be only one, viz., the rectangular hyperbola, which would be the envelope of an infinite number of such curves. The limit to the vertical height to which such a hyperbolic torque curve could usefully be taken would be the limiting torque at which the rear road wheels would slip. The curve corresponding to these conditions is that shown at A B C in Fig. 7. Modification is needed even in this curve, however, if the acceleration is to be graduated with time. To provide for the acceleration not growing faster than a certain number of feet per second per second in a second it is necessary to replace the vertical line O A with the parabolic arc shown dotted.

To conform to these ideals the car would probably need either electric or hydraulic transmission. Both of these have been shown to be capable of giving a hyperbolic torque curve, and the former has been found able to give a graduated acceleration. Any successful application of them should therefore find a wide use both on road and rail.

Court Enjoins Devious Route

ALBANY, N. Y., Oct. 7—Supreme Court Justice Rudd on Saturday issued an injunction restraining C. Gordon Reel, state highway superintendent, and the highway commissioners from letting a contract for a proposed state road between Trenton and Remsen, Oneida County. The restraining order was obtained at instance of Lester G. Wauful, a taxpayer of Oneida County, who declared that under the original highway scheme, a straight road between the two towns was provided for, but this was changed by the Highway Commission last March by deviating so that the village of Prospect, N. Y., would be included. His lawyer argued that Prospect is being taken care of by a county road and that if the Highway's Commissioner's order were observed, residents of the direct route would be the sufferers.

MILWAUKEE, WIS.—To reduce the number of accidents due to collisions between street cars and automobiles in Milwaukee, the Milwaukee Electric Railway & Light Company is using large display space in the daily newspapers, warning drivers as well as passengers to use more caution. The campaign was carried on heaviest during the period of the Vanderbilt cup races, when thousands of outside motorists brought their cars to Milwaukee.

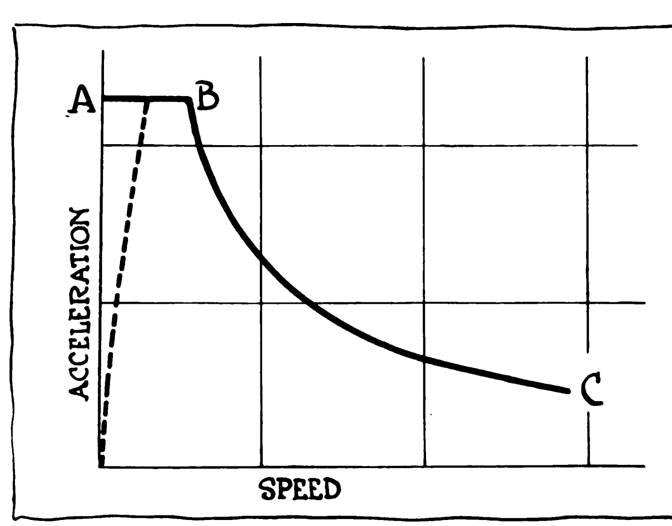

Fig. 7—Curve showing ideal acceleration

Nagent Wins Ardennes

Makes High Score in 269-Mile Race of Much-Mixed Elements, Including Speed, Reliability and Hills

SPA, BELGIUM, Sept. 27—Speed, regularity, and endurance were the determining factors in the 269-mile race held in the Belgian Ardennes. Unable to obtain the exclusive use of the set of roads, the route was divided into twelve sections, of which eight had to be covered on a regularity basis according to cylinder area, and four at speed; of these four there were three straight sections and one rather difficult hill-climb. Some very high speeds were maintained by the small racing and touring cars, and under the formula the small motors had an advantage over the big ones, for although these latter were the fastest they did not succeed in winning high places on the list of awards.

In the racing section highest points were won by a Nagent, a four-cylinder of 2.7 by 4.8 inches bore and stroke, whose time for the four-speed sections of respectively 7, 9, 4, and 8-mile stretches were 63.1, 64.1, 63.3 and 52.1 miles an hour. This last time represents the hill-climb. Second place went to a Mathis of 2.7 by 4.7 inches bore and stroke, third to an Alfa-Legia of 2.5 by 3.9, and fourth to Christiaens six-cylinder grand prix Excelsior. This car was the fastest in the meeting, its highest average being 93 miles an hour, but it was at a disadvantage on the regularity sections, where an unusually high average speed had to be maintained on roads open to all kinds of traffic.

In the touring classes Germany had all the glory, an Opel winning first place, followed by a Benz. French cars were not very well represented, and two Flanders were classed respectively twenty-first and twenty-sixth.

LOS ANGELES, CAL., Oct. 4—With the annual Los Angeles to Phoenix road race less than 1 month away the indications point to ten entries. Entry fees have been received for only six cars but others are certain to come in.

The changing of the route will make the course even sportier than before as the cars will again have the heavy sand of the California desert with which to battle.

The distance is 450 miles and is over part of the old route, used prior to last year, and part of that of last year. Out of Los Angeles the cars will follow the boulevard to Pomona and, from a spectacular standpoint, the race will prove as attractive as ever.

For the first 100 miles the cars will have good roads. Then will come the first taste of desert and for the next 50 miles there will be many dangerous places. Beyond Mecca more sand will be encountered and from there on to Clamys and Brawley the race becomes a true desert battle. The Mammoth Wash will prove the undoing of more than one contestant and the cars will be put to their best before reaching Yuma where the machines will be placed in a control for the night.

Unless the time of starting is changed the cars will have a long wait over in Yuma as the first machine is due to reach there well before noon. The first cars will leave Los Angeles about 10 o'clock and the last at midnight.

The prize money will amount to about $3,500 and for the track races in Phoenix $4,000 has been offered.

Crowd of 4,000 at Asheville Climb

ASHEVILLE, N. C., Oct. 3—Under ideal weather conditions, the first sanctioned A. A. A. hill-climb in Asheville was held today, 4,000 people witnessing the cars climb the steep French broad avenue hill, a grade of 12 per cent. for nearly 5 miles, the distance of the climb. The summaries are: Cars under 161 cubic inches: First prize, cup—won by Studebaker 20; time 55 3-5 seconds. Second prize, $5—won by Studebaker 20; time 1 minute 10 2-5 seconds.

Second event, for cars with piston displacement of 161 to 230 cubic inches: First prize, cup—won by Ford; time 52 2-5 seconds. Second prize, $10—won by Studebaker 30; time, 56 1-5 seconds.

Fourth event, for cars with piston displacement of 301 to 450 cubic inches: First prize, cup—won by Buick; time, 49 4-5 seconds. Second prize, $5—won by Nyberg; time, 56 2-5 seconds.

Sixth event, free-for-all: First prize, cup—won by Nyberg; time, 53 1-5 seconds. Second prize, $10—won by Ford; time, 54 1-5 seconds.

Seventh event, cars with bodies valued at $1,600 and under: First prize, cup—won by Studebaker 20; time, 56 1-5 seconds. Second prize, $5—won by Chalmers; time, 64 3-5 seconds.

Sunbeam Breaks World's Record

LONDON, ENG., Sept. 30—New marks were made at Brooklands, when a 15.9-horsepower Sunbeam lowered the world's records for 900 miles, 12 and 13 hours, and the 1,000 miles. A 30-horsepower, six-cylinder Sunbeam put up new figures for the world's record of 50 miles in 32 minutes 16.4 seconds from a standing start, thereby reducing the record by almost 35 seconds. The Sunbeam company attempted to lower the figures recently put up by the 12-horsepower Star car for 12 hours. The engine dimensions for the two cars were identical, namely 80 millimeters by 150 millimeters. The speeds of the Star car ranged from 66 3-4 miles per hour, to 67 3-4 miles per hour. The average speed for the 12 hours, was 66.82 miles per hour. The first few miles ranged from 76 to 85 miles per hour.

Again on September 21, this same firm put up new figures for the distances mentioned at the beginning of these notes. The 15.9 horsepower, four-cylinder Sunbeam added 3 miles, 203 yards to the 12-hour record, which is now 910 miles, 1,738 yards, and by covering the 1,000 miles in 13 hours, 8 minutes and 25.1 seconds, reduced the old time by 1 hour, 45 minutes, 50 3-5 seconds. When the final burst was made, the official time was returned for the 1,000 miles as 13 hours, 8 minutes and 25.1 seconds, thus creating a world's record.

DES MOINES, IA., Oct. 7—The annual reliability run of the Iowa Automobile Association which was to have started from Des Moines Monday, October 7, for a circuit of the state has been postponed until October 14.

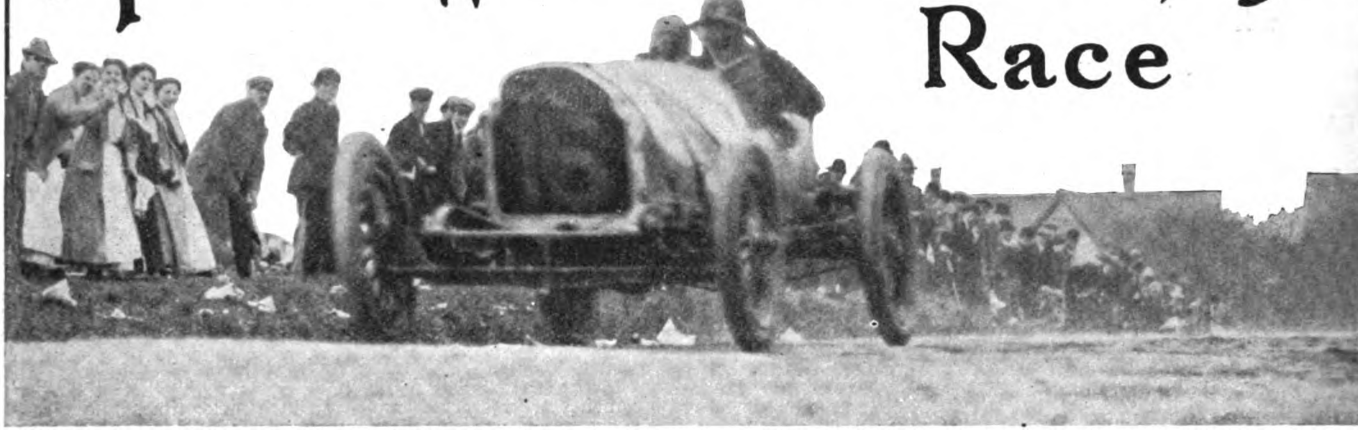
Digest of the Leading Foreign Technical Journals

(Continued from page 721)

and 2.5, taken from Fig. 3, do not result from a range of useful motor speeds running from 1,200 to 1,800, but from one running from 1,120 to 1,800. It is rather an advantage that now the range of the high speed, extending from 37.5 to 60 kilometers per hour, has been somewhat enlarged, because with the direct drive the friction losses of the gearbox are switched out and it therefore becomes possible to drop the motor speed a little lower without feeling the effect in the running of the vehicle.

By checking the results it is thus confirmed that with a four-speed gear ranging over the ratio of 1 to 4 [and, it should have been added, with a motor whose best working range lies between 1,120 and 1,800 revolutions per minute.—ED.] the intermediate gears should be proportioned as 1.6 to 2.5, and rather a little lower than higher. And at the same time the applicability of the easy graphic method to other gear combinations has been demonstrated—From article by Von Löw in *Zeitschrift des Mitteleuropäischen Motorwagen Vereins,* end of August.

Mason Wins Pabst Trophy Race



Bill Endicott skimming the high spots during one of his bursts of speed in the race for the Wisconsin Challenge Trophy

MILWAUKEE, WIS., Oct. 5—The small car races which were run off on Thursday, Oct. 3 were a sort of anti-climax to the big Vanderbilt Cup classic of Wednesday. These races were the Pabst Blue Ribbon Trophy race for 28 laps, or 220 miles 3,704 feet, and the Wisconsin Motor Challenge Trophy event, which is for 22 laps, or 173 miles 2,156 feet. Mortimer Roberts, driving a Mason Special, romped away with the longer run, while the Wisconsin Challenge went to Harry Endicott, also driving a Mason car. Only two cars finished the Pabst race, these being Roberts' Mason and Hastings' F. A. L. Special, the latter having averaged 52 miles an hour for the entire distance, while Roberts averaged 58.8 miles an hour.

Although there were four prizes offered for the Pabst race, only three awards were made, the third place being given to Chandler, also driving a F. A. L. Special, after he had completed twenty-three of the twenty-eight laps. There was no other car running to which the fourth award could have been accorded. It was nearly dusk when Hastings' F. A. L. crossed the tape for the twenty-eighth time, and it would have been impossible for Chandler, still 50 miles behind, to have driven the remaining five laps owing to the growing darkness. Consequently, Starter Wagner gave him the checkered flag at about the same time that he signaled the other F. A. L. on its final lap.

The Wisconsin Motor Challenge Trophy race had five entries, but at the appointed time only the three Mason cars lined up for the twenty-two-lap run. Two of them finished the race, Endicott's No. 5, which came in first in the time of 186 minutes 44.79 seconds, and Mason's No. 3, which required 222 minutes 40.35 seconds to cover the distance of nearly 174 miles. After going for three laps, Snyder's Mason developed clutch trouble, which put it out of the race. In this race, too, an award went begging.

Eight cars lined up for the start of the Pabst Blue Ribbon Trophy event, which was run simultaneously with the Wisconsin Trophy race. Nikrent, driving a Case, was the first to be sent off, following him Rooney in a Bergdoll. Then came Spencer Wishart driving the first of the three Mercers entered in the event. After him Hastings in a F. A. L. Special, while Roberts in Mason No. 16 was the fifth. Pullen, piloting the second Mercer, was next away, then Chandler in F. A. L. No 18 got the word. Hughes was the last to get away in the third Mercer.

Hughes drove the same car which he used on Wednesday in

Roberts driving his Mason Special to victory in the last lap of the 220-mile race for the Pabst Blue Ribbon Trophy

the Vanderbilt, but in order to do this he was obliged to change motors. The Vanderbilt Cup race is limited to cars having piston displacements between 301 and 600 cubic inches, while the Pabst Trophy race required that the piston displacement should not be over 300 cubic inches. The motor which Hughes used in the Vanderbilt race had a bore only .017 inch greater than that of the engine used for the Pabst race.

On the first lap Roberts took the lead, making the distance of nearly 8 miles in 7 minutes and 35 seconds.

In the following circuit the leader retained his position, and the only change in the eight cars was Wishart's nosing of Hastings out of the seventh position.

In the fourth lap Hughes slipped from second place to fourth, owing to his being forced to stop at the pit for water. One of the water connections of his Mercer had been jarred loose, heating up his motor considerably in the run from the point on the course where the break occurred to the pit. Pullen, who had made the lap in 7:32, now assumed second place, while Nikrent was a close third, being only 19 seconds behind. Wishart, in this lap, nosed Chandler out of sixth position.

After filling his radiator Hughes was off again at a lively clip, cutting down his rivals' lead at every turn. In the fifth lap he snatched third place from Nikrent, who was having trouble, while Chandler came into fourth place. The fifth lap was the undoing of both Nikrent and Rooney, both of whom were forced to give up the struggle after completing about 40 miles. Nikrent's car was disabled by a cracked crankcase, while Rooney's Bergdoll snapped a connecting-rod.

By this change of fortune Wishart came into fourth standing, while Hastings became sixth, Chandler fifth, Hughes remained third, Pullen stayed second and Roberts was first.

For the sixth, seventh, eighth and ninth laps there was no change in the places of the contestants. Roberts was still leading, Pullen second, Hughes third, Wishart fourth, Chandler fifth and Hastings sixth. Hughes made the ninth in 7:02, which helped to put him in second place when Roberts was forced to stop on the backstretch to repair a break in the gasoline supply pipe of his Mason. Pullen then succeeded to the premier position and for the next ten laps the race was a duel between Hughes and Pullen. At the end of the tenth lap the order was Pullen, Hughes, Roberts, Wishart, Chandler and Hastings. For four laps, often repairing the gasoline line, the eleventh, twelfth, thirteenth and fourteenth, Roberts remained in fourth position, but was gaining on the leaders every mile.

Getting ready for the Grand Prix—The technical committee inspected the cars very carefully up to the start of the race

Meanwhile, Hughes and Pullen were fighting it out to a finish, although the former was gaining rapidly on his team mate. At the end of the tenth lap Pullen was in the lead by 52 seconds. On the next round Hughes cut this down to 24 seconds, and on the twelfth circuit he had passed his rival and was 4 seconds ahead. Hughes' average speed for eleven laps, or nearly 87 miles, was 62.12 miles an hour, while Pullen covered the same distance slightly faster—62.6 miles an hour.

It was in the fifteenth lap that Spencer Wishart's Mercer gave out. From the eleventh lap up through the fourteenth he had been in third place about 6 minutes behind Pullen and Hughes, and was making these rounds in good time, well over a mile a minute. But on the fifteenth round he was obliged to give up the struggle, for the crankshaft of his motor broke on the backstretch.

At the end of the sixteenth Pullen was less than a minute behind Hughes and was pushing the leader to the limit. But in the next round Hughes blew a tire, which put Pullen in the lead again by 15 seconds.

Hughes lasted for three more laps, which he made in fast time. The nineteenth was made in 6:55, and it put him a little over 2 minutes ahead of Pullen. Barring accident, it looked as though Hughes would repeat his Eigin victory. But in the twenty-second lap he had to give way to the other Mercer driver, as his No. 19 Mercer had broken a universal joint, a damage which prohibited immediate repair.

Pullen was now an easy leader, being 8 minutes ahead of Roberts, who did not fare much better than did Hughes, for after going only one more lap, something went wrong with his transmission and the trouble was of large enough proportions to prevent his finishing the race.

After Pullen and Hughes went out, Mortimer Roberts, who had previously been running third, came into the limelight.

In the twenty-third lap the three cars running were the two F. A. L.'s and the Mason, Hastings' F. A. L. running a poor second to Roberts. Chandler was far in the rear.

Roberts finished the race in 225 minutes 8:71 seconds, averaging 58.8 miles an hour for the 220 miles, while Hastings finished in 255 minutes 5:1 seconds, averaging 52 miles an hour. When Hastings finished it was getting dark and the judges decided to flag Chandler and to give him third place without waiting for him to finish.

Anderson's Stutz car rounding a curve in the Grand Prix

Race for the Wisconsin Trophy

LITTLE interest centered in the Wisconsin Motor Challenge Trophy race, which was all Harry Endicott. At the same time he drove a heady race and made good time with his little Mason. Mason, also driving a Mason car, ws the only other car to finish the race, coming in far behind Endicott. Although there were five entries for the event, Kulick, who was to have driven a Ford Special, withdrew, as did Heber, whose entry was an E-M-F.

At the start only the three Mason Specials were in evidence. Snyder in Mason No. 2 being the first to be sent off. Then Mason was started, while Endicott, in entry No. 5, was off last. Snyder's running was better than that of his two teammates for the first lap, but Endicott did not take long to head him off, and at the end of the second lap he was way ahead of the other two. Mason was third, and the second place would undoubtedly have gone to Snyder, whose car is much faster than Mason's, which is a remodeled touring car, had the former not developed clutch trouble in the fourth lap, which trouble proved to be so serious that Snyder had to withdraw in favor of the other two Masons.

Endicott's fastest lap was his fifth, which was run in 7:29, and which is good going for a small machine. He made only two stops during the entire run of 173 miles, the first being on his first lap, when a spark-plug was replaced.

The Falcar was the only one to finish without trouble of any kind. Not a stop was made at the pits by Hastings, even to fill his tanks. Wishart in the Mercer ran 100 miles without a stop till he went out for good. Robert's Mason special, the winner of the larger class, made one stop on account of a broken gas lead. This was repaired by putting in a piece of hose. When he started out again the car stopped after a few yards because he had forgotten to turn on the gasoline again at the tank.

Endicott, the winner of the small-car race, made two stops, the first after one circuit when a spark plug was changed. The other was in the seventeenth lap for gasoline. Mason, driving the Mason No. 3, an old stripped touring car, held the record of the day for stops, making five during the 173 miles of the Wisconsin Motor Challenge Trophy contest.

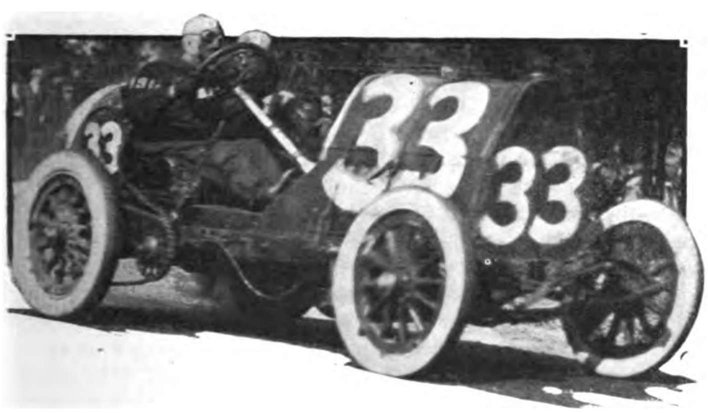
There were eight stops at the pits in the Pabst Trophy race, two for tire troubles. There were two cases of mechanical trouble. The other stops were for fuel, water and oil.

Fiat Wins Grand Prix at Milwaukee

(*Continued from page 711*)

changes were on the right rear wheel which has the hardest service. Refilling fuel, oil and water tanks were responsible for more stops than any other cause, and mechanical difficulties were comparatively few, necessitating only ten stops altogether, three of which put the cars out permanently.

Anderson with his Stutz holds the palm for the longest non-stop run of the day. He made only two stops during the entire 410 miles of the race and ran the first 215 miles without a halt.



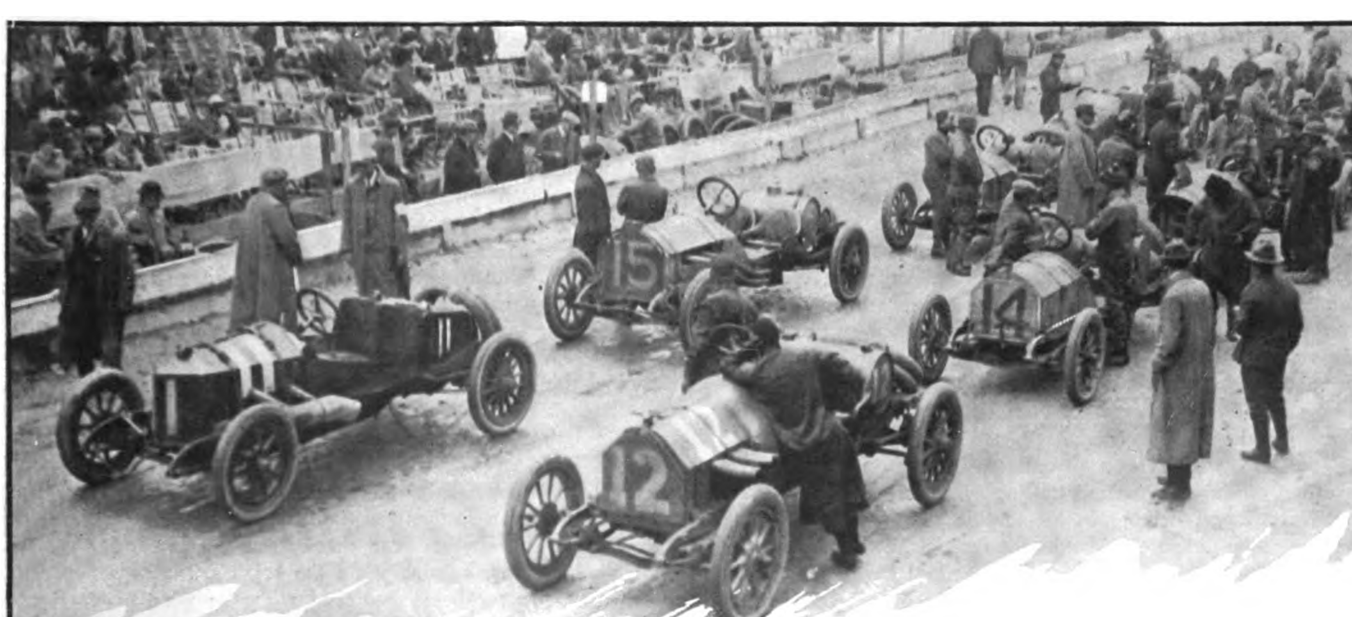
Tetzlaff speeding his Fiat on the Town Line straightaway

He had no mechanical trouble, and he changed but one tire throughout the race, replacing the demountable wheel on the left rear in the twenty-seventh lap. At the same time he took on gasoline and oil. His only other stop was on the next to the last lap, when he refilled his gasoline tank and was away again in 40 seconds.

Like Anderson, Bragg made only two stops, the first being after he had run 166 miles, when he changed both rear tires and took on gasoline and oil. His other stop was at the end of the thirty-seventh lap when he refilled his supply tanks and changed the left rear tire. Bergdoll made but four stops, the first to take on gasoline and replace a spare tire which had been changed on the back stretch, getting away in 46 seconds. When the race was half over he lost 3 minutes and 40 seconds at the pits in changing tires, renewing his supplies and tightening up shock absorbers. After running 30 miles more he stopped 45 seconds to put a strap around the fuel tank which was beginning to work loose. He stopped again for gasoline and a spare tire in the thirty-eighth lap and in the forty-third to put on two rear tires.

Barney Oldfield started the ball rolling at the pits, when after his first circuit of the track he replaced a rear tire. He had not gotten away when Burman pulled up after completing 15 miles and adjusted the valves of his engine. He had not had time to properly tune up the engine before the race; in fact, the start had been delayed 10 minutes to give him a chance to get it in order. Hughes stopped in his third lap to change spark plugs and again in the fourth for the same purpose. Then there was a lull at the pits till Oldfield drew up for another tire change. Tetzlaff stopped twice for tires and fuel after running 80 miles. Before he got away Horan pulled up to replace a spare and take on gasoline, but waited to change a right rear tire. He had started out when the shouts from his pit told him that the jack had been left in the track in the excitement, and the mechanic did a record-breaking sprint back to pick it up. Even at that, Horan was away in less than 2 minutes. When the race was two-thirds over Horan lost 6 valuable minutes for Burman, who relieved him, by running in on the rim from the back stretch where he had blown a tire. This damaged the wheel so that it had to be replaced by one from Burman's Benz before a tire could be put on.

De Palma holds the record for rapid tire change, when at his first stop in the twenty-fifth lap he replaced a tire in 37 seconds. At the end of his next circuit of the course the Italian stopped again, this time to put oil on the rocker arms. After another 15 miles he halted again and worked at his motor for nearly 4 minutes adjusting the valves. His last stop was made in the



Lineup of the contesting cars for the Pabst Blue Ribbon Trophy race, showing a typical morning scene of road race preparation

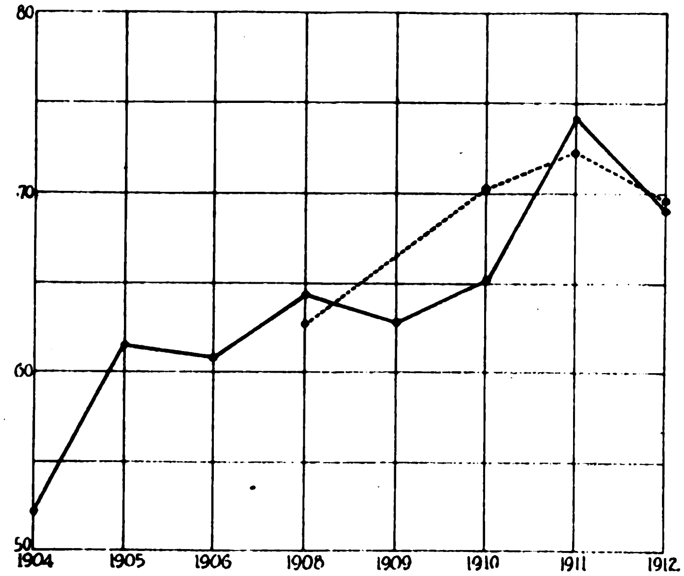


Diagram showing average speed in each year. Heavy line—Vanderbilt cup race. Dotted line—Grand Prix

thirty-seventh lap when he changed a tire and took on water.

The record of Clark's Mercedes is nearly as good as that of the Stutz. Clark made but two stops, the first one being after running 190 miles, when he took on gasoline and oil. His second and last stop occurred in the thirty-fifth circuit of the course, when he lost over 10 minutes in repairing a leak in the water cooling system. Clark was the most fortunate so far as tire troubles were concerned, as he did not change a tire throughout the race.

Bob Burman, in Benz 31, was the first to get away, followed by Fountain in a Lozier. Fountain is a Milwaukee pilot, and he drove the same car which Nelson, its owner and entrant, drove in the Vanderbilt Cup race of Wednesday. Next came Teddy Tetzlaff, demon driver of them all, at the wheel of Fiat 33. He was trailed by Hughie Hughes in the sturdy Mercer. The ill-fated De Palma was off 30 seconds later in his Mercedes 35. Spencer Wishart, who drove a Mercer in the Pabst race of Friday, was in command of another Mercedes, entry number 36. Clark was next off in Mercedes 39. Bergdoll, at the wheel of the immense Benz 40, followed. After him was Bragg, Fiat 41, who had withdrawn from the race following Bruce-Brown's death, but who was persuaded at the last minute to compete. Benz 42, which was scheduled to be driven by Joe Dawson, winner at Indianapolis in June, was sent away by Horan instead. Gil Anderson in the Stutz, which looked small beside the immense foreign machines, got the word next, and finally came Oldfield in Fiat 44. Although a favorite with the crowd, no one expected Barney to go the distance. He has never finished a road race before. More than that, he finished in the money.

Tetzlaff took the lead in the first lap, with Bragg second and Bergdoll third. Wishart and De Palma were in fourth and fifth places, respectively, while the others came around in the following order: Burman, Hughes, Horan, Anderson, Fountain, Clark and Oldfield. The latter would no doubt have shown up better on this first circuit had he not been delayed by tire trouble. This was the first stop at the pits, but the crowd spurred the veteran driver on.

The second lap saw only two shiftings of positions among the cars in the rear position. Wishart took Bergdoll's place in third position, while Hughes overtook Burman, forcing the latter into seventh position, and putting Hughes in sixth. All this time Tetzlaff was driving in his terrific slam-bang style, much the same as he did in the Vanderbilt race of Wednesday. After completing his second lap, Burman stopped at the pit with engine trouble, the same trouble, by the way, which delayed the start of the race for 10 minutes. In his third lap Burman was permanently out of the race, his big Benz having succumbed to a broken piston.

Burman out, Anderson came from ninth into seventh place. Hughes, who had to stop at his pit on his third lap to change a spark plug, went back to last place at the end of the third. The shift brought Clark up to tenth, Oldfield having passed him. Fountain was running now in eighth place, while Horan became sixth. The leaders retained the same position which they had held during the second lap.

The third was Wishart's last lap; in the fourth his motor was disabled by a broken crankshaft, a break which prohibits quick repair. Bergdoll now became third, while De Palma moved up to fourth place. Horan succeeded to fifth place, Anderson to sixth, Fountain to seventh, Oldfield to eighth, Clark to ninth and Hughes to tenth. Tetzlaff, way in the lead, was reeling off the miles at a lively clip. Bragg was a good second.

The fifth saw no changes in the positions of the leaders, the only difference in the ten contenders being that both Anderson and Fountain passed Horan. Hughes, running last, came to the pit again in the fifth lap with more spark plug trouble.

In the sixth lap Clark passed Oldfield, who was obliged to stop to replace a right rear tire. The veteran driver made quick work of the change, but he did not regain his lost ground until the ninth lap. There was no other change in the line-up in the sixth lap, Tetzlaff still leading by a good margin and hotly pursued by Bragg, Bergdoll and De Palma.

It was in the seventh lap that De Palma snatched third place from Bergdoll, who stopped for fuel and an extra supply of tires to replace those used on the backstretch. This wait put Bergdoll into sixth place, Fountain and Anderson passing him as well as De Palma. Tetzlaff and Bragg were still running first and second, respectively.

The eighth lap brought out no differences in the line-up, while in the ninth the only position change was in Oldfield's taking eighth place from Clark. In this lap Fountain went through the straw bales on the Fond Du Lac road turn, but he was soon on the road again, no one having been hurt, and the car apparently none the worse for the mishap.

In the eleventh Tetzlaff made his first stop at the pit, thus giving his lead to Bragg, who was running nicely, and whose car had performed so far without a hitch. Tetzlaff changed a right rear tire and was soon away again in pursuit of Bragg. In this lap Horan, who had been running seventh, passed Anderson, Bergdoll and Fountain and took fourth position momentarily, only to drop back on the following round. The Stutz car then took fifth place, Bergdoll sixth and Fountain seventh. Bragg retained the lead over Tetzlaff from the eleventh through the fourteenth lap, closely pursued by the former. All this time De Palma was running third, and Anderson, except for the thirteenth lap, when he was momentarily nosed out by Bergdoll, was in fourth position. In the fourteenth lap Bergdoll blew a tire on the backstretch at station 4 and the delay put the Benz entry into seventh position, both Oldfield and Fountain passing it. Hughes was still worrying along in last place.

The fourteenth lap was Tetzlaff's fastest and also the fastest lap ever covered over the Wauwatosa course, he making the circuit in 6 minutes 7 seconds, at the average speed of 77.2 miles an hour. This hitting it up gave Teddy the lead again, which he held through the next lap, Bragg running consistently and but a few seconds behind. On lap seventeen Tetzlaff made a pit stop which cost him 2 minutes and 22 seconds, and put Bragg in the lead.

At the end of the seventeenth lap the cars stood Bragg, Tetzlaff, De Palma, Anderson, Bergdoll, Fountain, Oldfield, Clark, Horan. The Mercer car 34, Hughie Hughes, went out for good in this lap, leaving only nine cars still running. Hughes' car was disabled by a broken gasoline line. Two laps previous to his withdrawal, Hughes' car threw a wheel at station 7, but controlled the car, keeping it on the road. Another wheel was substituted, his car being equipped with the wire type. Bragg averaged 67.5 miles an hour for the seventeen laps.

Through the twentieth lap nothing of note took place, although on the next round Bragg lost his lead, which he had held from the seventeenth lap. He was obliged to stop for gasoline and he changed both rear tires at the same time, losing in all 2 minutes. De Palma and Tetzlaff were both so close that they passed Bragg while he was stopped, putting the Cincinnati driver into third place, Tetzlaff into the lead again and De Palma second. Tetzlaff was also forced to change a rear tire, so that, in the twenty-second circuit, De Palma was leading, with Tetzlaff second and Bragg still third. The other cars maintained practically their same positions in the nineteenth, twentieth, twenty-first and twenty-second laps. De Palma, then leading, had averaged 72 miles an hour for twenty-two laps.

De Palma retained the lead through the twenty-fourth lap, with Tetzlaff second, Bragg third, Bergdoll fourth, Anderson fifth, Oldfield sixth, Clark seventh and Horan eighth. But in the next lap Tetzlaff succeeded in nosing De Palma out of first position, while the positions of the rest of the cars remained the same. De Palma had been forced to stop at the pit to change the left front tire and to take on water and gasoline. His pit stop consumed 2 minutes and 9 seconds. More delay at the pit on the twenty-sixth lap allowed Bragg to take second position from De Palma, while Tetzlaff was still in the lead. No change in the positions of the other cars took place in the twenty-sixth lap, nor in the next four laps.

In the thirty-first lap it was seen that something was wrong with Tetzlaff, who, since he had regained the premier position, had been going at a lively pace. Finally the car was seen coming down the track at a slow pace, and it was found that he was out of the race with a broken radius rod, practically repeating his performance of Wednesday in the Vanderbilt Cup race.

Bragg succeeded to first place again, De Palma second, Bergdoll third, Anderson fourth, Oldfield fifth, Clark sixth and Horan seventh. The rest of the race for first place was simply a struggle between Bragg and De Palma, Bragg with the newer car having the best of the argument. Bergdoll was third up to the forty-third lap, although there was plenty of excitement for the crowd in the closeness between this car and Anderson's Stutz, which was the only American remaining in the battle.

Through the fifty-first lap Bragg was leading De Palma by over 2 minutes, while Anderson was third, Bergdoll fourth and Oldfield fifth. In the last lap, after De Palma had gone into the ditch, second position went to Bergdoll and third to Anderson. Burman was driving for Horan up to the forty-eighth lap when the car was flagged by the officials.

Contests Have Their Lessons

ROAD racing in America for 1912, which ended last week with the exception of the Desert race, has not done so much good to the American maker as in former years. Not because the lessons to be learned have not been in evidence but chiefly because the manufacturers have been conspicuous by their absence. 1912 has not been a manufacturers' year in road racing; rather it has been a year characterized by sporting car owners, who have entered their machines in different events for the sport of the affair and not because of any holdings they may have had in any company building machines. As is always the case there have been the exceptions, examples where manufacturers have thrown their entire energy into the contest and have come out with flying colors, carrying away laurels that have aided the engineering department and the selling organization.

That many American automobile makers have withdrawn from road racing and speedway racing for the present is and has been apparent but it is very problematic if next year does not see several of them equipping racing teams to campaign the entire country. This is assured in that every company that has gone into legitimate racing this season has reaped a good harvest. The expense of competition has been less than in any previous year: With educated drivers, the amount of practice work before any meet has been cut to the minimum.

There are hundreds of things that the American maker can learn from road racing. A few examples will suffice: There are several high-class, high-priced American machines in which it is necessary to have a service station man set the brakes in order to do the job properly; in fact, their salesmen recommend it. On the best foreign machines the brakes can be adjusted with the car travelling at its highest speed on the road. Here in itself is a lesson in accessibility that the American maker can carry to his own engineering department and work into his new models.

The foreigner is learning new lessons every year in racing. With him the days of bulk and power as the only means of victory are over. The race is not now to the biggest motor or the heaviest machine. Reduction in weight and efficiency in motor are now major factors. These have been made factors because the foreign makers have gotten together and revamped racing conditions according to the needs of the hour and the progress of the times.

When the long-stroke motor was in the spotlight he framed his regulations to test it. The looked-for lessons were learned and the industry profited. Now that smaller motors are desired by the entire country, now that lighter weight is being asked for, he has framed his regulations along these lines and will solve these problems.

In the meantime America is going on as she has been going on for three or four years, spending each successive season as "a tale that is told." There has not been any effort to frame regulations for contest that will measurably advance the industry. The manufacturer who wants to bring out his new machine with smaller motor, lighter weight and combining various other details has to do so at the anticipated expense of being a second-rater, knowing that the unlimited cylinder sizes of other makers will surely go against him. In spite of this handicap a few of our makers have shown progress, they are compelling attention and they are getting good results.

It is time that our manufacturers were awake to the situation. It is high time that they grasped the potentialities of well-conducted, well-regulated racing. Hundreds of lessons are still to be learned from it but if our manufacturers still claim not to have any time in which to sanely discuss engineering tendencies and formulate racing regulations which are not only in conformity with the trends of the years but which will also act as pioneering factors, then they should not aim so strenuously in avoiding the spirit of the rules and try to win at any cost.

It is absurd to spend thousands and tens of thousands in racing if the governing regulations are not in step with the development of the industry. If the public want racing, and their attendance at this year's races has shown that they do, then make this racing a value to the maker, a value to the dealer and a value to the spectator. This can be done.

Everybody is asking for a solution of long-stroke, weight as a factor, wire wheels *vs.* wood wheels, and many other questions. There is an opportunity for racing to solve practically all of these, but in order to do this, the racing rules must be revised each year in respect to those fundamentals that determine such points.

Waldon Defends The Annual Model

Packard Representative Declares It Evidences Progress Made in Industry and Meets Wishes of Public

Season Plan Is Also Treated—Greatest Problem, Says Speaker, Is Even Production Throughout the Year

S. D. WALDON, of the Packard Motor Car Company treated the subject of annual models before the recent convention of sales managers of the Automobile Board of Trade. Mr. Waldon presented the subject from the favorable point of view, showing the reasons that have actuated manufacturers in retaining the idea of annual models. Mr. Waldon's address was as follows:

The original "automobile season" opened with good driving weather in the spring and continued through summer and fall. Every maker produced his output so as to make deliveries during this period. The mechanical developments of the season were incorporated during the winter in the model to come out with the opening the next spring. This plan produced a tremendous demand at the opening of the season because it combined the natural demand of spring with the stimulated demand on account of the new vehicle with its improvements.

In those days we had the automobile show in the fall in an endeavor to prolong the season and to get business to tide the factories through the winter, but it did not work out that way. The only way to shorten the winter seemed to be to advance the opening of the season into it. This was done at about the rate of a month a year but with each advance toward midwinter the close of the preceding season seemed to keep its same distance ahead. There were always two influences combined to retard sales, in winter, the unfavorable weather and road conditions for the use of a new car on the one hand, and the fact that the new car of the fall would be made obsolete by the new one in the spring, on the other hand.

Moving the opening ahead to close up the dry spell might be likened to the cat that gets started chasing its tail, unconscious of the fact that its own approach withdraws the tail.

It was not until we had passed mid-winter and were opening the season in the fall months that the interval between seasons was materially reduced. The public purchased in the months from October to March because the vehicles were the newest models and with every latest improvement, and continued to buy through spring and summer because of good driving conditions. The year in this part of the country may for purposes of this discussion be divided into two equal sections. Six months, April to September, when conditions are favorable for the use of a new car, and October to March, 6 months in which the average purchaser is loath to break in the varnish of a new car in the mud and slush, and in a great many cases cannot be persuaded to take a demonstration. The 6 months from April to September are good driving months, and able to take care of themselves. The 6 months from October to March are unfavorable to automobiling, and need a stimulus if one is to be had.

The greatest gap between seasons occurred when the 6 months of winter weather preceded the offering of the new models in the spring, and the minimum gap when the 6 months of good driving weather is preceded by a new season, which opened in October.

When the new model appeared in the spring all the advantage of good driving weather was added to the stimulant of the new models and the demand was greater than could be cared for, then, but with a tapering off as winter approached, and with every argument against purchasing during the cold weather.

When the new model appeared in the fall it furnished its own incentive to purchase during the first 6 months of bad weather, and, of course, the good weather and roads of spring and summer carried the volume along almost to the opening of the new season. Opening the season at the commencement of winter gave the factory and dealers courage and enthusiasm to drive ahead with manufacturing and selling campaigns during the bad winter months.

How to run our factories on an even keel all the year round is the vital question before all of us and it seems to be best answered under the plan we have used in the past by not combining in the spring the two influences of new models and good weather and road conditions, thereby for a few months producing a pressure upon the factory that it is incapable of handling at that time, and with a subsequent reaction, but by keeping these influences separate and using the stimulant of the new goods at the beginning of winter to produce sales for dealer and factory alike through the 6 months of bad weather and with the natural driving season following to maintain a fairly uniform demand throughout the year.

The plan of selling by seasons grew out of necessity. Manufacturing economy demanded the largest possible factory orders that could be run through without change or interruption. Sales department efficiency demanded an up-to-date car, and mechanical developments were being made by all companies at such a rate that no one could afford to run longer than a year without calling a halt and introducing the improvements. A year was the smallest unit of time to satisfy the manufacturing department, and the longest unit the sales department dare give.

So long as radical and real improvements are made in motor cars so long will some such plan as we have all been working under be necessary to meet the requirements of both the manufacturing and selling end of the business.

There is no denying the fact that it is a big undertaking to change over a large factory from building one car or line of cars to another, and no company would go to the expense and trouble if it were not justified by the returns on the additional business obtained as the result.

When finality of design is reached and there is no opportunity left for genuine and marked improvement then we may all abandon the idea of yearly models and build the same article continuously. I say we may do it, because even after we reach a point where we build the same thing year after year it may be desirable to manufacture in blocks of one year's output.

The chief objections to those who oppose the season plan are wrapped up in the difficulty of accurately estimating the public's requirements as well as the developments of competition. The temptation to make the manufacturing run a little larger so as to secure greater production economy is always great, while sometimes the best laid plans are spoiled through competition educating the public to some other type of construction than you have to offer. The hardships of the season plan fall upon the company who for any reason has cars to sell that have been made obsolete by the new models of competition.

It would practically make no difference whether the industry were operating on the season plan by series, which amounts to about the same thing, or the continuous model plan.

A genuine improvement is a valuable selling asset and if made the most of through advertising by some prominent company immediately sets a new standard by which all cars are measured. It is not selling cars by seasons that should be criticised. The root of the objection is in the improvements that are made in the new models, that add to their value, and detract from all others.

Suppose that during the past 10 years we had been operating under the series plan. The result would probably have been just the same. Every manufacturer would try to make as many of one kind of vehicles as possible, probably a year's run. The same selling reasons would necessitate the introduction of improvements at not greater than yearly intervals. All would have been introducing their series at about the same time or trying to get out first with the general result of gradually advancing the opening date, and a convention at this time would probably be looking to obtain some change in the general scheme.

Suppose on the other hand the industry had had no set time for announcement but was split up into twelve divisions, each bringing out its new series in a different month of the year. All but one twelfth of the companies would have had obsolete models and there would always be the incentive for the purchaser to wait another month and see the next crop of new things.

In the last analysis any complaint against the season plan should be directed against the quantity of improvements, the rapidity with which they have been developed and the speed with which manufacturers have been obliged to work to keep abreast of the times.

If it were not for the changes what good or harm could the season plan do? Without improvements it is not a new model, and there is no stimulant for the prospect to buy.

The last 7 or 8 years we have been regularly confiding to ourselves that we could see the final car. We have always had this or that thing to add, and then the final car would be finished and might be manufactured without change for 5 years or more. But the new requirements that have been developed by the user have prevented us from ever catching up, and it is probable that the next 5 years will hold just as many improvements and the necessity for breaks in our manufacturing and selling for their introduction as we have had in the past.

A motor car is the most self-advertising article there is. It is as much a part of the owner as his clothes. It lends itself perfectly as a medium for the expression of his sense of beauty in color and form. More different trades contribute to its making than to any other popular article in the world, and every trade is an opportunity for improvement. With the automobile industry now standing fifth in size in the United States, with the great incentive to individual initiative on the part of every member of it, and what is even more important with the keen personal interest in the cars of some one of us, of every successful business man in the country, it will be surprising, to say the least, if the next 5 years fail to produce some startling improvements over our present vehicles.

We are all here to build up a good name and to make money, and both can be best done by giving the public what it wants.

Above all things the public wants evidence of progress, whether it be the same thing for less money or a better thing for the same price. The average buyer retains his car 3 to 5 years and then will buy again more or less readily, depending upon the advantages offered by so doing. The public has been educated too well by the last 10 years of the season plan and the addition of improvements by years to take kindly or quickly to any other basis. It is more of a task to go against the brute strength of such a combination demanding improvements by years than any individual maker cares to undertake, and it seems inevitable that the situation must be allowed to eventually solve itself through reaching an approximate finality of design.

It is perfectly certain that no matter what we may do on this subject in the way of resolutions and recommendations, each one of us will go home and do what he thinks is the best for his business.

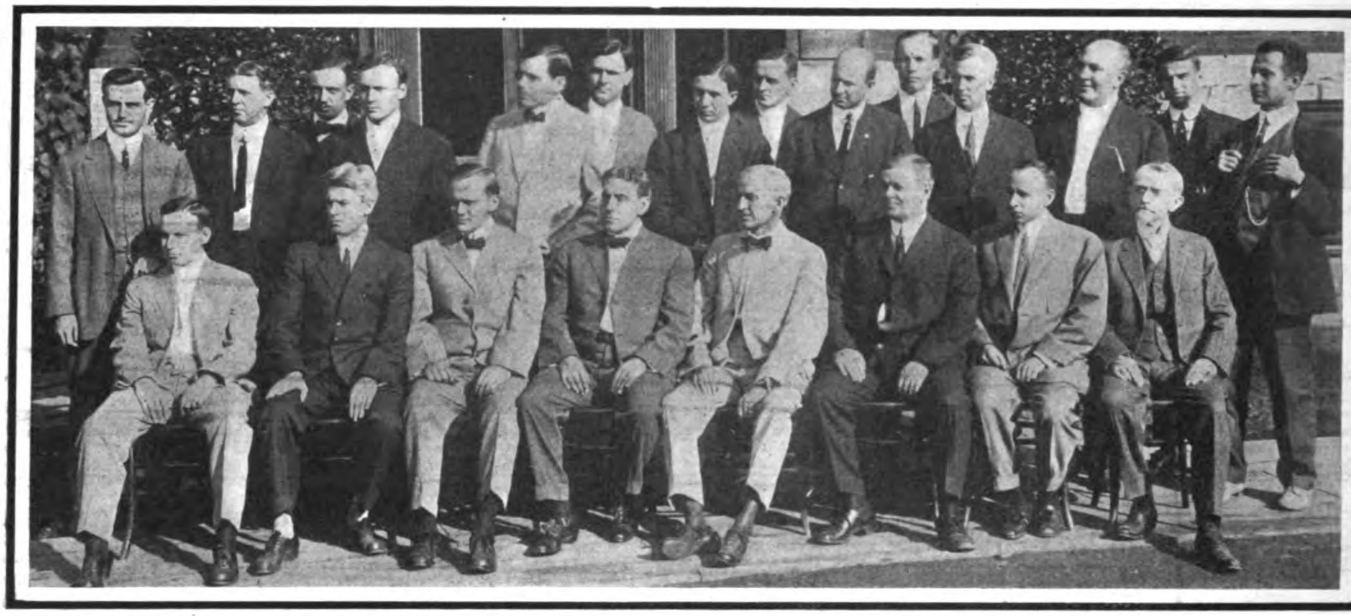
A well-known automobile company has run the same model for four years, practically without change. They have no patent on the plan and everyone else has a perfect right to do likewise, but if all the rest of the industry did the same, except one man who produced something new every year, that one man would have a tremendous advantage, which would not disappear until he had exhausted all opportunity for genuine improvement.

The season plan will have good cause for being so long as we continue to make marked improvements in our vehicles necessitating intervals of time for changing over our shops and permitting our dealers to clean up one output before beginning on the next. The season plan will cease to be just as soon as there are no marked improvements to make the new vehicles more desirable at the expense of the old and of others.

Arizona's New Law in Effect

PHOENIX, ARIZ.—The new state registration law is now in effect. Under its provisions every owner of a motor vehicle must register each machine in the office of the secretary of state. A complete description of each car, including the name of the maker, factory number, style and motor power, must be given. The registration fee is $5 for a machine of 40 horsepower or less, A. L. A. M. rating. The motorcycle tax is placed at $2. This law does away with city numbers, which have heretofore been the source of much confusion.

MONTREAL, QUE., Oct. 7—That Montreal's motor trade is in a flourishing condition, is evidenced by the automobile show which will take place in Montreal during the week of January 4-11. There will be two shows run concurrently, one at the Drill Hall and the other in the Armory.



Gathering of the executive, sales and advertising staff of the Waverley Company at Indianapolis, Ind., to discuss the company's product

WAVERLEY Men in Conference—The executive, sales and advertising forces of the Waverley Company, Indianapolis, Ind., recently met in conference in that city to discuss the Waverley product and to devise means of accumulating data and opinions regarding special features and possible refinements from the entire sales organization.

Wilson Resigns—E. B. Wilson has resigned as general sales manager of the Poss Motor Company, Detroit, Mich.

Bus Line Opened—A motorbus line has been opened from Albany, N. Y., to New Salem, East Berne, Berne and Gallupville, N. Y.

Durval Branch Manager—W. D. Durval has been appointed branch manager of the Diamond Tire Company of Canada, in Toronto, Ont.

Ford Opens Branch—The Ford Motor Company has opened its Minneapolis branch and its St. Paul sub-branch. W. C. Anderson is manager.

Essenkay Invades Omaha Territory—The Essenkay Tire Filler Company has opened a salesroom at Nineteenth and Farnam streets, Omaha, Neb.

Sells 15,120 R-C-H Cars—Contracts for 15,120 R-C-H cars for delivery during the selling season of 1913 have been closed by the R-C-H Corporation since July 1.

Road Progresses Rapidly—Rapid progress is being made on the Hamburg-Buffalo, N. Y., brick road and it is expected the entire work will be completed in a month.

Cortland Club Erects Signs—The Cortland (N. Y.) Automobile Club has just completed erection on roadways of 325 signs in addition to 500 that were already up.

Ride for Incurables—The Ontario Motor League of Canada recently took the inmates of the Hospital for the Incurables around Toronto for their annual outing in automobiles.

Albany Officials Want Car—City engineer Lanagan of the Albany, N. Y., board of public works has made application to the city government for the installation in his department of an automobile for service of his employees who are summoned frequently to various parts of the city to make surveys and measurements.

Preparing Map of Ontario—The Ontario Motor League of Canada is preparing a new and accurate map of the Province of Ontario, showing new roads, old roads that have been improved, condition of the various highways, the material of which they are constructed—all these points being clearly indicated on the new map.

Opposition to the Automobile—With the extension of good roads into rural districts near Shreveport, La., where automobiles never have been seen before, there is some opposition to them being manifested by the ignorant classes. Obstructions have been placed on the roads and glass scattered.

Second Trip Around World—Joseph R. Drake, treasurer of the Hupp Motor Car Company, Detroit, Mich., who last year completed a trip around the world in the little Hupp car, started Wednesday noon from the Hotel Pontchartrain for a second and more comprehensive journey around the globe.

Arizona to See New Records—The Arizona Fair Commission has offered $600 to the driver who will lower the world's mile circular track record on the local track during the week of the state fair, beginning October 28, at Phœnix, Ariz. Barney Oldfield, Teddy Tetzlaff, Hughie Hughes and several others will start to beat the record on October 31.

Demonstration Tours to Officials Proposed—Demonstration tours are being recommended by the Ontario Motor League of Canada to its affiliated clubs, the plan being to take municipal officers, aldermen, reeves, and police officials for a complimentary ride to show them samples of bad roads and instances where traffic regulations could be immensely improved.

Automobile Factor in Strike—The strike on the Georgia Railroad, a small but important line connecting Atlanta with Augusta, has called the automobile into action again as a mail wagon. The Postmaster of Washington, Ga., has been making daily trips to Athens, Ga., by automobile for the mail and has been carrying with him each time cashiers of Washington banks, who were in dire need of ready money as a result of the beginning of the cotton movement.

South Bend Wants Fire Engine—Specifications for the $6,500 hook and ladder truck for the South Bend, Ind., fire department, which was provided for in the city's appropriations for next year have been approved by the board of public safety. Bids will be received up until the morning of Oct. 24; it is probable the contract for the improvement will be let at that time. The truck is to be equipped with a 70 horsepower engine and it must be able to develop a speed of 35 to 40 miles per hour.

Vaughan with Olds Company—Guy Vaughan, former engineer for Wyckoff, Church & Partridge, of New York, has joined the engineering staff of the Olds Motor Works, of Lansing, Mich.

Windsor Representing Chicago Firm—Mr. Harry A. Windsor has been appointed Detroit representative for the Fulton-McCutchan Company, of Chicago, Ill., with offices in the Majestic Building.

Dayton Undertaker Uses Automobiles—R. R. Whitmer, of Dayton, O., is the first undertaker in that city to adopt the automobile for funeral purposes and has conducted automobile funerals in many surrounding cities.

Oakland Factory Branch Opened—A factory branch of the Oakland Motor Company has been opened at New Orleans, La. W. C. Gray is in charge of the new agency, which has secured quarters at 745 Baronne street.

Warren's New St. Louis Building—The Warren Automobile Company, local agent for the Warren line in St. Louis, Md., is erecting a new building on Locust street in the center of automobile row. It will be used as a show and salesroom.

Milwaukee Awards Truck Contracts—The board of public works of Milwaukee, Wis., has awarded the contract for furnishing complete two new motor police patrol cars to the Charles Abresch Company, of Milwaukee, at approximately $7,500.

Giving Instructions on Russell Knight—The accompanying illustration shows the branch managers, salesmen and officials of the Russell Motor Car Company, Toronto, Ont., being instructed by Engineer Evans in regard to the new 6-cylinder Knight motor.

Boston Buys Another Truck—On the recommendation of Sealer of Weights and Measures Wooley, of Boston, Mayor John F. Fitzgerald signed an order granting the department permission to purchase a Kelley truck for city use in transporting the scales and sealing apparatus around Boston.

Colorado Springs Receives Park—The Garden of the Gods today has been formally presented to the city of Colorado Springs and dedicated to the use of the entire world. Honor was paid to the memory of the late Chas. E. Perkins, whose children and heirs carried out his wishes that the great natural park be preserved to the people.

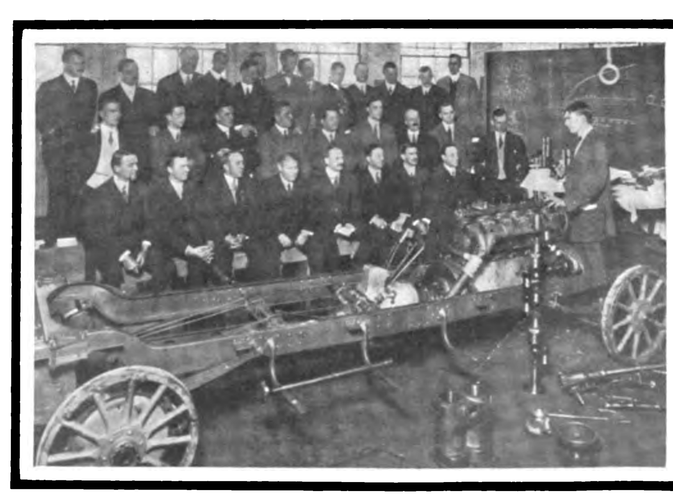
Baker Electric's Convention—A convention of the Baker electric dealers and salesmen will be held in Cleveland, O., where the Baker Motor Vehicle Company is located, October 16, 17 and 18. About one hundred and fifty Baker dealers and salesmen will convene. There will be shown for the first time the new coupé model, which has just been announced.

Pierrepont with Wisconsin Company—Robert Pierrepont has accepted the position of factory manager of the Wisconsin Motor Manufacturing Company, of Milwaukee, Wis., which builds a line of motors for pleasure cars and trucks and has a large plant occupying nearly 10 acres at Forty-fourth and Burnham streets, just west of the Milwaukee city limits.

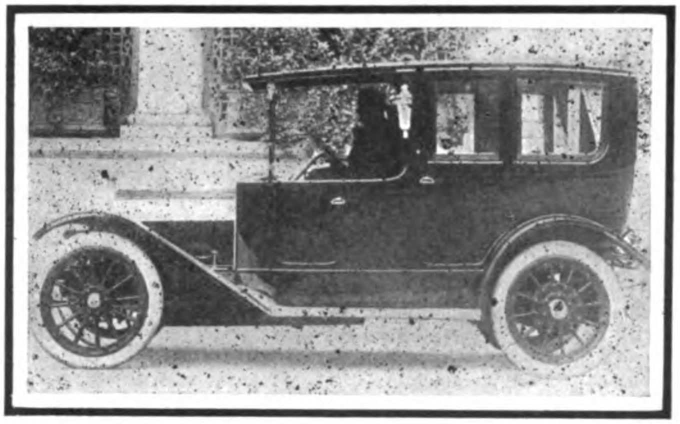
University Teaches Automobile Engineering—The University of Missouri at Columbia, Mo., is to teach students how to assemble, construct, operate, care for and repair automobiles. H. B. Shaw, Dean of the School of Engineering, has announced this new course as elementary automobile engineering. Lectures and laboratory work will combine this course.

Nashville to Mammoth Cave Tour—Twenty-five cars made the tour from Mammoth Cave, in Kentucky, to Nashville, Tenn., in connection with the Tri-State good roads convention, which was held at Mammoth Cave recently. The party inspected several classes of roadway and had an opportunity to examine the work after having been in use several years. The visitors were entertained at The Hermitage, the old homestead of Andrew Jackson.

Marmon's Hundred Century Run—Ten thousand miles in 100 running days is the feat to be attempted by the Marmon's Hundred Century car which left Indianapolis, Ind., Wednesday, October 2, on a remarkable touring test. The Hundred Century car is a new Marmon 32 touring car and is the property of Mr. M. L. Templeton, of Indianapolis, who will pilot the car on its hundred century jaunt. Mr. Templeton is accompanied by his wife and by Mr. and Mrs. J. G. Boston.



Sales organization of the Russell Motor Car Company, Toronto, Ont., receiving instruction on the six-cylinder Knight motor



New limousine of the Mercer Automobile Company, Trenton, N. J.

New Branch Manager—M. E. Gamble has been appointed manager of the Boston branch of the Universal Motor Truck Company.

Vail Makes a Change—Edward L. Vail, Boston, Mass., has accepted a position as sales manager and traveling representative for the Hoffecker Speedometer.

Leominster Club Posts Signs—The Leominster, Mass., Automobile Club has been busy recently posting signs under the direction of Dr. H. Porter Hall.

Establish Branch at Lexington—The Kentucky Automobile Company will establish a branch at Lexington, Ky. Work on the new structure in that city has already been started.

Havers Moves in Boston—The Boston agency of the Havers Six has moved into new quarters at 121 Massachusetts avenue, recently vacated by the Roberts & Sherburne Company.

Maine Number Plates—Cyrus W. Davis, Secretary of State, is preparing bids for the 1913 number plates to be used by Maine automobilists next year. The number ordered for this year was 10,000.

More White Trucks for Canada—Seven more White Motor Trucks have been delivered to the Hudson Bay Company for service in their departmental stores at Winnipeg, Calgary, and Vancouver, Ont.

Correction on Santa Monica—In THE AUTOMOBILE for September 26 it was stated that a National car won the Santa Monica race of 1909. This was a typographical error as the National won this race in 1911.

Top Company's Detroit Store—The National Top & Curtain Company, Detroit, Mich., organized to handle Jiffy curtains, has just announced the opening of a store on upper Woodward avenue, near Willis.

Beloit Boosters Go to Milwaukee—Two hundred Beloit boosters drove to Milwaukee, Wis., on October 2 in 40 cars to spread the gospel of Beloit products and good roads along a 70-mile trail to the Wisconsin metropolis.

Goes into Garage Business—J. Mavor, lately distributing agent in Western Canada for the Halladay automobiles, has given up this agency and opened a garage and repair shop in the Western portion of Winnipeg, Ont.

Detroit Show Space in Demand—Space for the Detroit, Mich., automobile show next winter is already in demand, judging by the applications received by Manager Walter Wilmot. More space will be required this year than last.

Lowell to Have Fire Trucks—At the last meeting of the Lowell City Council an order was passed appropriating $16,000 for the purchase of three motor chemical engines and hose wagons for the fire department to add to the motor equipment.

Winnipeg's Highway Convention—The interest in the Canadian Highway Convention, which takes place in Winnipeg, Ont., October 9 to 12, is rapidly growing, and it is now probable that over 400 delegates will be in attendance from the Western Provinces.

New Montgomery Traffic Ordinance—To prevent interference with traffic automobile and hack stands have been designated by the Montgomery, Ala., authorities. Automobiles and other vehicles will not be allowed to stand at the curb at places other than those designated.

Stuart Going West—George L. Stuart, one of the first motor dealers in Portland, Me., who handled the Cadillac there until recently when he sold out his interest in the agency, has decided to move to Los Angeles, Cal., with his family where he will go into business shortly.

Automobile Hinders Real Estate Business—Real estate men in Montgomery, Ala., are blaming the automobile for the alarming decrease in the sales of city property. They say that young men who a few years ago invested their surplus money in properties now are buying automobiles.

Louisiana's Road Improvement—One hundred thousand dollars is to be spent at once on rural roads immediately east of New Orleans, La. This provides for a network of improved highways that will add materially to the territory that can be reached by automobile from that city.

Cropler Establishes Tire Branch—F. S. Cropler, for several years connected with the old G & J clincher tire people, has taken over the old Federal Tire agency in St. Louis, Mo., and has established a factory branch there. This factory branch will be the distributing point for the Southwestern States.

Springfield Club Elects Officers—The annual meeting of the Springfield, Mass., Automobile Club was held recently at the Hotel Worthy and the secretary reported that the association was in a flourishing condition. He stated that 87 new members had been added to the club's roll during the year, making the membership now 345.

New Mercer Limousine—The Mercer Automobile Company, Trenton, N. J., has brought out a limousine known as type 35 E. This car is shown in the accompanying illustration. It is built on the regular Mercer 35 AB chassis, and unlike the ordinary limousine, it presents a very low appearance. An idea of its height can be judged from the fact that a man a little taller than the average can stand on the curb and look over the top. It has a wheelbase of 118 inches.

Indianapolis to Have Garage—Indianapolis, Ind., within a short time, excepts to have one of the finest municipal garages in the country. A conference of city officials was held recently, and, as a result, City Controller Harry R. Wallace consented to recommend to the city council a bond issue of $110,000. Of the amount that will be received from the sale of the bonds, $40,000 will be used in erecting a municipal garage. The fire headquarters, which will cost $70,000, will be equipped with motor apparatus.

Automobile Incorporations

AUTOMOBILES AND PARTS

BENTON, ILL.—Benton Motor Car Company; capital, $65,000; to deal in automobiles and accessories. Incorporators: H. Stotlar, W. S. Cantrell, A. H. Fraunfelder.

CHICAGO, ILL.—Metzger-Herrington Argo Company; capital, $50,000; to deal in automobiles, motors and vehicles. Incorporators: C. J. Metzger, B. F. Brady, R. A. Herrington.

CINCINNATI, O.—Federal Motor Supply Company; capital, $250,000; to deal in automobiles and accessories. Incorporators: G. W. Platt, E. C. Schmitt, R. L. Dollings, A. M. Draddy, M. F. Platt.

CLEVELAND, O.—Cadillac Automobile Company; capital, $50,000; to deal in automobiles and accessories. Incorporators: T. B. Bolton, W. H. Marlatt, F. H. Pelton, E. Jenkins, E. D. Hayes.

DETROIT, MICH.—Traveler Motor Car Company; capital, $10,000; to deal in automobiles and accessories. Incorporators: W. J. McIntyre, Joseph P. McIntyre, Joseph Lavigne, William L. Kenfield.

LACROSSE, WIS.—Parket-Hirt Company; capital, $5,000; to deal in motor cars and accessories. Incorporators: E. W. Parker, Joseph F. Hirt, Harriet E. Parker.

MENOMINEE, WIS.—D. F. Peyer Company; capital, $75,000; to manufacture automobile trucks. Incorporators: D. F. Peyer, F. J. Trudell, Harry S. Emerson.

NEWARK, N. J.—Ka Dix Newark Motor Truck Company; capital, $100,000; to manufacture commercial and fire fighting trucks. Incorporator: G. F. Kallberg.

NEW YORK CITY, N. Y.—New York Electrical Vehicle Association, Inc., capital, $50,000; to deal in motor vehicles. Incorporators: George Tierman, Frank H. Parcello, Robert G. Redlefsen.

NEW YORK CITY, N. Y.—Used Car Company of New York; capital, $5,000; to deal in automobiles. Incorporators: Andrew F. McNamara, Gustavo Galiani, Jacob J. Kramer.

NEW YORK CITY, N. Y.—Viking Manufacturing Company; capital, $25,000; to manufacture automobiles. Incorporators: R. Condon, A. O. Briggs.

PATERSON, N. J.—Standard Auto Company; capital, $2,500; to engage in the automobile business. Incorporators: Christian Braun, William F. Drexler, Henry Stoeher.

RACINE, WIS.—Wallis Tractor Company; capital, $300,000; to manufacture farm tractors. Incorporators: W. C. Quarles, Markey Wells.

ROCHESTER, N. Y.—Electric Car Sales & Service Company; capital, $10,000; to deal in electrical motor vehicles and equipment. Incorporators: Max Bernstein, Minnie L. Bohrer, Glenn H. Leaty.

TORONTO, CAN.—Standard Motors Company, Ltd.; capital, $40,000; to manufacture automobiles. Incorporators: George S. Skinner, Harry N. Newman, George P. McHugh.

TORONTO, CAN.—Toronto Electric Motor Car Company; capital, $300,000 to manufacture motor cars. Incorporators: James A. Riordans, Albert E. Adams, Edward C. Coleman.

To Motorize Douglas Fire Department—Fire Chief W. J. Nemock has recommended to the Douglas, Ariz., council that automobile tractors be substituted for the horses now used to draw fire engines.

Has New Quarters—The Day Automobile Company, handling the New Orleans, La., agency for the Paige-Detroit and the Alco companies, has moved into new quarters on Rampart street.

Ford at Rochester Expands—Thomas J. Northway, local Ford distributor, at Rochester, N. Y., has completed plans for the construction of a three-story steam-heated salesroom to cost $12,000.

To Collect Mail—Two automobiles will soon be put in use for the collection of mail, in Omaha, Neb., if the proper machines can be secured at a price satisfactory to the post office department officials.

Coal Men Use Trucks—Retail coal men are figuring on utilizing the motor trucks in Minneapolis, Minn., due in part to the uncertainty regarding teamsters and also because horses are difficult to buy at present.

Cox Heads Fordham Company—G. F. Cox was appointed on Saturday, Rochester, N. Y., manager of the Fordham Company, recently organized with capital of $3,000, for the purpose of manufacturing motor vehicles.

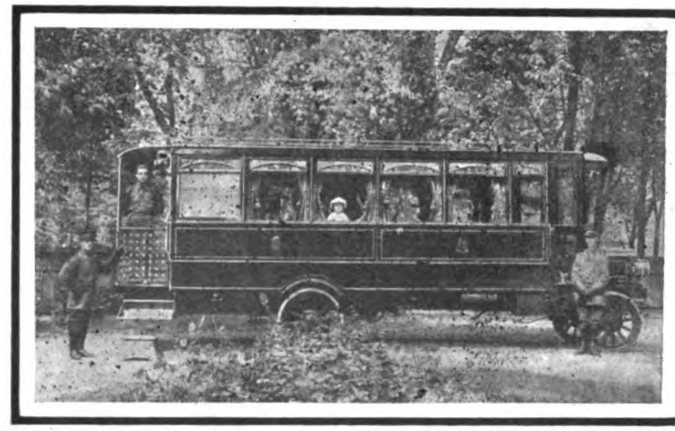
Present for Buffalo Club—The Buffalo Electric Vehicle Company presented recently to the Country Clubhouse of the Automobile Club of Buffalo, N. Y., a charging plant capable of recharging three automobiles at one time.

Washington Dealer Changes Name—The Auto Exchange & Supply Co., 1722 Fourteenth street, Washington, D. C., N. W., has changed its name to the Washington Car Equipment Co., and will shortly remove to larger quarters.

Rochester Builds Police Garage—Work was begun last week on the construction of the Rochester, N. Y., police garage. The building was staked out and Contractors Crossett & Lloyd planned to start immediate construction.

To Sell Rotary Valve Motor—The Parker Motor Company of this city has been formed to promote the sale of a rotary valve motor which is the invention of Victor C. Parker, formerly with *Modern Power*, of Winnipeg, Canada.

Camillus-Elbridge Road Open—The Automobile Club of Syracuse, N. Y., announces that the Camillus-Elbridge state road is open, which means that a continuous stretch of state highway now extends from the West Camillus hill to Auburn.



Pullman Packard owned by U. H. Dandurand, of Montreal, Que.

Duluth Club Active—The Duluth Automobile Club, Duluth, Minn., has started a roads campaign. It is laying out a new Twin City-Duluth road, which is to reach from Sandstone, the half-way point, through Superior, instead of direct to Duluth.

Lockport After Speeders—Lockport, N. Y., fell in line last week with the ordinance limiting the speed of motor vehicles in the city limit to 15 miles an hour. Signs have been posted in conspicuous roads and arrests under the law can now be prosecuted.

Studebaker Men Meet—About thirty branch managers and officers of the Studebaker Corporation met at a dinner recently at the Pontchartrain Hotel, in Detroit, Mich., the occasion being the annual meeting for the discussion of the coming season's campaign.

Hudson Agency Moves—Increased business has made it necessary for the Hudson agency in New Orleans, La., to occupy more spacious quarters. A completely equipped repair shop has been installed in connection with the new sales rooms at Baronne and Perdido streets.

Clubs in Canadian League—The Ontario Motor League has to date affiliated in its organization eleven automobile clubs in the province which are as follows: Aylmer, Brantford, Chatham, Hamilton, Kingston, Niagara Falls, Ottawa, Peterboro, Stratford, St. Catharine's and Woodstock.

Ohio Road Report—The Ohio State Highway Commission has made a report showing the progress made in the improvement of the highways of the state up to date. During the year road construction has been accomplished to the extent of $1,122,060.97. The total length is 658,046.4 lineal feet.

Omaha Show Draws Visitors—Ak-Sar-Ben week and the fall garage show of the Omaha automobile show brought hundreds of visitors to Omaha, Neb. All of the garages were prettily decorated in Ak-Sar-Ben colors and in the colors of the show association, green and white. Most of the dealers had a complete line of their 1913 models on display.

Good Roads Convention at Birmingham—Delegates from all parts of the state are assembling at Birmingham, Ala., for the annual convention of the Alabama Good Roads Association. The Birmingham Motor Club is cooperating with the local Good Roads Association in directing the affairs of the convention. Three hundred delegates are expected.

Express Company's Packard Order—A significant step in the conquest of local transportation by the power vehicle is the order recently placed by Wells, Fargo & Company with the Packard Motor Car Company for 100 motor trucks of 2-ton and 3-ton capacity. These trucks, costing $286,750, will be used to supplant the express company's horse-drawn wagons in the larger cities of the United States.

Luxury in Automobile Travel—U. H. Dandurand, of Montreal, Can., has succeeded in getting luxury in motor travel, together with independence from hotels, by using a Pullman Packard. On a 3-ton Packard truck chassis has been mounted a body whose interior arrangement is similar to that of a private railroad car. Twenty-five persons are easily carried on short trips and for long journeys there are accommodations for the comfort of eleven, including chauffeur and cook. The accompanying photograph shows the truck.

Automobile Incorporations

GARAGES AND ACCESSORIES

CLEVELAND, O.—Service Garage Company; capital, $10,000, to deal in automobiles and accessories and to operate a general garage. Incorporators: Roy J. Ramson, Karl W. Volk, Fred Desberg, Walter McMahon, John W. Willdis.

COLUMBUS, O.—J. C. Sherwood Rubber Company; capital, $20,000; to deal in all kinds of rubber tires. Incorporators: John C. Sherwood, William S. Sherwood, Robert C. Creppen, Parnell J. Cull, Charles L. Creppen.

DALLAS, TEX.—Hazoline Auto Supply Company; capital, $10,000; to sell automobile accessories. Incorporators: Edwin Hobby, Forrest E. White, J. W. Crotty.

DAYTONA, FLA.—Daytona Auto Supply Company; capital, $1,000,000; to sell automobile accessories. Incorporators: A. G. Hunt, H. C. Thompson.

LOUISVILLE, KY.—McPherson Automobile Company; capital, $10,000; to engage in the automobile repair business. Incorporators: Franklin McPherson, Catherine McPherson, Olive McPherson.

NYACK, N. Y.—Nyack Garage, Incorporated; capital, $15,000; to engage in the garage business. Incorporators: Alan Leggett, John J. Laine, Paul J. Douboise.

SHEBOYGAN, WIS.—Wald Manufacturing Company; capital, $30,000; to deal in automobile accessories. Incorporators: Ewald F. Pawsat, Herman Pawsat, Felix Benfy.

ST. LOUIS, MO.—Lewis Automobile Company; capital, $26,000; to conduct a garage and general repair shop. Incorporator: H. D. P. Lewis.

TORONTO, CAN.—Bulldog Tire Company; capital, $300,000; to manufacture tires.

WHITE PLAINS, N. Y.—General Rim Company; capital, $150,000; to supply motor vehicles and accessories. Incorporators: William Kuhl. Robert W. Ashley, Frank Oberkirsch.

CHANGES OF NAME AND CAPITAL

AKRON, O.—Buckeye Motor & Cycle Company; increase of capital from $5,000 to $15,000.

BALTIMORE, MD.—Hupp Motor Car Company; increase of capital from $500,000 to $750,000.

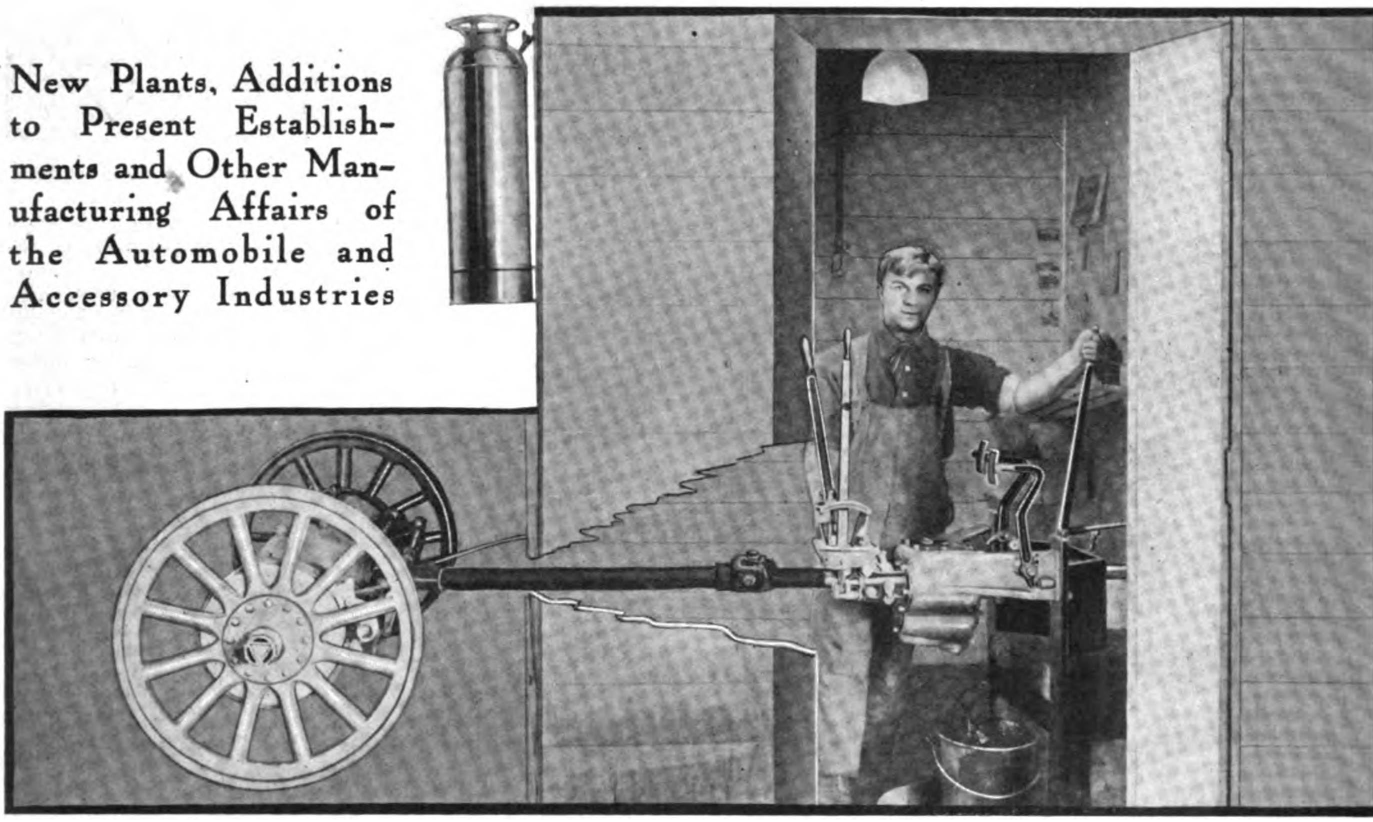
DETROIT, MICH.—Haves Manufacturing Company; increase of capital from $500,000 to $750,000.

DETROIT, MICH.—Kelsey Wheel Company; increase of capital from $500,000 to $1,000,000.

LOUISVILLE, KY.—Kentucky Automobile Company; increase of capital from $24,000 to $65,000.

WAUKESHA, WIS.—H. L. Kenyon Company; increase of capital from $100,000 to $200,000.

New Plants, Additions to Present Establishments and Other Manufacturing Affairs of the Automobile and Accessory Industries



Showing soundproof vault employed for testing differential and transmission gears by the Hudson Motor Car Company, Detroit, Mich.

It is impossible for a tester to do good work with the din of a machine shop surrounding him. To successfully cope with this situation and allow the tester to train his ears to detect the slightest sound which would indicate that the gears in the differential and gearset were not working as they should, the Hudson Motor Car Company, Detroit, Mich., has erected a sound-proof vault in which this part of the work is carried on. The drive mechanism is mounted on the special frame shown in the illustration and the clutch arranged so that the power can be applied when desired. The shaft which drives the mechanism enters from the exterior of the vault, passing through the wall resting in a bearing at that point. One man can operate the mechanism and is sufficient for the testing work. The length of time in the testing work will vary but twenty sets of differentials and gearsets can be tested in a working day. The gears can be shifted in the usual manner and the silent running of all gears is assured by the fact that the noisy ones are not permitted to pass through the test in the silence chamber.

GOODRICH Company's Recent Addition—Although the present floor space of the Goodrich Tire Company, Akron, O., is between 60 and 70 acres, this is at present being augmented by the new building which is shown in the above illustration. This structure of six stories and basement is 270 feet long and 157 feet wide.

Lewis Company in Detroit—The Lewis Spring & Axle Company, Jackson, Mich., has moved its control department to Detroit, Mich., with headquarters in the Boydell Building. Fifty men will be employed.

Supplies DeTamble Windshields—The Columbus Automobile Parts Company, Columbus, O., has closed a contract to supply the DeTamble Motor Car Company, Anderson, Ind., with windshields for the 1913 cars.

Century Electric's New Quarters—The Century Electric Motor Car Company, Detroit, Mich., has removed its factory to the new building erected by the company at Woodward and Lathrop avenues and has started work with two shifts, night and day.

Wagon Company to Make Trucks—The Tiffin Wagon Works of Tiffin, O., is preparing to enter the field of motor truck manufacturing and expects to place a line of trucks on the market in the spring. Agents have already been signed up to market the trucks.

Tudhope Company Moves to Windsor—The Tudhope Motor Company, Orillia, Ont., Canadian manufacturers of the Flanders Six, which was formerly known as the Everitt, will move to Windsor, Ont., shortly. Recently a site for a new factory was bought. The change will bring the concern much nearer to the Flanders Manufacturing Company of Detroit, Mich.

Hudson Factories Double—The Hudson Motor Car Company, Detroit, Mich., has factory floor space of 172,811 square feet. Last winter a new factory was added, bringing the total to 236,411 square feet. There will now be added two more plants, bringing the total floor space up to 363,611 square feet.

Lowell to Have Tire Plant—The Patterson Rubber Company, a Massachusetts corporation with a capitalization of $500,000, has decided to locate at Lowell, Mass., where five buildings will be erected and the company will soon begin the manufacture of automobile tires. About 1,000 employes will be put to work. John S. Patterson, of Providence, R. I., is president of the new concern.

Eight New Overland Buildings—The Willys-Overland Company, Toledo, O., has eight new buildings in process of construction at the Toledo plant. The largest of the group is a five-story concrete building, 102 feet by 127 feet in size. The others range from 34 feet up to 60 feet by 48 feet up to 216 feet in dimension. These buildings represent an outlay of several hundred thousand dollars and when finished will house 2,000 extra workmen.

Toledo Truck Company Building—The Toledo Motor Truck Company, Toledo, O., is building a one-story brick and structural steel building, which will be 54 feet by 236 feet in size.

Goodyear Works Night and Day—Due to increased business of the Goodyear Tire & Rubber Company, Akron, O., it will be necessary to keep the factory going night and day for some time.

New White Plant—The new factory of the White Motor Car Company, Cleveland, O., will be ready for occupancy about December 1. This new structure will be 240 feet by 160 feet in size.

Krebs Purchases Elmore Plant—The Krebs Motor Company, Clyde, O., has purchased the old plant of the Elmore Automobile Company. B. A. Becker is president of the Krebs Company.

Ford's New Assembling Plant—The contract for the new assembling plant of the Ford Motor Company, Detroit, Mich., in Memphis, Tenn., has been awarded and the estimated price is $176,000.

New York's Fifty-six Automobile Factories—According to the last United States census New York City has fifty-six automobile factories. In 1899 there were only three, with a combined output of $6,194,000.

Manhattan Rubber's Addition—The Manhattan Rubber Manufacturing Company, Passaic, N. J., has awarded contracts for an addition to factory building "F", which is to be 70 feet by 90 feet in size.

Tires to Be Made Soon—Tyer Rubber Company, Andover, Mass., has its new addition nearly completed and in a couple of weeks the company will be manufacturing tires of all kinds for motor vehicles.

Apperson in New Deal—Elmer Apperson is head of a new concern that has been organized to make the Wilson Never-Miss self-starter of the compressed air type. A new plant will be erected at Kokomo, Ind.

Ford's Proposed Denver Plant—The Ford Automobile Company, Detroit, Mich., is reported to have secured a site on Broadway and Exposition avenue on which to erect an assembly plant four stories high.

Factory Manager Quits—The resignation of Benjamin A. Rhodes, as general superintendent of the Stoddard-Dayton Automobile Company plant, was recently announced. The resignation takes place at once.

Equipment Company Erecting Factory—The American Auto Equipment Company, Toledo, O., maker of automobile trimmings, will erect a large new factory and will be in the market for new tools, etc.

Hudson's Fireproof Building—The Hudson Motor Car Co., Detroit, Mich., has let the mason and concrete contract for the erection of a new fireproof factory building on Jefferson avenue. It will cost $50,000.

Morton at Chalmers Factory—Robert L. Morton, manager of the Keystone Motor Car Company, Harrisburg, Pa., left for Detroit, Mich., recently to arrange for shipments of Chalmers cars to meet the present demand.

Niagara Company's Dunkirk Plant—The Niagara Gasoline Motor Company of Buffalo, N. Y., has acquired a site and will immediately erect a new large plant for the manufacture of gasoline engines at Dunkirk, N. Y.

Northway Company's Plant—The Northway Motor Company, Detroit, Mich., has let contracts for an addition to the plant, to be three stories high and to be 50 feet by 104 feet in size. The building will cost $32,500.

Pump Company Moving to Buffalo—The Automobile Pump Company, Springville, N. Y., is moving its plant from that place to Buffalo, N. Y. Most of the employes will move to Buffalo and continue in the Pump company's employ.

Edwards Adds Longest Plant—The Edwards Motor Car, Louisville, Ky., has taken over the motor truck plant of the Longest Brothers Company, of that city, and will enlarge it. C. G. Stoddard and H. J. Edwards, New York City, are interested.

Miller Rubber Company Active—Increasing demand for tires, rubbers and reliners for automobiles at the O. K. Vulcanizing Works, Binghamton, N. Y., has necessitated the doubling of stock of rubber goods made by the Miller Rubber Company, Akron, O.

Eclipse Machine Company's Addition—Plans have been completed for the construction of an addition, 125 feet by 60 feet, to the plant of the Eclipse Machine Company, Elmira, N. Y. The addition will be of brick and steel construction and will provide additional room for more machines and also a factory store-room. The Eclipse Company makes automobile screw machinery for automobiles.

Continental Equips New Factory—The Continental Motor Company, Ellicott Square Bldg., Buffalo, N. Y., has leased a plant and will equip it with machinery for the manufacture of automobiles and motor trucks. Frank V. Whyland is general manager.

Lamp Company Builds Addition—The Guide Motor Lamp Manufacturing Company, Cleveland, O., is laying plans for a new factory addition. The building will be 50 feet by 120 feet in size, two stories high, and will be built of brick and reinforced concrete.

Ex-Cel Truck Company's Factories—The Ex-Cel Motor Truck Company, Jamesburgh, N. J., has awarded contracts for the construction of its new plant. It will consist of five factories, each one story high, and 50 feet by 100 feet in size. The estimated cost is $35,000.

Buick Insure Its Employes—The Buick Motor Company, Flint, Mich., has taken out a policy under the new compensation law, which will cover all expenses incurred in every accident. This includes physician's and hospital services for three weeks in case of every accident.

Goodyear Planning New Plant—The Goodyear Tire & Rubber Company, Akron, O., is planning to erect an addition to its plant. The new building will be 250 feet by 60 feet in size, and five stories high. The cost will be $150,000. This will be the third large structure erected by the company during the present year.

Guests of Packard Company—Representing the commercial organizations of forty-five nations, the members of the International Congress of Chambers of Commerce were guests of the Packard Motor Car Company at luncheon in the plant in Detroit, Mich., Thursday, October 3, and made a complete inspection of the big motor car factory.

Chicago Manufacturer Moves to Marinette—The Chamber of Commerce of Marinette, Wis., has practically closed negotiations with a large manufacturer of motors for pleasure and commercial cars, now located at Chicago, for removal to Marinette. The Chicago concern is given a bonus in the form of a site for a factory and a suitable structure in which manufacturing operations may be carried on for the present, and during the construction of a new plant. It is stated that the Chicago concern awaits formal organization and incorporation upon the successful completion of negotiations with Marinette commercial club.

New Starter Factory—The Merralls Starter Company has been organized in Detroit, Mich., with a capital stock of $150,000 to manufacture a compressed air type of starting apparatus, which is the patented invention of W. A. Merralls. It has not been definitely decided as yet whether the concern will locate here or in the East, but in all probability Detroit will be chosen. It is proposed by the new concern to erect a two-story factory to take care of an output of about ten starters a day. Plans for such a structure have been made and they call for a building measuring 60 by 160 feet.

Latest addition to the plant of the B. F. Goodrich Company, Akron, O.

J-M Two-Ring Demountable Rim; Star Headlight; Rebound Check and Shock-Absorber for Ford Cars; Brackets for Carrying Plates on Fords; Handy Fire Extinguisher; Clockless Time-Recording Stamp

LaMay Chemical Extinguisher

DEMOUNTABLE rim consisting of two rings and fastened to the wheel at five points in the latest addition to the manifold line of the H. W. Johns-Manville Company, New York City, which is now being offered to the automobile public after extensive tests carried on with this device have been completed.

The illustrations here given show the rim in place on the wheel and off the same, ready for changing a tire. The rim each ring of which is formed with a flange forming a base for the tire bead to be pressed against, is secured to the wheel in the manner seen in Fig. 1, by the use of clamps C. These clamps grip the recess R formed between the innermost portion of the rim and the bead flange formed on the outer side of the wheel, so that when the nut N is turned tight on its bolt piercing the wooden felloe, the portion P of the rim is pressed toward the inner side of the wheel. The felloe band being tapered does not permit the rim to come off toward the center of the car. The rim itself, as stated before, consists of a continuous ring R1, Fig. 2, and a split ring R2, fitting inside the ring R1 and being secured near its ends by holes engaging studs which project from the inner surface of R1. The openings O in both rims are provided for the tire valve.

The *modus operandi* in mounting and demounting rim, as well as the tire on the same, is very simple, and this work may be done with a good deal of speed, due to that factor as well as to the light weight of the rim, which is made of cold-rolled steel. When the rim is in place on the wheel the clamps press upon the recess R of the rim, as shown by the examples of C and C1 in Fig. 1. To release the rim from the wheel the special J-M combination tool is applied to the nut N holding the clamp C in place and, operating always on the clamp occupying the highest position on the wheel, N is given one turn, which relieves the pressure on the clamp and permits it to drop by gravity, guided by the slot S. After the clamp has dropped the nut is turned back far enough to hold C taut against the wheel felloe and after this has been done in the case of all the clamps, a slight outward pressure on the rim brings it off the wheel.

Fig. 1—J-M demountable rim in place on an automobile wheel

An illustration of the engagement of the ends of the split ring R2 fitting inside the ring R1 is seen in Fig. 2. When both studs V engage the holes in R2, the two rings form one unit with two flanges accommodating the tire and holding its beads in secure relation. To take the tire off the rim the split ring is removed by prying the end E of R2 off its seating in R1. This is done by inserting the tapered end of the J-M tool between the two rings, on the side of the rim next to the chassis when in place on the car. R2 is made with a depression between which and a flange is formed the recess R referred to above. The depression, which extends all around the ring, fits into an annular groove which is formed on the ring R1. In combination with the two studs and the five clamps, it makes the locking positive. The split ring is replaced on the continuous ring by engaging the stud of the end punched for the tire valve and pushing it into the ring with a foot, the second stud being put in place by a slightly accentuated pressure of the foot. After this the rim is replaced on the wheel, securing all clamps when they are in their lowest position by first loosening the nut which results in the clamp dropping over the recess R, and then tightening it, whereby it is fastened in place.

Mitchell Shock-Absorber

The Mitchell rebound check and shock-absorber, specially constructed for Ford Model T cars by the Mitchell Shock-Absorber Company, Lawrence, Conn. The design resembles that of some other accessories constructed for the same purpose, but the novel idea utilized in the Mitchell device consists in the combination of the coiled spring and strap, as illustrated in Figs. 4 and 5. The former figure shows how the accessory is made for and attached to the front axle of the car. It is composed of two units held together by a horizontal plate, the ends of which are shaped with clamps gripping the lower flange of the I-beam axle. Each unit consists of a base-plate B carrying the coiled spring S1 seated around a projection of the baseplate and bearing against the top plate P mentioned above. Two straps are fastened to the plate B, the shorter one carrying a buckle, while the longer one is laid over the front end of the frame F and is secured to the buckle end of the other strap.

Due to the difference in construction of the two axles, the outfitting for the rear portion of the machine differs from the front axle equipment in several particulars. Reference to Fig. 5 shows the most prominent one, which consists in using a flanged two-piece collar C, the halves of which are held together by bolts, which, when drawn tight in the holes of the collar flanges, hold C positively in place on the rear axle housing. Plate P used in the front axle is eliminated in the rear equipment, while base-plate and straps are also used.

Ford Car License Tag Holder

H. B. Klingensmith, 296 Willow street, Meadville, Pa., has designed a license bracket by means of which the number plate of a Ford car may be attached to the support of one headlight, resulting in a solid engagement of the plate and putting the same in a protected position. The license plate, as secured to lamp support, is seen in Fig. 6, and the detailed construction of the bracket in Fig. 7, consisting of a casting M, the front portion of which is screw-threaded for two bolts B, while an extension has three holes for bolts C, permitting of fastening a plate P to it. In installing the bracket on the car, the headlight is taken off its support and the bracket is so placed against it that the forks of the support bear in the grooves C. The bracket is held in place by the plate P, the three bolts C being drawn just tight enough to prevent rattling of the bracket on the support. The number plate is then put in place, the bolts B being drawn through the slots in the plate and drawn, by means of their nuts, to the same degree of tightness as the bolts C. After this the headlights are replaced on the supports.

Magnetograph Electric Recorder

As time clocks used for recording the working time in shops are ordinarily subject to a great deal of strain, the Magnetograph, operating by electricity and without a clockwork, is made by the Magneta Company, 1955 Park avenue, New York City. It has absolutely the appearance of an ordinary small time clock of the tabletype, but it is operated by a small electrical odometer mechanism inside, which draws electric current fed to it from a city conduit through a plug. This time-stamp mechanism is regulated through contacts closed every minute by a master clock which comes with the Magnetograph.

Electric Star Headlight

An electric headlight which is vibration proof and very simple in its construction is the Electric Star Headlight, manufactured for the coming season by the Milwaukee Bronze Casting Company, Milwaukee, Wis. The line of this company's products is distinguished by the so-called quick-change feature consisting in the use of a removable reflector hub which represents the base for the electric bulb. The hub carries all the wiring and being practically independent of the reflector body may be used as a trouble-hunting light. It slips into the central opening of the reflector body and is locked there by a slight turn. A turn in the opposite direction unlocks the hub again; the bulb itself is carried in an Edi-Swan socket immune against vibration.

LaMay Chemical Extinguisher

Garage owners should be interested in the new fire extinguisher made and sold by the LaMay Machine Works, Rochester, N. Y., shown in the initial illustration. This device, which is 3 by 14 inches and weighs 5 pounds, is of the conventional cylindrical shape and contains a specially prepared chemical solution under pressure which forces it out of the cylinder through a nozzle, when a red button on the top of the extinguisher is pressed. It is claimed that a stream from 30 to 40 feet in length may be produced by this apparatus, whose capacity for chemical is one quart. The liquid immediately puts out gasoline, kerosene or acetylene fires, according to the maker, and as it is a non-conductor of electricity, it may also be applied where a short-circuit is the cause of an incipient conflagration. Furthermore, the liquid does not injure any fabric. The extinguisher is refilled by unscrewing the head, filling in a quart of Auto-Chemical solution made by the LaMay company and pumping air into the cylinder by a pump attached to it.

HIGH-Tension Magneto—In which the pole-pieces are formed with an extremity to increase the efficiency of the apparatus.

The subject-matter of this patent, consisting in the peculiar shaping of magneto pole-pieces, is illustrated in Fig. 1. The magneto comprises a magnet M to which pole-pieces P are attached, each of which has one end extended in a direction around the armature A and toward the other pole-piece, so that these extensions E are located diametrically opposite. The inner face of each pole-piece adjacent the extension is formed with a recess R, this design making it possible for the armature to cut the greatest possible number of lines of force twice during every revolution.

No. 1,039,543—to William O. Kinnington, Bloomfield, N. J., assignor to the Simms Magneto Company, Inc., New York City. Granted September 24, 1912; filed October 10, 1911.

Double-Cone Clutch Mechanism—Two male clutch members are mounted on hubs which are pried apart by a wedge.

This patent relates to the clutch construction, Fig. 2, in which the frictional engagement of two cone surfaces C C1 with surfaces F on a driven shaft is kept up by the tension of a spring S connecting their inner centers. Both these surfaces are mounted on the same driving shaft, being slidable thereon by means of hubs H and H1. Each hub is formed with an abutment and between the abutments enters a wedge W carried by a pivoted arm which is connected to a disengaging lever L fitted with a declutching pedal. When the pedal is pressed and the wedge driven in, the latter separates both abutments and the clutch sections to which they are engaged, against the tension of the spring S, effecting disengagement of the clutch sections.

No. 1,039,495—to Paul Daimler, Stuttgart, Germany, assignor to Daimler Motoren-Gesellschaft, Untertuerkheim, Germany. Granted September 24, 1912; filed September 16, 1911.

Internal-Combustion Motor—A two-cylinder design in which two reciprocating and one rotating crankpin is used.

The engine referred to in this patent comprises cylinders cast in pairs, the pistons of which have connecting-rods being on a driving connection D having two bearings R for the ends of the connecting-rods and one C serving as a crankpin, being set eccentrically with reference to the crankshaft S. The piece D is fulcrumed at F to a connection C1 which has one end fixed at the side of the crankcase. In the operation of the motor the crankpin C revolves around the crankshaft S, while the point F reciprocates vertically, remaining always higher than C. The ends of the connecting-rods alternately ascend and descend.

No. 1,039,493—to Elmer L. Courtwright, Tacoma, Wash. Granted September 24, 1912; filed December 20, 1911.

Shock-Absorber for Automobiles—Comprising resilient friction surfaces pressed against the periphery of a container.

This patent refers to a shock-absorber consisting of a casing lined on its inside periphery with a friction surface against which bear friction members or shoes F which normally do not

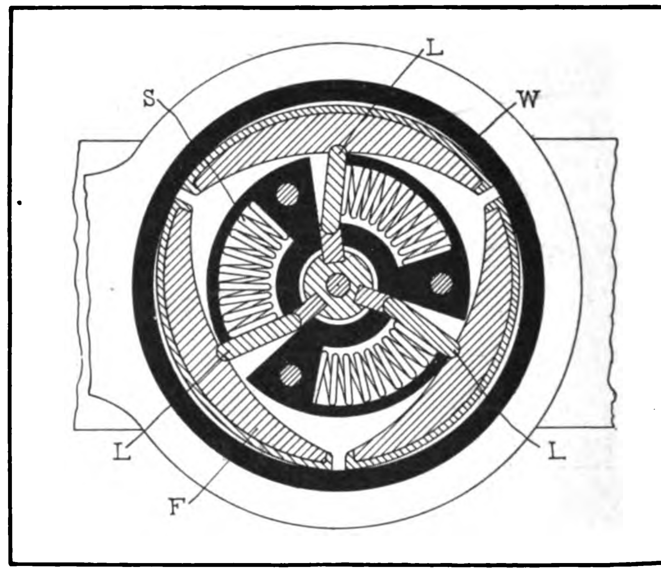

Fig. 4—Martin friction shock-absorber

conform in shape to the wall of the casing. Links L are so connected to the friction members that if they are turned around their central fulcrum, they press the shoes against the wall of the casing, if turned in one direction, or are resisted by the compression of springs S interposed between them (the links) if turned in the other direction.

No. 1,039,305—to George Cushing Martin, Los Angeles, Cal. Granted September 24, 1912; filed September 11, 1911.

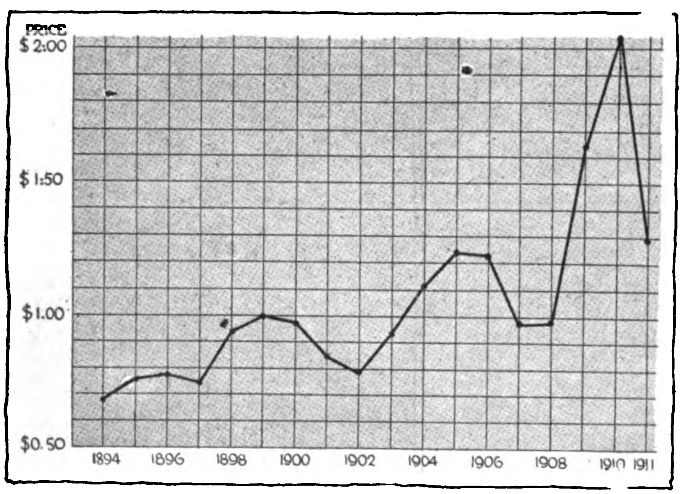
Vol. XXVII New York—October 17, 1912—Chicago No. 16

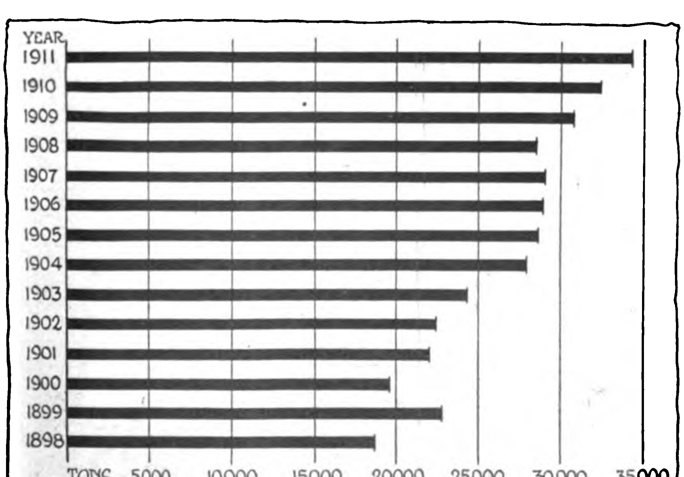
The Automobile

World's Rubber Production On Verge of Vast Increase

With Extension of Plantations to Prospective Limit of 2,000,000 Acres and the Activity to Exploit the Virgin Fields of Wild Rubber, Prospects Favor Larger Yields



Curve shows how the average price of up-river fine has varied since 1894. The apex shown in 1910 resulted from the extra demand exerted by the automobile industry



Consumption of rubber in the United States between 1898 and 1911 in long tons, indicating the influence of the automobile industry on the amount required

Synthetic Rubber a Chemical Success, But a Remote Possibility as an Element in Commerce

RUBBER is grown in every tropical country in the world. In some of the states that lie within the tropics the topography is mountainous as a general thing; in others there are deserts, but from a broad viewpoint, there is some land fit for rubber raising in every land that lies within the torrid zone and some rubber grows in each.

On the borders of the tropics there is also considerable rubber produced, but as a factor in the industry it is of small importance. This year the total crop will approximate 90,000 long tons of 2,240 pounds; some excellent authorities state that it will be nearer 100,000 tons. The former figure is the one most generally adopted by the statisticians.

Of the world's production in 1912, the Amazon Valley will be represented by 40,000 tons, or about 45 per cent. of the total. All of this is denominated wild rubber, despite the fact that in Brazil there are a few small plantations, the oldest of which is 14 years old. These plantations are virtually botanical gardens and experimental stations.

The productive rubber territory in the Amazon Valley has been scratched so far, but that is about all. Back of the navigable rivers, which furnish waterways 32,000 miles long, or more than the distance around the earth, the main artery of which, the Amazon proper, and its direct western branch reach from Para to the foothills of the Andes, over 2,000 miles, there is a wilderness that rarely has been penetrated by explorers and never has felt the influence of exploitation.

As it has been proven on the rare occasions when the explorers have traversed some of these jungles, the rubber forests now being drawn upon represent a small part of the total existing supply. In the wide territory opened up by the new Marmore-Madeira Railway in the remote southwestern part of Brazil and across the border of Bolivia, the potentialities of the Amazon supply will be much increased. No man can estimate with anything like exactness the extent of the rubber fields in Brazil and its surrounding states, but the proof of the fields and forests is represented by 40,000 long tons of the product.

It is said that the collection of rubber means the cost of a human life for each 2 tons marketed. At that rate the mortality in the Amazon collections would amount to 20,000 human lives a year. The simple fact that rubber collection is so deadly explains the reason for the lack of definite statistics covering the extent of the field. Unhealthful conditions, lack of sanitation and the ignorance of the labor employed are the chief reasons for this appalling mortality.

The Marmore-Madeira Railway project is by no means the only great transportation measure under way in Brazil. There are numerous shorter and less important lines under some stage of construction and an immense activity has been noted this year in highway improvement and the betterment of the waterways.

Brazil is alive to the fact that her industry in rubber now has competition in the markets of the world and realizes that a commercial basis must be reached in order to hold the lead she has always enjoyed in the rubber industry.

The law of January 5, 1912, which provides for remission of import duties, relaxation of export duties, bonuses for production of rubber and its manufactured products as well as supplies for the great army of labor, experiment stations and numerous other factors to develop the industry and bring about a greater production, which may cost in cash outlay as much as $15,000,000 a year, is already at work. With the new territory opened, new land planted and old forests conserved, the production of the Amazon Valley will probably increase immediately and it is predicted that it will easily reach 60,000 long tons a year within 5 years.

The chief rival of Brazil is the British colonial plantation rubber, located in Malaya and Ceylon, the production of which will be in the neighborhood of 20,000 long tons this year, some say 22,000 tons.

Both Ceylon and Malaya have been covered in some detail in previous issues of THE AUTOMOBILE, but it may be said that the yield of Malaya will be about 15,000 tons and that of Ceylon 5,000 tons this year.

The wild African rubber is not a factor in the automobile industry, but in the colonial possessions of various European nations on both coasts the plantation idea is being developed with much success. The German, Dutch, French and British colonies and the protectorate of Belgium are trying it. The yield to date has not been considered an important factor, but there is a total acreage of about 10,000 that is being extended with rapidity. The trees are mostly immature, but appear favorably in comparison with other plantation trees. The seeds from which these trees are grown comes from Ceylon and Malaya.

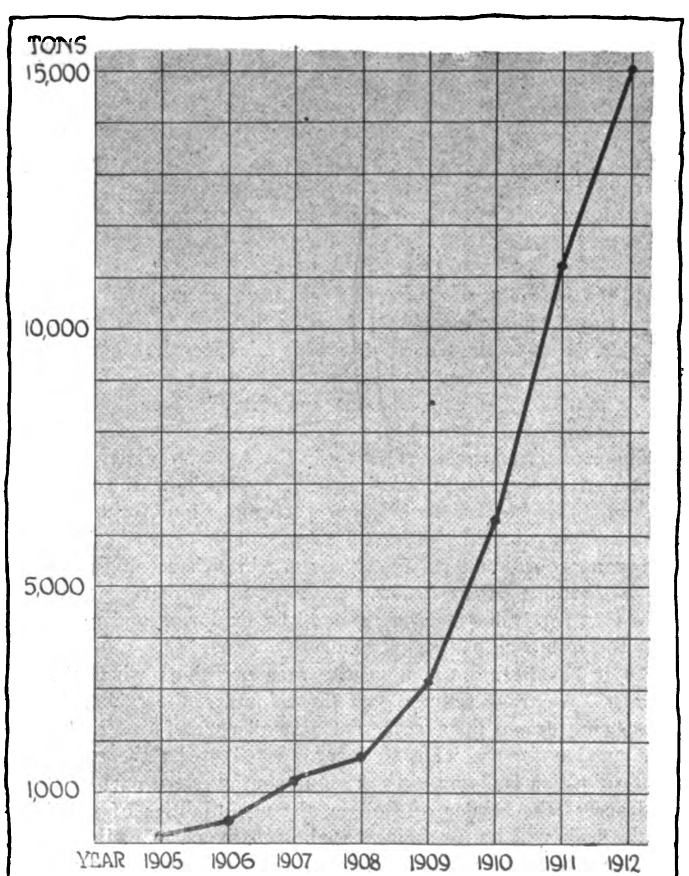
The native African rubber is derived from vines very largely.

Mexico and Central America are not important factors in the production of rubber for automobile use, but the fields of Mexico are of large extent, the acreage being estimated at 100,000, the eventual yield of which will be enormous. The Central American rubber is largely from the castilloa. Guayule is derived from a weed related to rubber, but bearing only a remote resemblance to it. Guayule production in 1911 was about 9,000 tons.

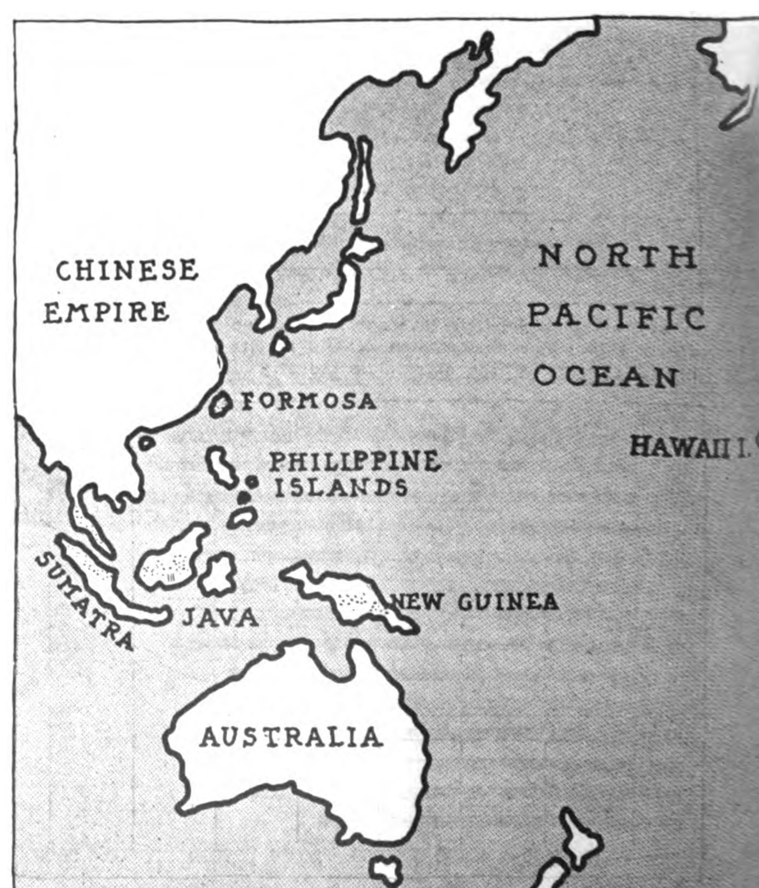
Burma, India, Borneo, New Guinea and the great islands of Sumatra and Java and some of the lesser islands of Oceania produce some rubber now and when their plantations are in full development the amount will be vastly larger. The native rubber is of no account for automobile purposes, but in each section the hevea is being introduced and in a few the castilloa, ceara and other rubber trees are being planted.

As Henry C. Pearson, editor of the *India Rubber World,* said recently in an editorial in that journal, any attempt to estimate the future rubber production of the world in definite terms is sheer vanity. Nevertheless, it may be said with conviction that unless a general blight falls upon the plantations, or somebody invents a process of producing synthetic rubber as good or better than present varieties of crude rubber at less cost, not only will the world's yield be vastly greater next year than in 1912, but the increase will continue indefinitely.

It is said that the plantations of the world embraced about 1,000,000 acres in 1912. It is planned to increase the plantations



How production of plantation rubber has increased in Malaya



Distribution of the world's rubber fields extends throughout of Malaya and Ceylon to 1,350,000. If the other sections expand to their reasonable limit, the total acreage of the world's plantations will reach 2,000,000 within a few years, taking no account of the vast projects to cultivate rubber in Brazil.

The plantation industry is too young to tell where the age limit will prove effective in checking the supply. The oldest trees under cultivation are the largest producers, the record being about 80 pounds of dry rubber a year from a 36-year old tree in Ceylon 16 miles from Colombo. So far the rule has been that the older they are the better they yield.

It is likely that a yield of 10 pounds a year from each tree in the plantation areas will be reached in time and if the proportionate yield increases at anything like the rate shown by some of the older trees in Ceylon and Malaya, it is not unlikely that a general average of 25 pounds or even considerably more may be reached at no very distant date. If the trees prove to be as productive as the one in Ceylon that yields 80 pounds a year for 3 successive years, the average yield of plantations where the trees are of similar age to the record holder might reach 50 pounds.

If all that is true and there is an average of even 100 yielding trees to the acre, the total production of the world may reach the incomprehensible total of 15,000,000,000 pounds, or about 7,000,000 long tons.

Among the newer plantation undertakings the cultivation of rubber in the Philippines, particularly in the Island of Moro, by Dr. Walter Strong and others, and on the Hawaiian Island of Maui and the Japanese protectorate of Formosa have proven successful. So far the yield has been small in the aggregate, but the promise in each field is large.

In Moro Dr. Strong has brought the hevea to a highly productive stage in a small way and has produced some rubber that is pronounced excellent by those in position to judge. The land available for rubber culture in the Philippines is very large in acreage and in the southern part of the archipelago, south of the typhoon belt, the climatic conditions are ideal. In the Philippine islands the labor problem is much nearer a solution on reasonable lines than it is among the various British colonies.

In Hawaii, while the topography of the country is rough, especially on Oahu and the main island of Hawaii, there are many stretches of country 5 miles long that may prove ideal rubber plantations. The rubber that has proved most successful so far in the experimentation is the ceara type. The commercial shipments this year will not be over 6 tons, but in due course the yield will be vastly increased. About 3,000 acres have been planted in rubber.

The Formosan experiments are rather new and so far are inconclusive.

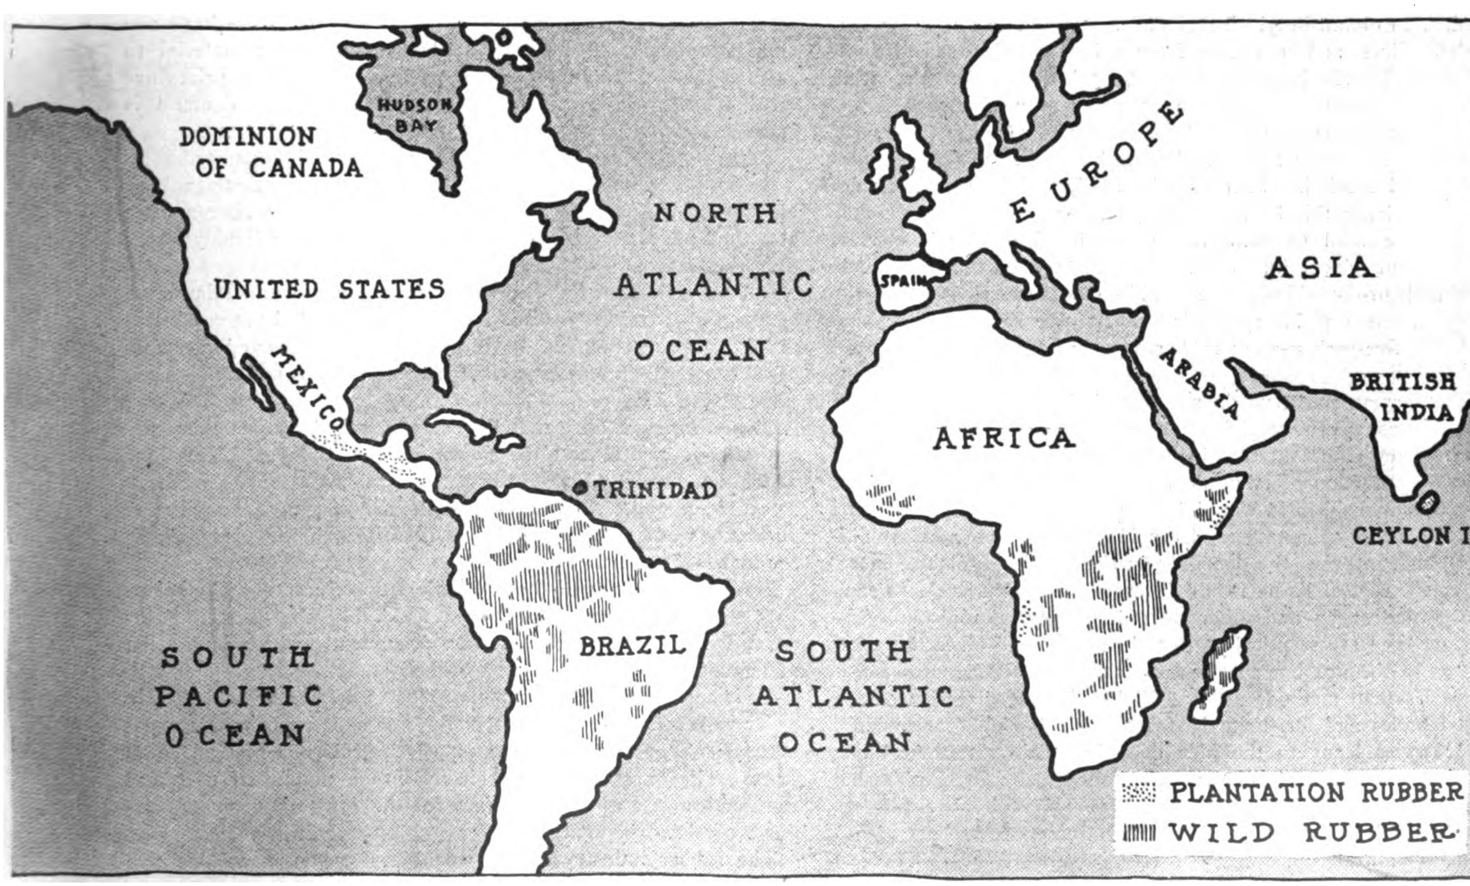
In the West Indies, Trinidad already has taken up the industry with vigor, and it is said that the valleys of Cuba afford the ground work for plantations growing some varieties of commercial rubber. The extent of the present acreage under plantation rubber may be estimated about as follows:

Malaya	600,000
Ceylon	150,000
Mexico	100,000
Africa	10,000
Elsewhere	100,000
Total	960,000

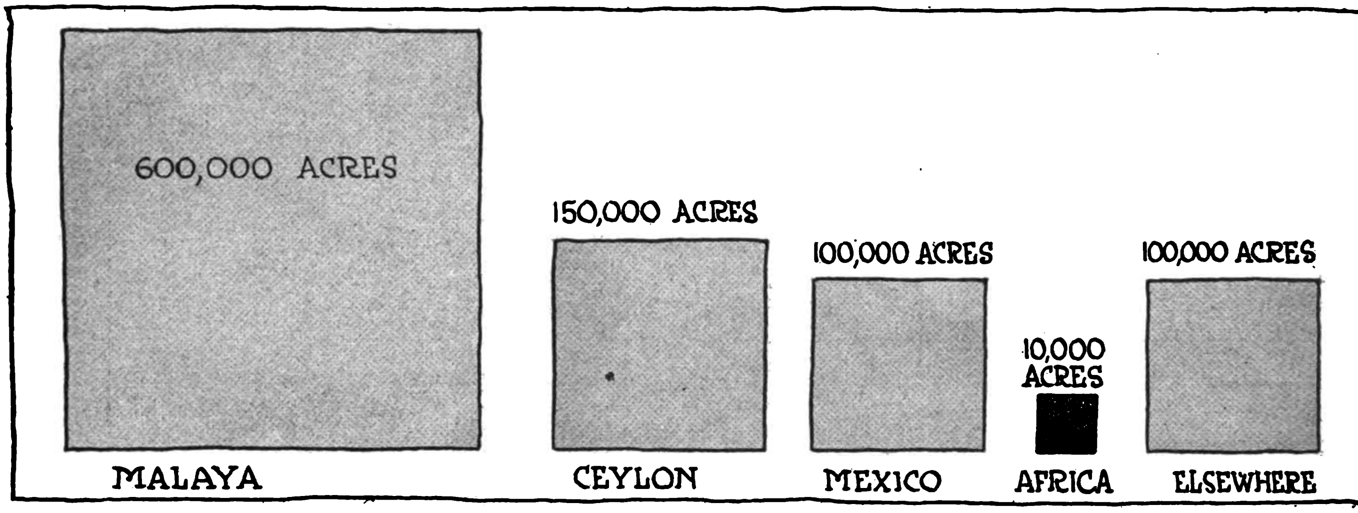
There is not a remote chance for exactness in estimating the extent of the wild rubber fields. The Amazon Valley is over half as large as the territory of continental United States and the rubber country of Africa compares with it in size. The islands of the East Indies increase the total of wild rubber lands enormously.

Aside from wild and plantation rubber another possible factor of future supply is synthetic rubber. There has been much said on the subject, but so far the actual, tangible results as affecting the industry have been negligible.

Synthetic rubber was discovered in 1892 by Professor William Tilden, of Mason College, Birmingham, England, by the sheerest chance. He had prepared a number of experimental combinations of isoprene, a derivative of turpentine, and hydrochloric acid. He found a substance resembling rubber in one of the tubes, but had failed to enumerate the exact constituents of the



the Torrid Zone wherever climatic conditions are favorable to the growth of the latex-producing plants, trees and vines



Acreage of the world's plantations, showing a total of about 1,000,000 acres under cultivation, one-third of which is now producing

experiment and despite years of labor failed to produce any more rubber.

With that much as a basis, the chemical science of the world has been busy at times ever since and periodically announcements have been made that synthetic rubber was an accomplished fact and that the wild and plantation industries better prepare to go out of business.

Some real progress, however, has been made within the past 3 years. Two chief groups of scientists are busy at present to commercialize their discoveries. The British group, headed by Dr. William H. Perkin, professor of chemistry at Victoria University, Manchester, believes he has the real solution. It was acknowledged that the use of isoprene, derived from turpentine, as a basis, while chemically proven, was too expensive ever to hold the promise of competing with Malayan rubber at a cost of 25 cents a pound. Professor Fernbach, of the Pasteur Institute, observed that it was possible to ferment starch or even sawdust to obtain butyl alcohol and acetone at less than present market prices, and to derive from such alcohol so-called fusel oil, which Dr. Perkin insists may be substituted for turpentine or other isoprene in the commercial production of rubber.

The chemical steps required, according to Dr. Perkin, as set forth in a statement to the *India Rubber World* are as follows: Take ethyl alcohol, which may be easily oxidized to acetaldehyde; condense this by means of potassium carbonate to aldol; convert the aldol (quantitatively) into butylene glycol; convert the butylene glycol into dichloride. Then pass this over soda lime and produce butadiene. This substance treated by the sodium method yields synthetic rubber. He says that the product is a five-carbon-atom rubber, closely approximating natural rubber.

The German scientists do not regard the British method very seriously as a commercial, or even as a chemical accomplishment. They point out that in order to produce sufficient starch for the production of ethyl alcohol needed in making 10,000 tons of synthetic rubber it would be necessary to use the yield of 1,000,000 acres of potatoes. Even if potatoes were not prohibitively high in price, the demands on the land due to the general rise in the cost of living would forever bar such use. As to sawdust, grape sugar and other possible elements in alcohol production, they are sceptical as to the sawdust and place the other factors in the problem in the same category with potatoes.

The German methods used at Kiel under the direction of Dr. Carl Harries and Dr. Fritz Hofmann, at Elberfeld, vary widely. Dr. Harries leans to the idea of polymerizing isoprene along somewhat different lines than those followed by Dr. Perkin, but says that the so-called sodium rubbers, although physically resembling rubber and susceptible to vulcanization, are not identical with natural rubber.

Dr. Hofmann takes coal as a basis for the production of the isoprene used in his process. He uses heat in reaching the final result.

That synthetic rubber is a scientific fact of importance to the automobile industry is proven by the recent delivery by Dr. Carl Duisberg in New York of a statement showing that a set of automobile tires had been made from the product of the Elberfeld factory which were used for 4,000 miles without puncture or serious signs of wear.

The most advanced scientists and those most closely identified with the production of synthetic rubber do not believe that it will appear on the market in the immediate future.

Two sets of tires have been made, one of which was presented to His Imperial Majesty of Germany. These eight tires represent the actual commercial accomplishments of the scientists during 5 years' labor.

At present rates of cost, the raw material needed to produce a pound of synthetic rubber has been estimated all the way from 5 cents to 50 cents. The labor, factory expense and overhead are uncertain items. If the product demands sufficient material to shorten the world's supply in any particular, bounding prices are inevitable for the particular element on which the demand is exerted.

Thus, even the cost of material is an intangible quantity.

Based upon present prices of material, the synthetic rubber makers claim that they will be able to supply the rubber market at a level under 60 cents. Some estimates are considerably lower than that figure.

But the activity of the inventors was spurred and stimulated by the high prices of 1910, and while their efforts have continued toward a solution, there have been only half-hearted attempts at production on anything that resembles a commercial scale since prices fell.

The scientists realize that they have arrayed against them the millions of capital and the power of the Malayan plantations which can produce high-grade natural rubber at a big profit at 25 cents a pound. They admit that their big fight will be with the plantations and that the victory will rest with the party whose product is cheapest.

Figuring the birth of the synthetic industry at 1909, the scientists state that when it is 36 years old, like the plantation industry at present, it will occupy a prominent position in the list of commercial factors of the world.

As it applies to the automobile industry, it may be said that in order to become an important factor, synthetic rubber must equal natural rubber at less price or excel natural rubber at an equal price. The question resolves itself into a matter of cost and that subject is a question of fact for the future and not an element of debatable nature under present conditions.

The rubber industry of the world has grown marvelously in the past half century. While rubber has been known for 400 years and has been used more or less for nearly a century, it really had its birth in 1839 when Charles Goodyear, a poverty-stricken scientist, happened to drop a handful of crude rubber mixed with sulphur on a hot stove and the process of vulcanization began.

Brazil in 1840 had a few rude manufactures and even prior to that date exported small lots of rubber. In 1827 the exports amounted to 31 tons.

To give some idea of the present extent of the industry, the following table of estimates covering the 1913 demand for rubber has been prepared by the Rubber Plantation Investment Trust:

Country	Estimated needs in tons
America	47,500
Great Britain	15,000
Germany	15,000
France	10,000
Russia	7,000
Belgium	1,500
Other countries	7,000
Total	103,000

Against this demand and compared with the product of 1912, which has been estimated roundly at 90,000 tons, the increase of 13,000 tons will have to be accounted for largely by the natural increase of the plantations.

The estimates made by experts are all more or less uncertain and vary widely. For instance, despite the fact that the plantation rubber auctions in London will dispose of over 20,000 tons of rubber in 1912, the more conservative experts only place the 1913 estimate on plantation production at 28,500 tons. Leonard Wray, Edward G. Salmon and others connected with the British plantation industry state without reservation that the rate of increase noted is much below the probable results.

Mr. Wray submits the following figures on Malaya's production that seem to indicate a vastly larger yield than the figures of the experts would appear to show. Mr. Wray's figures are as follows:

EXPORTS

Year	Tons
1905	130
1906	420
1907	1,020
1908	1,580
1909	3,010
1910	6,420
1911	11,120
1912	15,000

The acreage in Malaya in 1911 was 542,000, but the yield of 11,120 tons was from plantations comprising only 99,230 acres which had been planted by 1906, as it requires over 4 years to develop the trees to the point of yielding. An acreage of 179,227 is bearing in 1912, and it is estimated that the exports will reach the high total of 17,800 tons. The 1913 product of Malaya will be based upon an acreage of 241,138, and it is easily probable that it will run above 25,000 tons. With Ceylon, which has about one-third of the size of the Malayan fields under cultivation and which is increasing in about the same general proportion, the total yield of these two countries should be about 34,000 tons and other plantation projects will certainly increase the total quite materially.

Despite the calculations of experts it is not unlikely that the plantation yield of 1913 will be close to 37,000 tons.

According to the figures submitted, the whole product of South America will be only 39,000 tons in 1913. Just how that figure is reached is mysterious as no man can say what will come out of the Brazilian jungle. In 1911 the shipments from the Amazon Valley equaled 38,000 tons. In 1912 the Amazon shipments are estimated at 39,000 tons, or more. Neither figure covers shipments of manicoba rubber or any product outside the Amazon Valley. These elements are estimated at about 2,000 tons for 1912. Thus the estimate of 39,000 tons as the production figure for South America in 1913 seems too low. The working of the new law in Brazil will undoubtedly lead to some increase from the Amazon country and many experienced rubber men believe that 40,000 tons is none too much to expect from that section. With that as a basis, the figures of the Brazilian industry indicating at least 42,000 tons for 1913 do not seem to be too large.

The tabulation referred to is as follows:

ESTIMATED PRODUCTION OF 1913

Country	Tons
South America	39,000
Plantations	28,500
Africa	15,000
Central America	5,000
Other sources	3,500
Total	91,000

The table above does not specifically classify several of the newer fields, making no particular mention of Mexico, lumping that country with Central America. The apparent difference of 8,500 tons of plantations and 3,000 tons from South America may be augmented by an item of at least 2,000 tons not mentioned at all in the table. With these additions the total as above would be increased to 104,500 tons as the probable yield of 1913.

The consumption of rubber in the United States by years since 1898 is as follows:

Year	Consumption in Tons
1898	18,623
1899	22,674
1900	19,532
1901	22,327
1902	22,480
1903	24,345
1904	27,300
1905	28,046
1906	28,483
1907	28,634
1908	28,050
1909	30,669
1910	32,385
1911	34,152

In addition to the total of 1911 there was an item of 8,091 tons of guayule imported from Mexico.

The influence of the automobile industry may be read between the lines of the table above. In 1900 the domestic consumption of rubber was only 19,532 tons and there was no material demand from the automobile industry. In 1911 the consumption was 34,152 tons and the difference between those quantities represents approximately the use of rubber in the United States for automobile purposes, or 14,618 tons in 1911. Of course, other industries have increased in volume during the period covered by the figures, but reclaimed rubber and guayule probably cover most of the additional demand made by them upon the regular supply.

Certain it is that with the bulge of prices noted in 1910 and before and after the market reached its crest at $3.10 a pound, the consumption in other lines than tires was checked at the exorbitant levels.

The tire requirements for 1912 will probably reach 15,500 tons and in 1913 17,000 tons.

The inadequacy of supply at the time of sharpest demand from the automobile industry, together with coincident elements of manipulation by speculators may be seen in the accompanying table showing price fluctuations. Of course, it should be remembered that the grade quoted is up-river fine, and that while

Needs of rubber-consuming countries shown for 1913 in long tons

Trade News of the Week

Federal Rubber Doubles Capitalization—Gramm Dispute Settled—U. S. Motor Reorganization Details

Crude Rubber Higher in Inactive Market—Ohio Creditors Differ as to Plans of Procedure

MILWAUKEE, WIS., Oct. 14—The Federal Rubber Manufacturing Company, Milwaukee, Wis., and Cudahy, Milwaukee county, has increased its capital stock from $1,000,000 to $2,000,000. Since January 1 the factory has been working night and day and the actual sales have exceeded the pre-season estimates by more than $400,000. During the past season the company has done extensive construction and improvement work, valued at nearly $500,000. A principal improvement was the construction of a new central power, lighting and heating plant aggregating 3,500 boiler horsepower. There are employed at this time 1,750 men in the manufacture of pneumatic tires, solid tires and rubber goods of all kinds. B. C. Dowse is president; H. A. Githens is vice-president and Richard Ward occupies the position of secretary and treasurer.

Gramm Dispute Settled Out of Court

TOLEDO, O., Oct. 14—The difficulties between President John N. Willys, of the Willys-Overland Company, and A. L. White and W. T. Agerter, over the transfer of controlling stock of the Gramm Motor Truck Company, at Lima, have been amicably settled. Mr. Willys had brought suit, charging misrepresentation of the value of stock. The payment of all bonded indebtedness of the Lima plant has been announced and also the intention to double the capacity of the plant.

Findlay Company Again Defendant

TOLEDO, O., Oct. 14—The Findlay Motor Car Company, and its receiver John M. Barr, John Von Stein and the Farmers Bank Company, of Jenera, in Hancock County, have been made defendants in a suit brought by William C. P. Rhoades. Mr. Rhoades seeks to recover judgment on a promissory note of $5,000 asking for the foreclosure of a mortgage on land in Monclova township.

Crude Rubber Works Higher

Crude rubber has worked back to a basis of $1.10 a pound for up-river fine with little or no apparent reason for the upward trend. Consumers have not been aggressive in bidding for the firmly held but liberal supply and the trading on the advance has been somewhat smaller than was noted last week. On the other hand the sellers have not been liberal in conceding anything in order to make trades. Imports in New York are well up to the average. While pale crêpe from the plantations remains steady at the former figures, approximating $1.16 1-2 a pound, bales and sheets have yielded about 1 cent a pound.

Reorganizing United States Motors

Announcement of the reorganization plan to be used in rehabilitating the United States Motor Company along the lines of the article published in these columns last week has been made and progress toward completing the organization will come next. Under the plan adopted by the creditors the matter will be taken out of the hands of the United States District Court as soon as the details have been worked out on a satisfactory basis.

The first step to be accomplished will be to formulate and send out to those interested as creditors and stockholders a legal notice of the agreed plan. Then will follow the call for deposits of the stock certificates and the issuance of new certificates under the schedule as announced.

The financial part of the plan will be carried out under a system of underwriting, the details of which have been completed but not announced.

There has been much talk about the personnel of the new company but no decision has been reached as to who will lead. W. E. Strong, who has acted as chairman of the board since the extension of credit last June has been asked to remain with the new organization, but in exactly what capacity has not been outlined.

Ohio Creditors Differ as to Plans

CINCINNATI, O., Oct. 14—There is apparently a sharp division among the creditors of the Ohio Motor Car Company which is now in the Court of Common Pleas under insolvency proceedings. One committee of the creditors has issued a statement recommending that the plant be sold on the block as quickly as possible and urging the creditors to bring pressure to bear to

Automobile Securities Quotations

General Motors preferred sold ex-dividend Tuesday, the books being closed for payment of the regular dividend of 3 1-2 per cent. This stock has paid $8 a share during the past year, but the extra 1 per cent. was not in the nature of an extra dividend, being merely in the nature of a readjustment of the dividend period so that the bond coupons and the preferred dividend should not fall together. Goodyear common skyrocketed fifty points on bidding by insiders, but little stock came out as a result. The annual meeting of the company does not take place until December, but it has been pretty well understood that it will reveal astonishing conditions. The remainder of the list was irregular, with Goodrich, International and White lower and the rest of the list, where any change was noted, fractionally higher. Trade as whole was small in volume and without particular trend. Whatever movement appeared in the securities of United States Motor was downward, the Street apparently awaiting for a hint as to the intentions of the financial powers with regard to the reorganization. The table follows:

	1911		1912	
	Bid	Asked	Bid	Asked

have the whole manufacturing force discharged instantly. This report is signed by J. S. Monroe, E. J. Hess and C. M. Stadelman.

The other report takes a rosier view of the matter. It denies the accuracy and good intent of the other committee and states that a careful appraisement having been made, it was found that the plant is worth about $200,000, not including bills and accounts receivable, good will and stock holdings in other corporations. That figure is over $20,000 greater than the total liabilities, according to the committee.

The committee urges the creditors not to take any action until thoroughly informed of the facts. This report is signed by C. F. Pratt and A. E. Schafer.

In the meantime the receiver, E. G. Schultz, has completed and sold one car and several Breeze buggies.

Crawford Takes Dyer License

The Crawford Automobile Company, of Hagerstown, Md., has been granted a manufacturing license under the Dyer transmission patents. The company is one of the veterans of the industry, but has never approached major size in comparative production.

Market Changes for the Week

A number of important changes took place in the market the past week, the most important being the drop in lead and tin and the gain in Bessemer steel. Tin fluctuated throughout the week, closing at $4.90 per 100 pounds, a loss of $.10. Lead dropped $.02 1-2 on Saturday and remained at that figure to the end of the week, closing at $5.07 1-2 per hundred pounds. Bessemer steel experienced a gain of $.50, rising to $27.00 a ton on Friday and remaining at that price the rest of the week. Antimony remained at $.09 per pound throughout the week, and beams and channels were constant, closing at $1.61. Rubber rose to $1.09, experiencing a gain of $.02, due to the inactivity of the sellers. Copper electrolytic rose $.00 1-10, closing Tuesday at $.17 1-2. Copper lake remained constant throughout the week, selling at $.17 5-8. Open-hearth steel remained constant, closing at $27.50. The cottonseed oil market was decidedly weaker Tuesday, closing at a loss of $.15. The weakness in lard and the decline in cotton were both responsible for considerable selling pressure, causing the drop. The prices of petroleum and gasoline remained unchanged.

Lyons Buys Atlas Plant

New Concern Incorporated as Lyons-Atlas Company Will Continue to Make Knight Engines for Trade

Wells Fargo Places Order for Thirty-Five Trucks—Kelly Expands—Shanks Sales Manager

INDIANAPOLIS, IND., Oct. 15—With the approval of Judge Weir, of the Superior Court, Fred. C. Gardner, receiver for the Atlas Engine Works, this afternoon sold the property of the company to the Lyons-Atlas Company, organized and incorporated here today, with authorized capitalization of $500,000. The new company will continue the manufacture of Silent-Knight motors for the trade and also of the Diesel oil engines.

The property was bought subject to a mortgage deed of trust given by the Atlas company to the Indiana Trust Company as trustees. The new owner is to pay $46,100 interest on $1,050,000 in bonds secured by the mortgage deed of trust and also $105,000 incurred by the $1,500,000 bond issue as well as $48,187.04 secured by $63,000 worth of accounts and bills receivable. Also $80,000 cash to pay receivership expenses and debts incurred during receivership, together with $6,700 in judgments against Atlas personal property, merchandise, materials, patent rights, trademarks, account bills receivable, conveyed outright free of liens. The holders of common stock will receive nothing.

The stockholders in the new company have been in the manufacturing business in Chicago. The officers are as follows: James W. Lyons, president; William P. Lyons, vice-president; George W. Lyons, secretary-treasurer. The company will employ more than 2,000 men.

INDIANAPOLIS, IND., Oct. 16—*Special Telegram*—The company has parts on hand for the two models which the old Atlas company brought out, the four and the six-cylinder motors, each 4 1-2 by 5 1-2-inch, bore and stroke, but in the immediate future it is planned to turn out other models, plans for which are now going through.

J. W. Lyon, the president of the new concern, will be the active head of the company and will move to Indianapolis. As to the other officials nothing has been definitely settled outside of the decision to retain F. H. Baker as general superintendent. Mr. Lyon is a gas engineer expert and at one time was connected with Allis-Chalmers.

Wells Fargo Buys Thirty-Five Trucks

About one-third of the reported order for 100 automobile trucks for the Wells Fargo Express Company has been placed according to statements current in the industry. The present order numbers thirty-five and is divided among seven companies as follows: General Vehicle, nine electrics; American Locomotive Company, six gasoline trucks; Packard, six; Peerless, six; Mack, four; General Motors, four, and Lansing, one.

The cars will be distributed among the New York, Chicago, St. Louis and San Francisco establishments of the company. The trucks ordered are mostly of the 2-ton and 3-ton sizes.

Kelly Expands; Shanks Manager

SAN FRANCISCO, Oct. 10—Charles B. Shanks, who has been appointed general sales manager of the reorganized and enlarged Kelly Motor Truck Company, of Springfield, O., will assume active charge of that department within a short time. The company had just increased its capitalization from $500,000 to $4,000,000 and contemplates a big increase in manufacturing.

Appeal Patent Tread Suit

Validity of the Adams Midgely Tread Claims Depends upon Interpretation of the Term Interwoven

APPEALING from the decision of United States Circuit Judge Platt, against the patent of Calvin T. Adams covering a certain kind of automobile tire tread in which wire was interwoven to give greater life and non-skidding properties, the Metallic Rubber Tire Company and the Hartford Rubber Works Company appeared before the United States Circuit Court of Appeals last week.

The appellant is the assignee of Adams as to the patent in suit, which is numbered 609.320 and granted August 16, 1898.

The only claim contained in the application is as follows: "The combination with a cushioned vehicle tire, of a tread applied to the entire periphery of a tire, and having metallic wire interwoven with itself, parts of said interwoven wire lying substantially flush with the outer surface of the tread and forming cushioned anti-slip bearings covering the sides and bottom of the tread."

The defendant company manufactures a tire known to the trade as the Midgely tread which consists of embedding a series of wire coils in the rubber before vulcanization.

It was claimed that the Midgely tread infringed the Adams patent.

Judge Platt in the lower court decided that the defendant did not infringe and the case went up in due order.

In the present hearing the complainant's attorneys, Alfred Wilkinson and J. H. Roney, contend that the opinion of the court below was based only upon an erroneous view of the prior art, particularly outlining the alleged worthlessness of several old British patents and holding that the terms of the patent were sufficiently broad to cover the Midgely construction.

The defendant's attorneys, E. W. Vaill and Livingston Gifford, argue for an affirmation of Judge Platt on the grounds that there has been no infringement because the wire is embedded in the Midgely tire and the Adams patent applies only to interwoven wire.

As additional defenses it is alleged that the Adams patent is completely anticipated by the Phillips British patent of 1893; that in view of the prior art there is no invention; that the Adams patent has been abandoned within the purview of the statute and that the claim is inequitable.

The case apparently turns on the interpretation of the term interwoven, as contained in the claim in suit.

Offers Made for Newark Factory

NEWARK, N. J., Oct. 14—The trustee acting in the matter of the bankruptcy of the Newark Automobile Manufacturing Company has reported to the United States District Court that he has received an offer to purchase the factory building and real estate of the embarrassed company and also an offer to rent the same until December 1, 1913. A meeting of the creditors will be held October 21 to consider the offers.

Forestalling Another Car Famine

INDIANAPOLIS, IND., Oct. 14—The car shortage situation has become somewhat acute and there is the greatest difficulty in getting sufficient freight cars to move motor car shipments promptly. It is thought by some that the present situation is only a forerunnner of what is to come and that before many weeks there will be an alarming car famine.

Desiring to avoid a genuine car famine, local motor car manufacturers have already taken up with the railroad companies the matter of getting the greatest possible efficiency out of freight cars and moving all freight traffic promptly.

One day last week a conference between motor car traffic managers of the city and traffic officers of the New York Central Lines was held in the Board of Trade Building in this city. A rather thorough understanding was reached with the railroad men and it is believed beneficial results will obtain.

Motor car concerns represented at the conference were the Nordyke & Marmon Company, Cole Motor Car Company, National Motor Vehicle Company, Marion Motor Car Company, Ideal Motor Car Company, American Motors Company and the Mais Motor Truck Company.

Marks Patent in Court Test

BUFFALO, N. Y., Oct. 14—The Philadelphia Rubber Works Company, of Philadelphia, brought action last week in Federal Court to restrain the United States Rubber Reclaiming Works from infringing on a patent held by the former concern. J. Kearsley Mitchell, president of the Philadelphia Rubber Works Company, asserted that letters of patent on October 17, 1899, were granted to Arthur M. Marks for certain new improvements in the process of reclaiming rubber from vulcanized rubber waste.

These letters of patent, according to the complaint, were assigned to the Diamond Rubber Company, the Alkali Rubber Company, and to the Philadelphia Rubber Works Company, which is bringing the suit. The complainant requests that the Buffalo concern pay the rubber firm in Philadelphia the profits and income alleged to have been unlawfully derived in violation of the complainants' rights. The complainant asks also that its company be paid damages to the extent of three times the loss suffered by the Philadelphia concern. Decision was reserved.

Hartford-Connecticut Case Argued

Motion for a preliminary injunction against Walter H. Ellis, doing business as the Ellis Motor Car Company, of Newark, N. J., was argued on behalf of the Hartford Suspension Company before the United States District Court, of New Jersey, at Trenton on Monday. Decision was reserved.

The suit is one of several now pending, that have been started by the Hartford Suspension Company to protect its rights under the Truffault patents covering the principles embodied in the Truffault Hartford shock-absorber. The alleged infringement, as outlined in the complaint, consisted in the selling by the Ellis company of shock-absorbers made by the Connecticut Shock Absorber Company, which are alleged to contravene the rights of the complainant.

The case will probably be brought to issue before the end of the year and may be heard before spring.

In the argument Monday the complainant suggested that a bond of $20,000 would be acceptable as a release from the operation of a preliminary injunction pending the hearing of the case.

Clifford E. Dunn represents the Hartford company and Bartlett, Brownell & Mitchell act for the defense.

Court to Test De Tamble Bonds

ANDERSON, IND., Oct. 14.—A meeting of the creditors of the De Tamble Motor Company was held October 9. John C. Teegarden, temporary receiver of the concern, was appointed trustee for the $75,000 of unsecured claims. There is in addition to the unsecured claims a mortgage bond indebtedness amounting to $133,000. It was reported at the creditors' meeting that some of the bonds have been purchased at 10 cents on the dollar and an effort will be made to have the court consider the bonds at the price at which they were sold, instead of at par value.

Big Bay State Registration

In Past 9 Months 47,431 Cars Took Out Licenses, as Compared with 36,796 for 1911

BOSTON, MASS., Oct. 12—Massachusetts, which has had more cars registered each year than the other New England states combined, bids fair to continue its record when 1912 ends, for already there is every indication that the figures will show close to 50,000 cars on the list this year. With 9 months passed and 3 more to go there have been registered by the Highway Commission 47,431 cars while the full year of 1911 had 36,796 cars registered so that the increase to date over last year is about 33 per cent.

In the amount of revenue from the motor industry the Bay State is reaping a harvest again this year. The state has received $583,359 so far this year while the total for 1911 was $466,199, or $177,160 more than all of last year. That the figures will go above $600,000 seems certain. This is a remarkable growth in a decade, for 10 years ago the state received from motorists but $17,684. Here are the figures showing the amount of money received annually during these years:

1903	$17,684.00
1904	19,162.00
1905	24,490.50
1906	33,085.50
1907	92,096.50
1908	121,488.50
1909	169,973.54
1910	374,038.25
1911	466,199.75
*1912	583,359.00

*To Oct. 1.

The figures for registrations, operators, dealers, etc., show an increase all along the line, and this is particularly true of the motorists who register in the state for a couple of months, there being more than 100 of them this year. The following figures give the entire year of 1911 and up to October 1, of 1912.

	1911, entire year.	1912 to Oct. 1
Automobiles	36,796	47,431
Motor cycles	3,712	4,720
Manufacturers or dealers	829	1,064
Manufacturers or dealers (motor cycles)	13	22
Operators	10,232	12,988
Operator renewals	24,842	30,495
Chauffeurs	3,695	5,348
Chauffeur renewals	9,449	11,625
Examinations	5,386	5,512
Total fees	$466,199	$583,359

COLUMBUS, O.—At the close of business September 30, 1912, the Ohio State Automobile Department had issued 61,500 license tags since January 1 of this year. On September 30, 1911, the number issued was 44,800 and the total for the year 1911 was 45,788.

INDIANAPOLIS, IND.—During the three months ending September 30 the number of motor registrations in Indiana was 5,222, according to a report made by Lew W. Ellingham, secretary of state. During the same period of 1911 the number of registrations was 3,467, showing a gain of 1,755.

MADISON, WIS.—For the fiscal year ending July 31 the secretary of state of Minnesota reports receipts of $60,168 from license fees for automobiles and from chauffeurs. The previous year the total was $30,385.

Milwaukee Motor's Working Plans

MILWAUKEE, WIS., Oct. 14—The Milwaukee Motor Company, of Milwaukee, Wis., has been reorganized following the sale of the controlling interest by E. E. Warner and C. F. Kaiser, founders of the big works, to other interests. The new official personnel consists of the following: President, J. C. Coerper; vice-president, August John; secretary and treasurer, Henry John. August John will be general manager. J. D. Bowes, former vice-president, remains as a director of the corporation and will act in a managerial capacity. James Church, formerly of the Davis Gas Engine Company, has become associated with the reorganized motor company in a prominent mechanical capacity.

The Milwaukee Motor Company was organized in 1903 with a capital of $10,000 and today owns and operates a large factory, producing several thousand motors for pleasure cars and trucks annually. Additions to the works and improvements, including equipment, now being completed, aggregate in value $80,000 and will require a working force of more than 600 skilled laborers. The contracts now on the books amount to $1,000,000. The retiring president, E. E. Warner, will continue in an advisory capacity for a short time. He will then take a vacation, his first in 9 years, and re-enter business, the nature of which he is not willing to announce at this time.

Marmon Nominated as S. A. E. President

The following nominations have been made for the various offices in the Society of Automobile Engineers:

For president, Howard Marmon.

Vice-presidents, Russell Huff and John G. Perrin.

Treasurer, Herman F. Cuntz.

Members of Council, Joseph A. Anglada, Eugene F. Russell and Harold L. Pope.

The nominations were made by the regularly appointed committee on nominations and the election will be by mail vote in which all persons of either of the member grades may participate. The vote will not be announced until just prior to the annual meeting of the society during the second week of the New York automobile show about the middle of January.

Grabowsky May Continue Work

DETROIT, MICH., Oct. 16—An order modifying the injunction filed by John C. Kimble September 17 against the Grabowsky Power Wagon Company, of this city, was signed and filed in the Wayne County Chancery Court, October 14. The original injunction as filed by Kimble restrained the Grabowsky concern from carrying on business as well as preventing its sale. The intention of Kimble was merely to restrain the sale and the original order has been modified to this effect.

Canada's Industry Increases

MONTREAL, Oct. 11—The census reports of manufactures taken in 1911 for the calendar year 1910 are now compiled. Compared with the census of 1901 for the year 1900, they show an increase in the 10 years of 4,559 in the number of working establishments; of $798,829,009 in the value of capital; of 175,108 in the number of persons employed; of $127,274,301 in the earnings of salaries and wages and of $683,722,157 in the value of products.

The statistics of establishments for 1910 are given in the following table. The number of industries is 300 as compared with 274 in 1905 and 264 in 1900.

Establishments	Capital Employed	Employees	Salaries	Value of Products
19,209	$1,245,745,496	514,281	$240,523,651	$1,164,775,532
AUTOMOBILES.				
8	4,699,256	2,438	903,394	6,251,885
AUTOMOBILE ACCESSORIES.				
11	361,272	132	76,060	170,930

McGraw Company Cuts a Melon

EAST PALESTINE, O., Oct. 14—At the regular monthly meeting of the McGraw Tire & Rubber Company October 9 it was unanimously voted to increase the capital stock from $100,000 to $250,000. Acting upon the favorable report of the year's business made by President E. C. McGraw, the directors voted a stock dividend of 50 per cent. plus a cash dividend of 10 per cent.

The McGraw Tire & Rubber Company has made several important additions to the plant this year, including a laboratory.

Evolution of Fire-Engine

Progress Made in Past 76 Years Shown by Photographs Depicting Ancient and Modern Types

From Old Hand Pump to Advanced Model of Steam-Electric Automobile Apparatus Is Far Cry

JUST how much progress has been made in the past 60 years in building fire-fighting apparatus is vividly pictured in the accompanying photographs showing the fire-engine of 60 years ago and the highest type of automobile fire-engine of the present day.

The first photograph shows one of the first fire-engines ever built. It was used in Cincinnati in 1836 to 1853. Eight volunteer firemen pulled it to the scene of action. These same firemen operated the big hand pump, which threw a stream from a 2-inch nozzle a distance of 50 feet. The apparatus was considered a wonder in those early days of fire fighting.

After this early type of fire-engine, came the one drawn by horses, one which is still used but rapidly being replaced in this age of automobiles by the motor-driven fire-engine of the present day with a speed of 50 miles per hour and as far superior to the horse-drawn apparatus as that one is over the old hand pump engine.

The ultra-modern automobile fire-engine of the near future is shown in the last photograph. This is a steam-electric automobile apparatus that travels with the speed of the wind. A rate of 75 miles per hour can easily be attained by this automobile machine. It has lost all resemblance to its former brothers and sisters and is built on an entirely new principle with electrically-operated pumps. A single stream from a 3-inch nozzle can be thrown a distance of a city block or 200 feet up the side of a skyscraper. Two streams go just half as far but the volume of water is so great that it resembles a good size rainstorm that can flood any building in five minutes. The pumps operate silently. There is no smoke, no cinders or ashes to litter up the street where it operates. It is considered the last word in automobile fire-engine construction and is said to be the coming universally used automobile fire-engine.

Small Crowd at Springfield, Mass., Races

SPRINGFIELD, MASS., Oct. 12—Before a crowd numbering 3,600. a program of automobile races was given at the Imperial Park half-mile track this afternoon. The track was slow and the fields small. T. B. Shoemaker, of New York, acted as referee and representative of the American Automobile Association. There were no accidents and no protests were filed by the contestants.

The events comprised a 3 and a 5-mile free-for-all, won by Mercedes (Hickman) and Mercer (Grennon), respectively; 3 and 5-mile races for cars having less than 601 inches piston displacement, taken by Pope-Hartford (Kyle) and Mercer (Grennon); a 10-mile match race between Pope-Hartford, Mercedes and Zust, won by the first, driven by Kyle, in 15:06, and a 5-mile handicap taken by Grennon's Mercer.

Hoosiers Plan Run to the Pacific

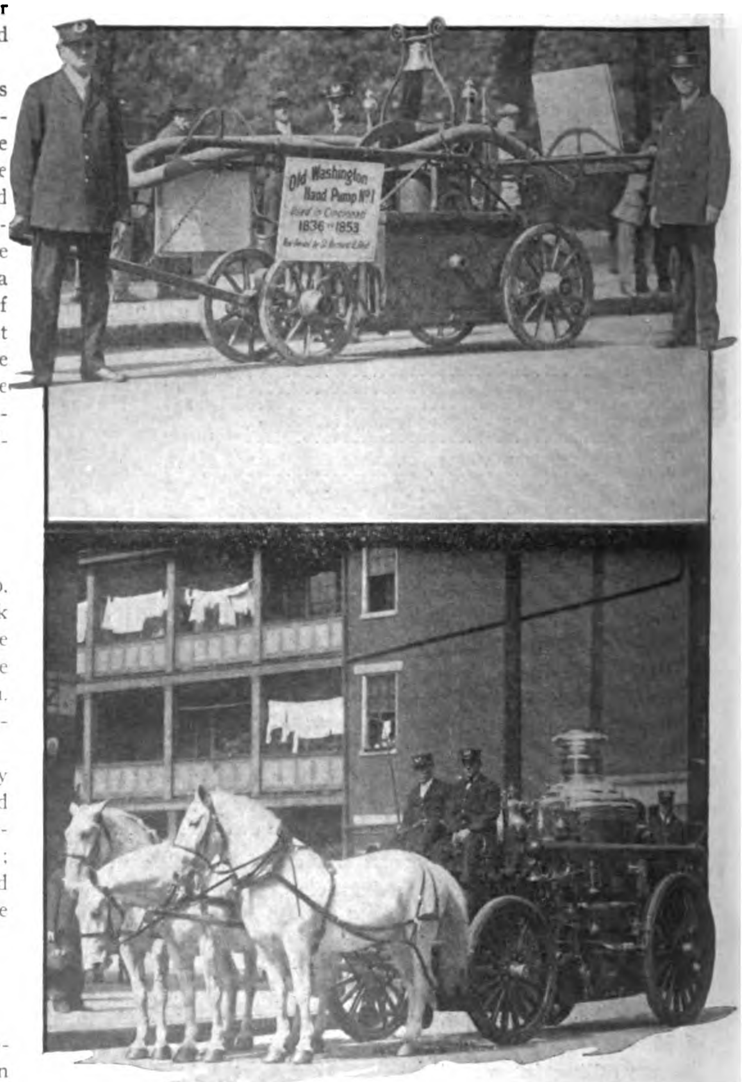
INDIANAPOLIS, IND., Oct. 14—At a meeting of the Indiana Automobile Manufacturers' Association here recently, a proposition to conduct the 1913 run to San Francisco was taken under advisement. It was proposed to follow one of the routes proposed for the rock highway projected by Messrs. Fisher and Allison, this taking the place of the Four-State Tour. The route proposed is through St. Louis, Kansas City, Omaha, Denver, Salt Lake City, Ogden, Sacramento and San Francisco, taking about 40 days for the round trip.

A plan also was proposed to run a special train for Indiana exhibits to the New York show in January, making stops en route at Philadelphia and Pittsburgh. The by-laws were amended to provide for the annual meeting in September and nine directors were elected.

May Open Yosemite to Automobiles

SAN FRANCISCO, CAL., October 12—Secretary of the Interior, Fisher will hold a conference in the Yosemite Valley, on October 14 for the purpose of deciding whether or not motor cars shall be admitted within the valley, which for several years past has been under Federal control and in charge of United States troops. A concerted effort is being made by the automobile men of California to secure the opening of the valley to the automobile, and it is confidently expected that Secretary Fisher will accede to the request.

It is recognized that the steep roads and narrow grades of the valley make precautions necessary, and it is probable, therefore, that the motor cars will be restricted to the use of one of the three roads entering the valley. Otherwise they will be permitted to use any of the three roads, but only during certain hours of the day assigned to them. The latter plan is the most generally favored by dealers and owners.



Upper picture shows most efficient fire-fighter in use back in 1836—it was a man-drawn, hand-pumping device—The lower cut shows the efficient type of horse-drawn engine, the best 20 years ago

Oil Man Talks Gasoline

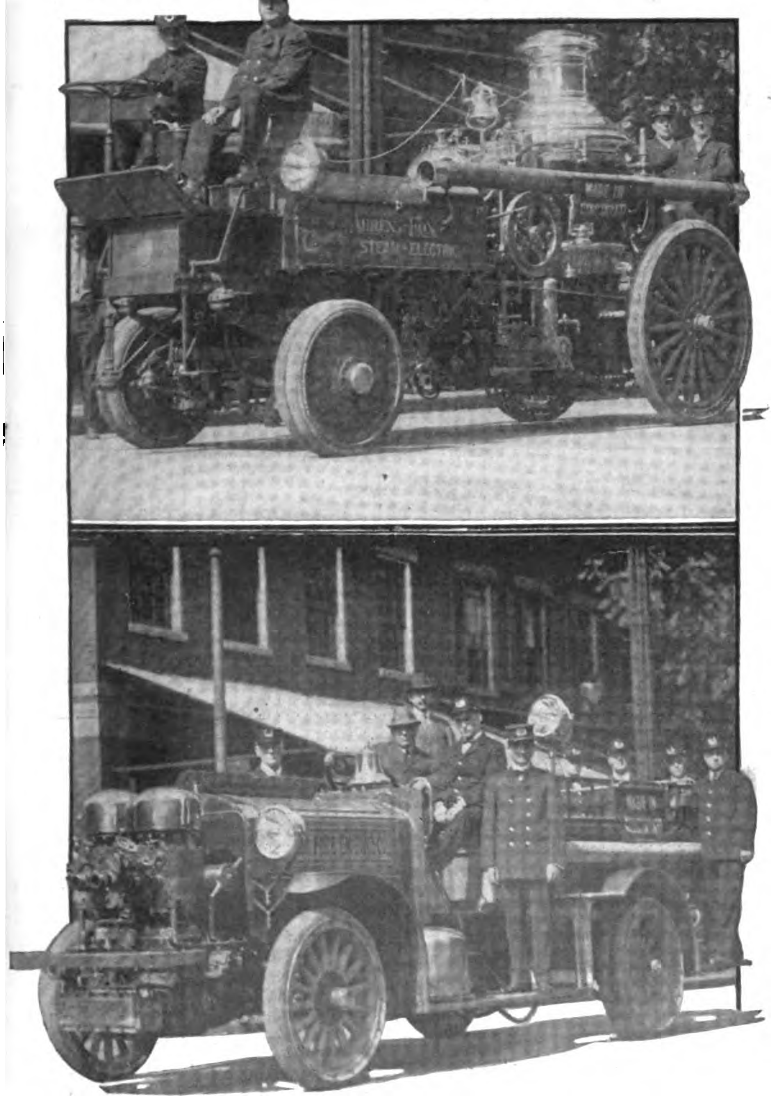
Sees Only Working of Supply and Demand Law in the Recent Series of Price Bulges and Jumps

Shows That Recently Discovered Oil Wells Produce Small Proportion of Potential Gasoline

FROM the viewpoint of the oil man, the extraordinary bulges that have marked the course of the gasoline market during the past year are simply evidences of the working of the law of supply and demand. The following article prepared by a prominent oil man outlines the situation as he sees it:

"In order to understand fully the situation in regard to supply of gasoline it should be understood that a considerable proportion of the oil produced is not suitable for the manufacture of gasoline.

"The state which produces the largest number of barrels (California) with a total of 81,134,391 barrels, produces only a comparatively small amount of oil suitable for gasoline manufacture, the bulk of this oil being only for fuel, road oil and asphalt production.



Two types of ultra-modern fire apparatus. The upper photograph shows a motor-driven fire engine which has a speed of 75 miles an hour and which uses electrically-operated pumps

"Dr. David T. Day, of the U. S. Geological Survey, in his report on the production of petroleum for 1911, states that while fuel oils increased, refinery oils declined. It is from the refinery oils that the gasoline production is secured.

"It should also be noted that gasoline can only be secured to the extent of the small percentage which is found in the oils, and where gasoline is not found in such percentage to pay for refining, the oil cannot be used for this purpose.

"The figures given below show that while the general production of oil for 1911 increased over 1910, there is no increase perceptible in 1912 over 1911, and in all cases where increase has occurred, the oil has been of such a character as to yield practically no gasoline.

"In the meantime the consumption of gasoline has increased yearly between 65 to 100 per cent. In other words, the oils from which gasoline can be drawn have not increased in quantity and it has been necessary to draw largely upon the accumulated stocks for the supply of gasoline.

"On account of the increased requirements for refinery oil, the price of crude oil suitable for refining purposes has risen approximately 33 1-3 per cent. during the last year.

"Not more than 6 months' supply of oil is in stock even in California where much of the oil is not suitable for gasoline manufacture, and in many cases, the supply on hand is much less.

"The total production of oil for 1911 (from the report of Dr. Day) 220,449,391 barrels.

"Delivered for all purposes during 1911, 229,567,581 barrels.

"While the reports for 1912 are not yet available, the records so far given show practically no increase over 1911.

"Stocks of refining oils:

December, 1910	93,038,828 bbls.
December, 1911	81,791,433 "
June 30, 1911	76,421,058 "

"The production from the fields which supply most of the refining oil stands as follows:

1910	126,255,667 bbls.
1911	127,215,812 "
(6 mo.) 1912	62,900,069 "

"In the meantime, some figures on the automobile business give the following number of cars in service:

	Pleasure Cars	Commercial Vehicles
December, 1910	350,000	No Record
December, 1911	550,000	No Record
June, 1912	859,000	32,000

"With an estimated production of the automobile factories for 1912 of 300,000 cars.

"To this must be added the number of stationary engines, gasoline traction engines, motor boats and yachts, the production of which has increased several hundred per cent. in the last 3 or 4 years.

"In other words, while the supply of oil has increased slightly, the supply of gasoline is not increased, but demand is going up by leaps and bounds, and as a consequence, the material is increasing in value."

Glidden at Hoosier Capital

INDIANAPOLIS, IND., Oct. 15—Charles J. Glidden, who is touring over the route selected for the A. A. A. national reliability tour from Detroit to New Orleans, reached this city today. He was escorted from Detroit by a number of cars and was received by the Hoosier Motor Club. Tomorrow's run is to Louisville. Mr. Glidden is using a Maxwell car.

Iowa Tour Finally Starts

DES MOINES, IA., Oct. 16—After three postponements the third annual Little Glidden tour of the Iowa Automobile Association left Des Moines early Tuesday morning for an 830-mile trip over Iowa. Five days will be consumed on the run and a complete circuit of the state will be made.

Harvest Proves a Bumper

Final Report of Government Shows 20 Per Cent. Increase Over Average of Last Year Throughout Land

Industrial Council Formed to Work for Safety of Employees—Automobile Trade Interested

WASHINGTON, D. C., Oct. 14—Crop reports as of October 1, just issued by the Department of Agriculture, are unusually favorable. This date is recognized by the Department as harvest time, and computations are made with reference to it. The composite condition of all crops on October 1 was about 20 per cent. better than last year, and 10 per cent. better than in an average season. The composite condition of all crops in each state on October 1, or at time of harvest compared with the same time last year and the averages of recent years is given in the table at the bottom of the page.

Industrial Safety Council Organized

MILWAUKEE, WIS.—The safety congress held at Milwaukee from September 30 to October 4 under the auspices of the Association of Iron and Steel Electrical Engineers has resulted in the organization of the National Council for Industrial Safety. which will conduct an American Safety Congress in 1913 at New York, and an international congress at San Francisco in 1915, in conjuction with the Panama-Pacific exposition. All of the big automobile manufacturers of America will be invited to join the National Council, the importance and magnitude of this and allied industries having received instant recognition.

Court Decides Against Insurance Company

The literature of automobile insurance litigation was enriched this week by the trial of the suit of William P. Hardenburgh, former vice-president of the New Jersey Zinc Works against the Employers' Liability Assurance Company, of London. Mr. Hardenburgh owned a car and, like a prudent man, insured it against road accidents. The policy of insurance was written by the defendant company. If there never had been any accident or claim made under the policy, Mr. Hardenburgh never would have known whether he was protected or not. As it turned out. he found that he was protected, but he had to take the matter to court to develop that fact.

The circumstances of the case, as they were brought out at the hearing on Monday before Justice Green in the City Court showed that while Mr. Hardenburgh was driving near Far Hills one evening about a year ago, he ran off the road and wrecked his car in the ditch.

To the average person the mishap was a road accident, but the Employers' Liability Assurance Company, of London, did not so construe it and through its representatives informed Mr. Hardenburgh that the accident occurred in the ditch and not on the road. But in addition the defense was put in that the road in question was not a real road, improved and protected by the authorities. In fact, it was only such a road as was under the jurisdiction of the Highway Commission. For that reason the company asked the court to dismiss the case.

The reasoning of the defendant did not appeal to Mr. Justice Green who instructed the jury to find a verdict of $635 in favor of Mr. Hardenburgh.

How to Avoid Freight Car Famine

Anticipating prospective shortage of automobile freight cars, when the shipping season opens in full blast, the National Association of Automobile Manufacturers, through James S. Marvin, assistant general manager, has issued a circular to the members of the organization warning them to be prompt in loading and unloading freight cars and cautions to members to load the cars to their full capacity if possible.

The circular recommends that shipments of supplies should be ordered in units of as much size as possible and to specify automobile cars so that the factories can reload such cars with their finished product.

Last winter and spring there was some complaint on the part of the railroads that automobile cars were tied up at various points of consignment because dealers failed to take prompt delivery.

TABLE OF CROP REPORTS TO OCTOBER 1

State	1912 Compared With		State	1912 Compared With	
	1911 Per Cent.	Average P. C.		1911 Per Cent.	Average P. C.
Maine	103	104	Missouri	124	103
New Hampshire	122	114	North Dakota	148	124
Vermont	115	113	South Dakota	213	108
Massachusetts	119	103	Nebraska	140	98
Rhode Island	111	100	Kansas	160	114
Connecticut	110	99	Kentucky	112	104
New York	117	101	Tennessee	99	98
New Jersey	115	103	Alabama	94	100
Pennsylvania	120	105	Mississippi	100	96
Delaware	113	106	Louisiana	101	100
Maryland	118	105	Texas	128	115
Virginia	110	93	Oklahoma	165	102
West Virginia	158	115	Arkansas	100	98
North Carolina	97	95	Montana	101	106
South Carolina	96	94	Wyoming	104	96
Georgia	87	92	Colorado	129	101
Florida	99	98	New Mexico	96	100
Ohio	105	99	Arizona	91	108
Indiana	107	96	Utah	112	100
Illinois	113	99	Nevada	100	128
Michigan	99	97	Idaho	97	105
Wisconsin	114	104	Washington	100	105
Minnesota	138	110	Oregon	113	113
Iowa	140	112	California	95	97

In the statement above the September 1 condition figures are used for oats, spring wheat and barley; the yields per acre, as reported on October 1 have overrun somewhat the yields indicated by the condition figures, which would tend to increase the above figures for some of the important oats, barley and spring wheat states, as Illinois, Minnesota, Iowa, North and South Dakota and Nebraska.

(Continued from page 763)

the market always responds with more or less accuracy to fluctuations in that grade, the curves are not concentric:

Year	Price
1894	\$0.64½ to \$0.73
1895	.70 to .81½
1896	.71 to .85
1897	.79½ to .89
1898	.82 to 1.06
1899	.91 to 1.10
1900	.83 to 1.11½
1901	.76 to .95
1902	.66 to .92
1903	.78 to 1.13
1904	.89 to 1.32
1905	1.13 to 1.35
1906	1.16 to 1.28
1907	.69 to 1.24
1908	.65 to 1.30
1909	1.13 to 2.15
1910	1.16 to 2.90
1911	.90 to 1.67

It will be noted from the foregoing that between 1894 and 1904 the average price ran around 90 cents and that from 1904, when the automobile began to exert some influence, the price rose to an average of $1.05 a pound during the next 5 years. In 1909 it bulged up to $1.64 on an average, and in the following year reached a general average of $2.02. The maximum price quoted is set at $2.90 because the real top of the market, 20 cents higher, was for only a certain grade of up-river and only held for a short time. The sharp decline since 1910 is the result of response to economic influences embodied in the universal law of supply and demand.

Improving Body Finish

Mechanical Improvements on the Modern Car Demand a Correspondingly Artistic Appearance—Use of the Dark Room

French Attain Best Results by Getting Preliminary Coats Worked Down Close and Hard

EARLIER issues of THE AUTOMOBILE have told the conspicuous part which good painting and finishing has played and is playing in making the automobile a beautiful example of craftsmanship.

The motto of the painter spells Improvement, which means that there is no going backward nor no standing still. The car is being improved mechanically and it must continue to be improved artistically.

One improvement connected with the varnishing of the modern motor car is the dark room. This department, adjoining the varnish room, is equipped with shutters and dark curtains. With the vacuum cleaner it can in a short time be made clean. The heating capacity is equal to anywhere from 70 to 100 degrees. It is provided with a system of ventilation through the ceiling which furnishes pure fresh air in a quantity sufficient to assist the drying of the varnish.

It is a room in which the freshly varnished surface set for anywhere from 24 to 48 hours at a temperature of not less than 70 degrees takes on a high, sharp brilliancy quite unattainable in a room flooded with light.

After this deep, high lustre is assured the work is removed to the light room, i. e., a room in which plenty of bright light prevails. Here, too, the varnish, cured and set to a degree of striking lustre, is further dried and its brilliancy given an increased permanence by the light shed upon it.

The basis for the installation of the dark room is founded upon the fact that in the light room there is always a movement of dust atoms. This movement can best be ascertained by looking into a shaft of sunlight penetrating the room. Through this shaft the particles of matter will be found floating in myriads. In the absolutely dark room this dust movement is eliminated, or at any rate more completely eliminated than in the room containing some measure of light. **So far as possible this room during construction should be made dustproof.** Through the use of it clean surfaces and brilliant finish are produced.

Many years ago French chemists established the fact that after a varnish sets up free from dust during the process of which the dark room is the preferred storage quarters, plenty of light, barring direct sunlight, not only increases the brilliancy of the high lustre established in the dark room, but serves to give the varnish a firmness of film and a capacity to respond to all the varied exactions of service which could be obtained under no other circumstances.

This consignment of work to the dark room immediately following the application of the varnish is called in New York, Chicago and other large cities the beauty treatment. It is not precisely a new method of developing varnish lustre, but rather the resurrection of an old-time carriage finishing room practice.

Another practice which the car owner in making a demand for an improved quality of painting and finishing is forcing upon the painter is this, namely, more thorough rough coat surfacing. By this we mean that the priming or first coat and the coats closely following this and including the foundation of roughstuff are to be worked up with greater care and accuracy than has heretofore been the case. This applies to both old and new work. An American paintshop expert lately returned from abroad declares that the painting and finishing of French cars excels not so much by reason of superior color treatment or varnishing, but rather through the painstaking attention given the foundation or surfacing coats of material —the finesse, in fact, lavished upon the many little and at first glance insignificant details of surface building.

Even the first coats are given the greatest possible attention. So carefully is the paint prepared and seasoned and made fine and smooth of consistency that where it is applied and brushed out it has a smoothness and an appearance of good workmanship that it is a pleasure to see. Over this coat a like excellent second coat is put on, brushed out clean and velvety, and when dry the surface is gone over with great care and all defects, etc., puttied.

Above this coat anywhere from five to six coats of roughstuff are put on in as many days. This body of coarse pigment is allowed from 3 to 6 days to cure out and harden, whereupon it is rubbed down to a smooth and level surface with artificial pumicestone, using with the stone a generous supply of water to keep the stone working free and prevent gumming up. This is the practice in vogue in this country, **except that no great attention is paid to getting these coats under the last coat of the roughstuff worked down as close and hard as the French method calls for.**

A vacuum cleaner working by suction forms an ideal cleaner for use in removing dust and dirt from surfaces that have been sandpapered. Practically every atom of dust is licked up with the cleaner. In this way the rubbing of the roughstuff is made much easier and the surface is kept free from things which serve only to give the painter trouble.

Two and three coats of color are now being used in order to establish a density of color over which, in due season, are applied three coats of varnish color, each containing a gradually diminishing quantity of color.

Above these pure and simple varnish color coats two and three coats of so-called clear rubbing varnish is used. **Into this varnish is put a few drops of the body color in order to preserve the integrity of the field color.** These coats are further rubbed with pumicestone flour and water to give the foundation body and stability.

Then, last of all, the surface is carefully washed, cleaned up, touched up if necessary, and flowed with a coat of some elastic finishing varnish.

The drying room or baking oven is another device which promises to materially assist in getting cars through the paintshop quickly and with plenty to admire. In many parts of the country these drying rooms are used in connection with the application of all the varnish coats. **By a little forcing of these plants two and even three coats of varnish may be applied per day. For first class work, however, this practice is not to be commended.**

In subjecting a finishing varnish for several hours to a temperature of say 140 degrees you of course get a very fine and well dried finish, but it is an open question if such a finish will stand up and hold its elegant looks to the same extent that a varnish seasoned under the natural conditions of ordinary varnish room practice will. Nevertheless it is more than likely—indeed it is certain—that **within the next few years the drying room or baking oven will find widespread use.**

In making plans to maintain the car in first class condition it is well at all times to bear in mind the hard service to which the chassis or running parts are exposed. Mud, dust, oil and grease saturate these parts. **To remove these substances requires a cleaning practice which in the very nature of the case must be more or less destructive.** For such parts, then, a varnish is needed and should be used which dries quickly and hard, after the manner of a baked finish, at the same time retaining elasticity sufficient to insure its durable wearing properties. Hoods and fenders should invariably be varnished with an elastic finishing varnish capable of withstanding the constant vibration and the expansion and contraction.

Argument for Correct Mounting of Shackle Springs Suggests a Convenient Graphic Method for Laying Out Spring Suspensions in General—New Planetary Gear from Germany—Safe Children's Cars—Seeing Sparks by X-Rays

FUNCTION of **Auxiliary Springs**—A study of spring and shock absorber action is presented by N. Duaner in *Le Génie Civil* having for its object to show how shackle springs should be used. The properties of an ordinary spring suspension are formulated mathematically and it is shown that the formulas confirm the established theories to the effect that (1) with a given flexibility of the leaf spring or helical spring the oscillations are more rapid the lighter the load and therefore more disagreeable and injurious, (2) that the load and the flexibility should vary inversely, and (3) that an increase in the frictions of a spring suspension always has the effect of reducing the amplitude and duration of oscillation. It is further shown that the dangers of unrestricted oscillation—in the way of breaking springs and catapulting passengers—should be counteracted and that the problem involved in doing so is intricate; so much so that in the artillery, for example, all spring suspension is dispensed with although a mitigation of shocks would be desirable. Shock absorbers under various names are with these facts in view devised for the especial purpose of reducing the amplitude of oscillations while avoiding the effect of increasing their velocity or, in other words, to effect a suspension whose movements are timed as those of a flexible spring and spaced as those of a stiff spring insofar as this may be done. In practice the requirements of these devices are (1) that they shall have no effect on small oscillations, (2) that their action shall be progressive, restraining a large deflection more energetically than a smaller one and (3) that their action shall be of short duration, so as to place the vehicle spring in its position of equilibrium with the static load as quickly as possible, ready to receive a new shock if one should arise.

[Compare herewith the theory that it is the function of auxiliary devices to leave every departure of the vehicle spring from its normal position perfectly free and unrestricted while braking the return of the spring to this normal position so effectually that if possible no oscillation to the other side of the position of equilibrium takes place. The Derihon device, designed on this principle, was described in THE AUTOMOBILE of June 13; another hydraulic device in the issue of June 20.—ED.]

If it is now assumed to be the main function of auxiliary devices to establish a decreasing flexibility in the spring suspension of a vehicle according to the severity of the shock received it becomes interesting to examine the conditions under which they correspond to this requirement. With ordinary springs, whether leaf or coil springs, it cannot be met, since their flexibility is approximately constant, but arrangements may be made for having several sets of ordinary springs enter successively into action as is done in practice by means of overload springs or buffers. Many of the shock absorbers, while unsuitable for sustaining a static load, are perfectly well adapted for establishing a decreasing flexibility and at the same time reducing the duration of oscillations, but in practice they are adjusted to only one load. Neither with a minimum load or with an overload do they leave the small oscillations free. The most interesting devices, because the simplest and most generally used, are the auxiliary springs which are applied as elastic shackles and which may be used with or without shock absorbers and with or without supplementary overload springs. By means of shackle springs it is possible to realize to a certain degree a suspension with variable flexibility, but as they are usually applied this advantage is not obtained. If they may be used to give additional flexibility in all cases when the maximum load is not carried to a suspension which has been designed for the maximum load their utility may be conceded.

[The author here shows by means of two separate diagrams that spring shackles mounted without initial tension are faulty and that those with unlimited action (being a range of flexion equal to that of the leaf spring) cannot serve any other purpose than at best that of correcting the action of a spring which is too stiff for its maximum load, but it would seem to be evident without special argument that an auxiliary spring should fill its framing when supporting its minimum working-load or, in other words, should be under the tension of that load, and also that, if its range is unlimited it must not only be long and cumbersome, but will continue to add its flexibility to that of the leaf spring throughout the range of action of the latter and thus fail to bring about the desired decrease of flexibility for the more severe shocks. However, in the remodeling of a vehicle or in transforming a heavy limousine or a vehicle of other heavy type into an open and lighter car it may be convenient, as noted by the author, to remodel the spring suspension by means of auxiliary springs with a long range of action and with an initial tension corresponding to the reduced weight of the new vehicle body. The smooth, restful spring action which is obtained from a leaf spring of suitable flexibility, because the friction between its leaves tends to moderate its oscillations, can scarcely be obtained by this means, however.—ED.]

A diagram of the spring action is useful to show how the auxiliary springs should be applied. In Fig. 1 the axis Ox represents the varying loads in kilograms, while the deflections of

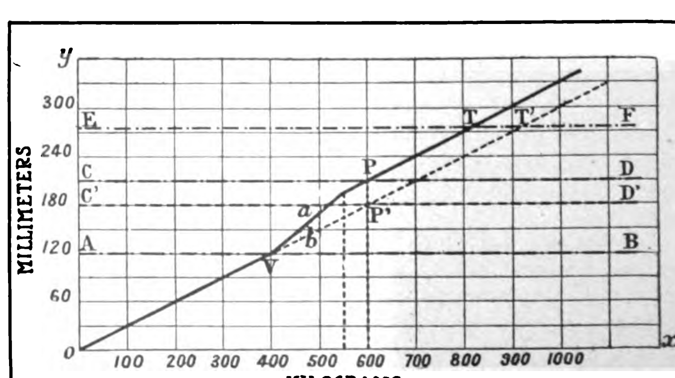


Fig. 1—Diagram of combined leaf-spring and shackle-spring action for minimum load of 400 kg. and maximum static load of 600 kg.

the spring equipment are counted in millimeters on the axis Oy. Assuming a flexibility for the leaf spring of 30 per cent. [which by the convenient French method of notation means that the spring gives a lineal deflection of 30 millimeters for each 100 kilograms of load—Ed.], the line OV is the flexibility curve for the leaf spring since it realizes this proportion of deflections to loads. Assuming further, that the load on the spring is 400 kilograms when the vehicle is empty and that 600 kilograms is intended as the maximum load, the line AB denotes the position of the axle when the vehicle is empty, while C'D' similarly denotes the position of the axle at full load. Usually some form of guard is employed to prevent the chassis from striking the axle, and by this means the range of the spring action under full load may be established at about 100 millimeters, in which case the line EF indicates the position of the chassis 100 millimeters above that of the loaded axle C'D'.

To simplify the consideration of the improved spring action, which may be effected by means of spring shackles of the general type shown in Fig. 2, it may now be supposed that one of these auxiliary springs is attached at each end of the leaf spring, instead of at one end only, as usual in practice, and that in combination they have a flexibility of 20 per cent., each of them 40 per cent. They are supposed to be placed in position under a tension of 400 kilograms, or 200 kilograms for each, and consequently begin to act when this load, which is the minimum load on the whole spring combination, is exceeded either by increased load or by shock.

The diagram now shows the modification of the flexibility curve which is effected if the range of each of the auxiliary springs is limited to 30 millimeters; that is, if an additional load of 150 kilograms, bringing the total load to 550 kilograms, compresses the auxiliary coil spring completely, taking it out of action as a spring. By measuring off 20 millimeters on the vertical corresponding to a load of 500 kilograms from its point of intersection with the flexibility curve of the leaf spring, as from *b* to *a* in the diagram, the direction of the modified curve is obtained and this curve (in this case a straight line) continues to represent the flexibility of the whole spring combination until a load or shock of 550 kilograms is reached, as shown in the diagram by the dotted vertical erected to represent this load. Thereafter, the leaf spring going into unaided action, the flexibility curve returns to what it was—one of 30 per cent.—but the position of the rear axle in relation to the chassis has been changed by the compression of the coiled spring so as to reduce the distance from the axle to the chassis by 30 millimeters, PP' in the diagram, which is equal to the range of the coil spring. The line CD therefore represents the position of the axle at maximum load with auxiliary spring equipment and the point T, corresponding to a shock of 825 kilograms, shows that the range of the spring, or the deflection possible before the chassis strikes the buffer, has been reduced as compared with the maximum shock of 925 kilograms indicated by T' for the leaf spring alone. This drawback to the attachment of auxiliaries may be obviated by means of a shock absorber or an overload spring for the most severe shocks. The advantage of the equipment, on the other hand, is plainly this, that with a leaf spring properly designed for the maximum static load and too stiff for the empty or lightly loaded vehicle a flexibility curve of 50 instead of one of 30 per cent. (French notation) is obtained for just those frequently occurring instances when a full load cannot be taken on board.

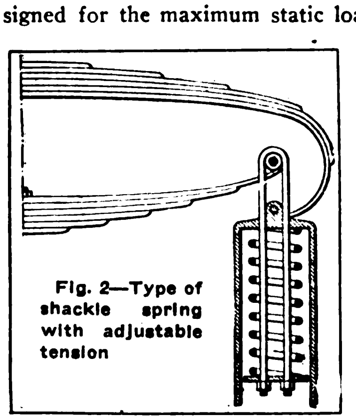

Fig. 2—Type of shackle spring with adjustable tension

If a single auxiliary spring for each leaf spring is used instead of two an examination of the conditions will readily show that, other things equal, a range twice as great and a quadrupled flexibility must of necessity be provided.

By operating at random in the attachment of shackle springs disagreeable surprises are, on the other hand, frequently encountered. The suspension is often unduly weakened; teetering of the vehicle body is produced by road shocks and at stops and starts and the vehicle holds the road badly at turns.—From *Le Génie Civil*, August 31.

—

VISUALIZING the Sparks—As a high tension current is used for producing the light phenomena observed with a Crookes tube, a Parisian inventor reasoned that a Crookes tube or bulb could be made to tell from the outside whether the sparks wanted on the inside of a motor cylinder are properly and regularly produced. He devised an instrument for this purpose which has the appearance of a very thick sharpened lead pencil. The pencil point is an electrode set in hard rubber and leads to a small Crookes bulb inside of the pencil, whose surface is a thin copper jacket serving as the other terminal. At the butt end a non-conductive plug with a hole through the center is inserted in the copper tube. The observer puts his eye to this hole to see what he shall see. The pencil point is to this end placed against any exposed portion of the ignition circuit of the motor, for example the top of the spark-plug, while the observer's hand clasps the copper tube firmly to ground whatever amount of current may be able to pass the Crookes bulb. Now, when the ignition circuit is closed, to produce a spark in the motor, a light becomes visible in the pencil. If the sparks are strong and regular, so are the fluorescences of the bulb. On the other hand, if no light appears the plug is short-circuited, and if the light is irregular and weak the spark is fouled or the porcelain broken.—From *Omnia*, September 21.

—

AUTOMOBILES for Children—At the exposition for "little inventors," which for some years has been held annually in Paris with a view to helping out inventors who are either too impecunious to help themselves or whose productions are so far out of the beaten industrial track that those who would be interested in them might be hard to find, there are this year shown automobiles for children. They have a 3-4 horsepower motor and their speed cannot exceed 4 kilometers per hour, not even on the downgrade. This result is accomplished by having the driving shaft actuate a low-pitch irreversible worm on the rear axle, so that the vehicle cannot push the motor. The clutch and the brakes work on the opposite plan of that followed in ordinary cars; that is, the driver must push a pedal to throw the clutch in and the brakes off. If he does nothing the car stops. This radical precaution against accidents to the children has at times been proposed for cars in general but has met with no favor among adults. It is now relied upon for making cars for young children popular.—From *Omnia*, September 21.

—

PLANETARY Gear of New Type—With a view to the problem, which eventually must be solved, of driving motor vehicles—for example, municipal garbage collection vehicles—very slowly and with many stops and yet economically, it is necessary that the power used should be very small and adapted for working at high speed, so that the vehicle may not be exposed to great stresses and may be built cheaply, and it is at the same time necessary that the power taken from the high-speed shaft of the little motor shall be geared down to a very slow motion of the driving wheels without encumbering the vehicle with a large and power-consuming gear box and without a multiplicity of gear reductions at various points, all of which would mean increased first cost, waste of power, wear of a number of parts and difficulties in keeping the vehicle in good repair.

A similar problem exists with regard to motor boats and turbine boats, where there is need of a simple reducing gear because

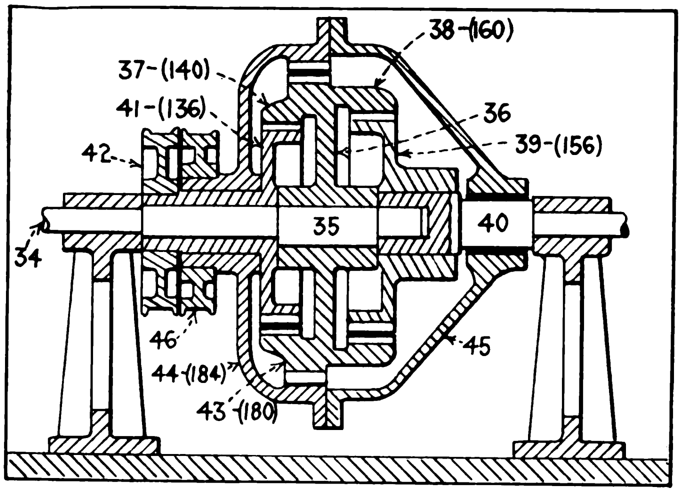

Fig. 3—Section of the Peters planetary gear for large reductions (with the number of teeth on each gear-wheel in parenthesis)

the engine operates to best advantage at high speed and the propeller at a relatively low speed. And in electric transmission the same problem appears again, in some cases reversed, the requirement being then to transform a slow movement into one of very high speed. Compactness in conjunction with great strength and facile operation for starts, stops, reversing and gear changes are in most of these cases of the greatest importance.

Consideration of this long-felt want has led in Germany to the development of a new type of planetary gear of remarkable design and mechanical properties. Fig. 3 shows a section through the driving shaft 34 of this mechanism in the form in which it has been placed in the market for use in automobiles, motor boats and turbines. The driven shaft 40 lies in prolongation of the driving shaft, being bored concentrically to receive it. Direct drive may apparently be obtained by locking together the two brake disks 42 and 46, while leaving them free to turn on the driving shaft, but the German description is silent on this point, and no locking device is shown. The construction, as illustrated, has only one reduction gear and a reverse. For each additional gear desired an additional brake disk and an additional pair of spurwheels would be required, but this complication may not be excessive as it is one of the characteristics of the mechanism that it may be made in very small dimensions and with very small gear teeth, even for the transmission of great power, as at any time at least one-third of all gear teeth are in engagement. [The engagement is not quite complete, however, but depends upon the small difference in the diameters of external spur wheels and the internal gears with which they engage, this difference barely exceeding the height of a gear tooth if great gear reductions are involved. Probably the engagement of a large number of teeth is realized closely enough for purposes of strength, considering that each tooth possesses a certain elasticity whereby great stresses will be distributed, perhaps well within the elastic limit of all the teeth involved. In this respect the use of small, thin teeth may even be of particular merit for the very special construction under consideration.—Ed.]

The middle portion 35 of the driving shaft 34 is formed eccentrically to the rest of the shaft, and on this eccentric portion is mounted the wheel 36, without being keyed, and to it there are secured the internal gear rings 37 and 38 as well as the external gear crown 43. These gears may, of course, be machined directly out of the material of wheel 36, if preferred. The spurwheel 41 is journaled upon shaft 34 and has an extended hub upon the end of which is secured the brake disk 42, by means of which this spurwheel may be held motionless. It is constantly in mesh with internal gear 37. Internal gear 38 is similarly in mesh with the spurwheel 39, and the latter is secured upon the end portion of the driven shaft 40. All driving is thus done through internal gear 38 and spurwheel 39, the forward as well as the reverse. On direct driving they are locked together. The casing within which the whole mechanism runs in oil is composed of two parts, 44 and 45, which are bolted together. During forward driving this casing revolves idly; held motionless it effects the reverse. Part 44 is formed with an internal gear constantly in mesh with spur gear 43 on wheel 36 and has an extended hub which is journaled upon the hub of spurwheel 41 and carries a brake disk 46, by means of which it may be held motionless. Part 45 is formed with a packed bearing in which the driven shaft 40 turns.

To operate the reduction gear, the brake 42 and thereby the spurwheel 41 are prevented from turning. The driving shaft, when revolving, rocks the wheel 36 around by means of the eccentric portion 35, and by each revolution of the shaft all the teeth of the stationary spurwheel 41 are thereby successively engaged by the teeth of the internal gear 37. But if the number of teeth in the internal gear is 140 while the spurwheel 41 has only 136 (as exemplified in Fig. 3, where the supposed number of gear teeth is indicated in parenthesis together with the reference numeral of each gear wheel), the internal gear 37 is compelled to turn backward an angle corresponding to four teeth for each revolution of the driving shaft, since it is only 136 teeth which corresponds to a full circle of engagement with the stationary spurwheel. The internal gear 38, being in one piece with 37, consequently also turns back the same angle and thereby drives spurwheel 39 forward, turning the shaft 40 in the same direction of rotation as that of the driving shaft. The speed reduction produced with the here supposed dimensions is now 140 to 4 in the first pair of gears and, as the internal gear 38 has 160 teeth while spurwheel 39 has 156, the total reduction is obtained by multiplying 140/4 by 156/160, giving 34 1-8 to 1. [In the German report it is figured as 312 to 1 on the supposition that the action between the last pair of gears is of the same nature as the action of the first pair, but this supposition seems to be at fault, since the four-teeth movement of gear 37, and consequently an equal angle of movement for gear 38, is an actual rotation which takes effect upon the gear 39 in the manner of ordinary gears; that is, in the proportion of the two gear diameters or that of their numbers of gear teeth, which is the same thing.—Ed.]

The reverse is effected by immobilizing the casing by means of brake 46. This forces spurwheel 43, with its 180 teeth, four teeth ahead for each revolution of the driving shaft, as for each revolution it must be engaged successively with all of the 184 teeth of internal gear 44 in the casing, on exactly the same principle which applied to forward driving excepting that wheel 36 is now turned in the opposite direction, which is the same direction as that of the driving shaft. And consequently internal gear 38 now turns the driven shaft in the reverse direction, as desired.

If more than one reduction gear are wanted, the wheel 36 is extended on the motor side to make room for more internal gears of smaller diameters and with corresponding spurwheels and brake disks, and the hubs of the latter must be journaled upon the driving shaft inside of the hub sleeves for the large spurwheel 37 and for the casing. It is stated that reductions of as low as 2 to 1 may be obtained, but it seems that in that case the gear teeth must be made relatively large or the eccentricity of portion 35 of the driving shaft more pronounced. With a rapid rotary motion of the wheel 36, as would occur with small speed reductions, the one-sided weight distribution, which would lead to vibrations, may, of course, be obviated by counterweighting this member.—From *Der Motorwagen*, September 20.

IMPROVED Goggles—In the German market goggles in which the glasses are made of quartz are now offered as a great improvement over the ordinary kind. The optics are more perfectly colorless and transparent and so much harder that their polished surfaces never get dulled or scratched by the action of dust and grit.—From *Allgemeine Automobil-Zeitung*, No. 38. [Quartz also sheds water better than glass and clouds up less readily.—Ed.]

Patrol Bodies Specified

New York Police Department Issues Requirements as to Design and Dimensions—Also States Purchase Conditions—Cars to Seat Fourteen

THE Police Department of the City of New York has taken sufficient interest in the motor police patrol to issue special specification for bodies for them so that all orders for future motor patrols will have to meet the specifications decided upon and reproduced herewith.

According to the commissioner of the Police Department, "the department is not essentially interested in the design of the chassis or engine, but the body design as specified meets all of the needs of the department and the dimensions are satisfactory in every respect."

When purchasing these chassis the department does so under competitive contract and the manufacturer is bonded to maintain the apparatus in first-class working condition to the satisfaction of the department for a period of 2 years under penalty of revocation of the contract for failure to do so. In the contract an equitable provision is made for accident or other damage due to neglect or carelessness on the part of the department; and the chassis manufacturer has not any recourse if his chassis is out of service for 50 or more days in each year of the two protected by the bond.

In size the new vehicle shows an increase over its horse-drawn predecessor, having a total seating capacity of fourteen, the inside accommodating twelve persons, while the driver's seat provides room for two.

In the particular wagon in question the body is mounted on the Garford service chassis with a wheelbase of 145 inches. The rear wheels are of dual type. The tires on all of the wheels are 36 by 4 1-2 inches.

With regard to the body construction this is entirely in wood, ash slats forming the two interior seats arranged lengthwise, with frame and panelling of the same wood at the side, front and back to a height of 34 inches from the floor. The entire space between the upper edge of the seat back and the roof is fitted with heavy wire mesh, as are also the front and back. Provision is made to cover the whole of this mesh area with a series of roll-up blinds of black waterproof material, having transparent celluloid insertions to admit light. These blinds are arranged outside the screens.

The two seats are hinged at the rear edge to permit of their being swung up out of the way as indicated in the drawing so that in case of emergency the floor space can be utilized to accommodate an ambulance bed. A stretcher, forming part of the regular equipment is carried under one of the seats.

When used for ambulance purposes the attendants stand on the rear step, a vertical handrail being provided at each side of the door.

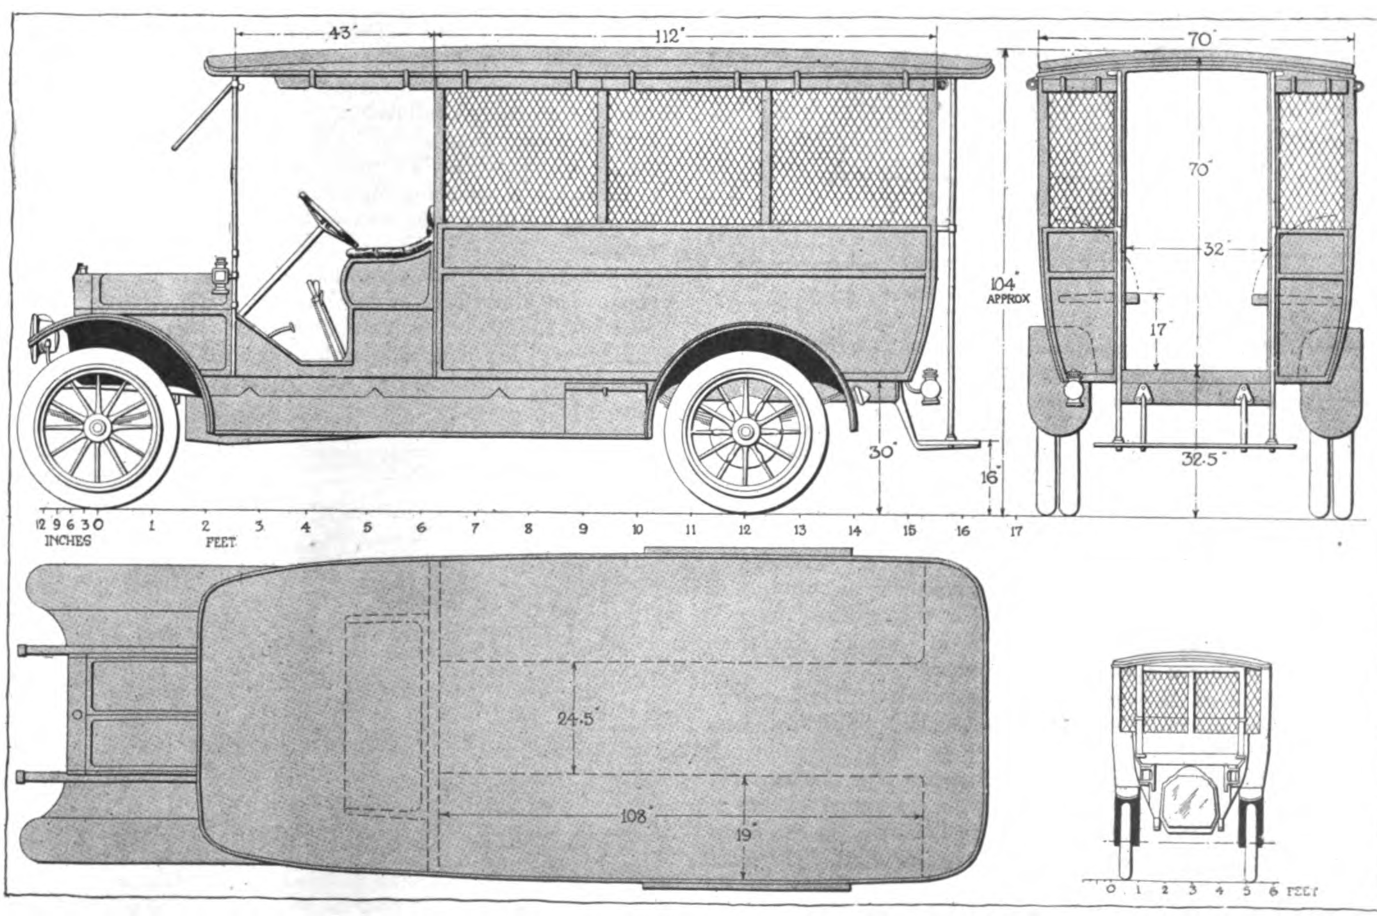
Heavy linoleum laid with brass strip binding covers the floor space, a wide tread plate being placed at the door. Emphasis may be placed here on the necessity of a clean sanitary result throughout all the interior finish, the flooring in particular.

Illumination of the interior is effected by means of a large center dome light covered with a wire mesh guard.

The only upholstery on the vehicle is on the front seat and this is of black leather tufted on both cushion and seat back. The gasoline tank is beneath this seat.

All the leading dimensions appear on the drawing, but the following particulars may be added: The weight of the complete motor-vehicle is approximately 4,200 pounds, the body itself weighing 1,000 pounds.

The speed capability of the machine is in the neighborhood of 50 miles per hour.



Style and dimensions of body specified by the Police Department of the City of New York for automobile patrols

Foreign Constructions Designs and Practices

Silent Couplings for Magneto Drive Now Insisted on by European Makers—Wood Pin Used by Many

General Observations on Shop Methods in Many of the Foreign Factories

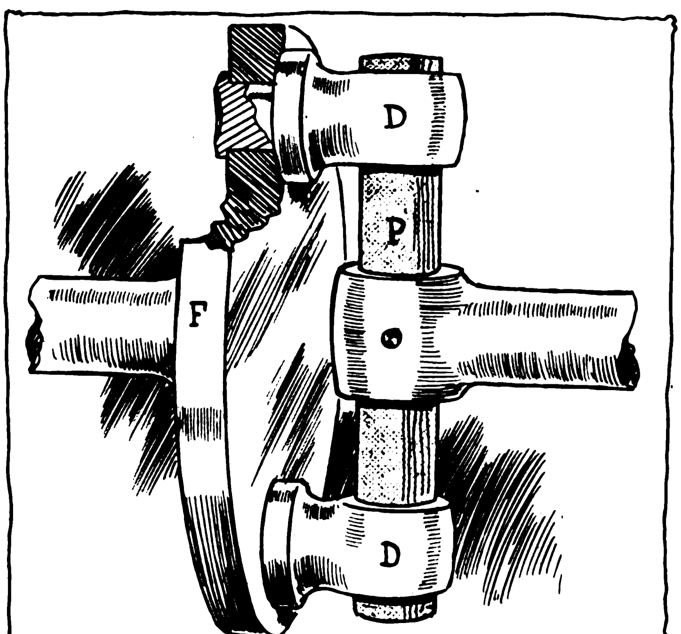


Fig. 1—Wood-pin coupling in magneto drive

EVERY effort for flexibility is recognized as a step in the direction of thwarting depreciation, but every joint has the voice of thirty little noise-devils at concert pitch. Designers in Europe think so and they govern themselves accordingly. It is no easy matter to master noise. It is equally difficult to fix the pitch and timbre of sounds that the combined murmur will not arouse the ire of the automobilist. Some makers of automobiles have the faculty of silencing noises temporarily! They put paint in the joints at every point in the chassis! Other makers destroy interchangeability by hand-fitting parts. No two automobiles are alike in this process and it is the owner who pays the bill by difficulty in replacing worn parts, and cost consequent upon such replacements.

The makers of the best types of automobiles are still looking for ways and means of eliminating noises without abating flexibility of mechanism. Fig. 1 shows a principle which is now regarded favorably. A wooden pin P is placed in the universal joint to transmit the torque. It may be of round section or rectangular and is carried in two dogs D carried in the flange F, which in turn is electrically welded to its shaft. The wood affords ample strength and gives the desired silence to the coupling.

Sprags for Truck Use Prove Necessary When Brakes Fail To Have Adequate Holding Power

Sidelights on Steel Tires, Spring Supports in France and Germany

On a street in Vienna recently a heavily loaded truck had its motion arrested by a guardian of the law in a garb that looked over-military. The street happened to be tilted in the direction of the slowly receding sun at 3 p. m. The driver of the truck accepted orders without so much as a murmur, but the truck, apparently not appreciating the interruption, began to back down the steep incline. The driver applied the brakes; they failed to hold. The situation looked serious for a moment due to the presence of a funeral procession with the head of the line perhaps a dozen yards behind the truck, but the driver instead of struggling with the brakes, tripped the sprag. The pavement was of granite block. How the sprag ever got a grip is a wonder, but it did take a hold and after stuttering a little it brought the big bulk to a standstill.

The sprag looked a little different and just a little better than the average of its kind. The illustration here offered of the sprag is clear enough to establish the fact that the angle of the sprag is favorable to good results. The hinged end is 18 inches from the ground. The bracket, in addition to being substantially made, is so placed under the side frame of the truck that the struggle of the sprag is to lift the load on the truck during the operation of snubbing the motion when the truck backs up. The sprag is short and stocky. The end is fashioned like a pinch-bar.

In America the truck sprag has not been used to any great extent. There are three or four American cities where hills are sufficiently large to warrant the use of the sprag. The sprag, in addition to being a good guardian against accident, is useful to the new driver to hold the truck on a hill while getting started again.

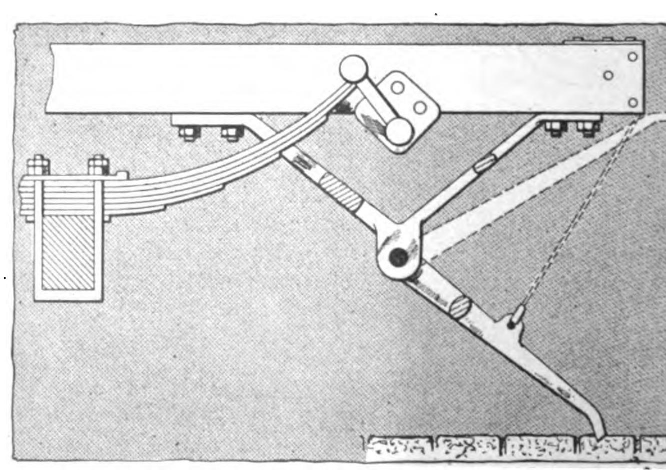

Fig. 2—Sprag design used on truck in Vienna

French Use Steel Tires on Heavy Trucks

Over 90 per cent. of all the trucks seen in actual service in Paris are fitted with steel bands instead of rubber tires. Some of the tires of steel are made narrow enough to give a high pressure of contact with the pavement to aid traction. In a few makes the steel bands are serrated. In one make observed the steel tires were wide, about 11 inches, but, instead of being plain, were drilled full of holes, each hole being about 3-4 inch in diameter. The holes soon filled almost flush with street dirt, but enough of a depression remained at the orifice of each hole to bite the pavement. Fig. 3 illustrates this tire with its steel band B and its series of three rows of circumferential holes extending three-quarters through the band.

The grade of steel used, by the way, in truck tires in France is far better than the ordinary steel obtainable on the open market. The metalloids in the steel are about one-quarter of the value as given in American specifications.

German System To Insure Good Springs

The remarkable easy-riding qualities of German railway cars make it desirable to look for the reason. The springs are responsible. They are flat springs, relatively wide, and sufficient plates are used, considering width, to make the section rectangular. In a word, a spring with a 5-inch width of plates has sufficient plates to bring the other dimensions up to 5 inches also. The same rule holds for other sizes of plates. The springs are made of long span with very little bow or camber.

The novel point is in the detail of suspension, Fig. 4, is that the mechanism used for linking the spring to its hanger H at each end is composed of a pair of links of a chain. They are sprung into grooves in the pins. One pin P1 passes through the eye of the spring, and the other pin P2 passes through the bore of the suspender. The links L1 and L2 are held in place by the pressure of the spring. This plan might be refined for use in automobile trucks.

Boards for French Truck Wheels

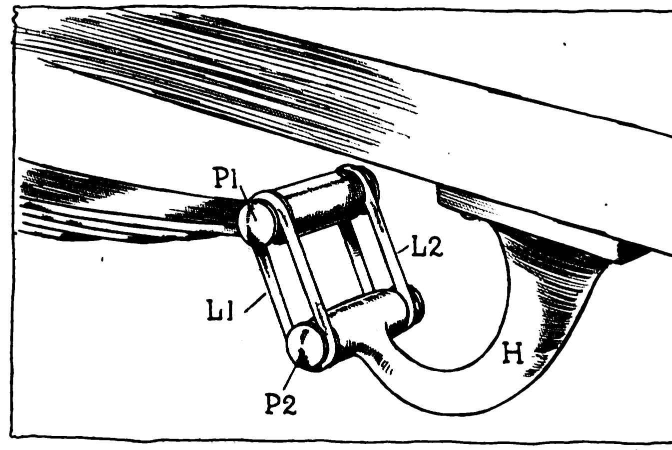

Fig. 4—German method of spring mounting to insure tight clips

It is extremely difficult to get hickory wood large enough to do for spokes of truck wheels of the larger sizes in Europe. Even southern white oak is scarce enough to influence the price and deliveries are uncertain. Steel wheels are being used, but they do not afford the peculiar elastic qualities of wood and the life of solid rubber tires suffers accordingly. Fig. 5 of a wood wheel seems to answer several questions. The wheel is built up—laminate of thin oak boards are glued together. The grain is alternated at right angles. After the wood is built up, it is turned round and the bore is made for the hub H. The metal work, consisting of hub and brake drum, is so made as to clamp the wood. The steel band B, 36 by 8 by 1 1-2 inches in diameter, face and thickness, respectively, is shrunk on. The wood in thin boards is easy to get. The wheel is strong and with careful workmanship there is not any danger of water getting between the boards and destroying the material. Two series of cross bolts hold the boards together, one series at the hub, the other at the periphery.

Welding—European Methods and Uses

English Engineer Describes Various Welding Methods—Tinman's Solder, Brazing Solder, Liquid Brazing, Autogenous Welding, Electric Welding and Slow-Heat Processes

Paper read by Alexander E. Tucker, F. E. C., before the Institute of Metals, London, Eng., September 26, 1912.

THE methods in practical use for joining metals may be divided in the order of their importance as follows:

1. *By metallic cements,* such as tinman's or brazing solder, which have to be brought to the plastic or liquid state, and whose constituents should be capable of alloying perfectly with the metals to be joined.

2. *By autogenous fusing,* in which the two parts are heated and liquid metal of the same character run round the mass, or the parts are heated to fusing point, and the surfaces worked together by pressure or hammering.

3. *By the use of a cementing metal under pressure,* generally that of a rolling-mill, and at ordinary or only slightly raised temperatures.

In respect to the first method, it is obvious that the fusion point of the solder must be lower than that of the articles to be joined, and the higher the melting point the stronger the solder; it follows that it is desirable that such solder or brazing spelter should be used whenever possible, the melting point of which is only a few degrees less than that of the metals to be joined. The solder should also have, if possible, the same characteristics, such as malleability, color and hardness.

Tinman's Solder—In the use of this care should be especially taken to avoid the presence of zinc, and in certain cases even a trace of zinc is especially prejudicial; it thickens the solder, and probably on account of its liability to oxidation forms a superficial scum which the ordinary spirits of salt is incapable of dissolving. If the presence of zinc be suspected, the addition of a few drops of acid will help greatly. Antimony is frequently present in tinman's solder—this, by forming a cement of higher tensile strength, may, under special conditions, make a joint of greater strength. In the use of solder, either soft solder or brazing solder, it is clearly the correct method to raise the work to the highest temperature that the solder and the work will stand, because under such conditions the penetration of the solder into the surfaces to be joined will be better, and further, the soldering medium may then be squeezed out to the maximum from between the surfaces by suitable means, and hence the requirement can be met, that the thinner the layer of cementing material and the closer the surfaces are together, the stronger the join. Additional strength, because of the additional intimacy effected, may be given to the work by rubbing the surfaces carrying the liquid solder together; in the same way it is always well to rub the soldering iron, when possible, over the work when it is used, the wetting of the surfaces is then more perfect, and no stripping of the solder is possible when this rubbing is done. In order to obtain a lower melting point in tin solder bismuth, and sometimes cadmium, is added.

The conditions here are very different from those in the case of the brazing of brass and copper, because it happens that all the metals employed in brazing and tinman's solders destroy the character of the steel they are intended to join if they are heated sufficiently with the steel, while they have no corresponding injurious effect when used for brass or copper work.

Soft Solder Advantages

When soft solder is used the thin gauge tubing is not so likely to be spoiled by deteriorating action on the steel, or by being oxidized at the heat necessary for brazing; and, further, on account of the greater liquidity of the soft solder, it will, when properly applied, sink into the small annular space between the lugs, etc., and the tubes more completely than can be expected with the more viscous flux and brazing solder. The reasons that soft solder is not used for such work are, firstly, because the heat of the enameling stoves makes its use risky; and secondly, popular prejudice—a soft soldered frame sounding badly to the untechnical layman.

It is a common habit of workmen and amateurs who have soft soldering to do, to depend on the ordinary bit, when they might use a bunsen or blowpipe. These, in many cases, would heat the work more generally than is possible with the bit, and would allow of the penetration of the solder into the surfaces, and the subsequent squeezing out of the excess of solder.

On the other hand, many forms of soldering bits are now in use, in which a bunsen burner connected with a light flexible tube is employed to heat the bit, and the flame can be conveniently made to heat the work as well. This form of soldering iron has many advantages. One of the best fluxes I have found for ordinary soldering can be easily made by macerating flux skimmings from galvanizing pots with weak hydrochloric acid. On filtering, the solution is ready for use and is an ideal flux, because of the chloride of ammonia present with the chloride of zinc. No iron or lead is dissolved if the acid added is not in excess. Solder is often used in the form of granules or strips of various sizes, and in this form is very convenient for routine work. In the case of spectacle frames or other light articles a large amount of work can be prepared, on each of which a small piece of solder, either in the form of a granule or a strip, is placed with flux on the part to be joined. The articles are then put in a tray, which is afterwards taken to a muffle working at a convenient heat, or in same cases it is sufficient to put the work on a metal plate, heated by a gas flame or even a spirit-lamp. Brass tubes are often made by bending the strip through dies and fixing a wire of suitable composition in the overlap with borax, or the borax may be mixed with finely granulated spelter. On passing the work through a furnace to raise it to a red heat, the spelter runs perfectly and a good join is made. The flux is then dissolved off the work, and the tubes are finished by drawing through dies with or without a mandrel.

Silver Solder Is Best

The best brazing, if it may be properly so termed, is done with silver solder; thus the blading used in turbines is all fixed with silver solder. It is, of course, of the utmost importance that the small pieces used in the construction of turbine motors shall be immovably fixed and cemented in position, on account of the heat and centrifugal strain to which they are subjected. Various silver alloys are used, but they are generally about 60 of silver, 23 of copper and 17 of zinc, the flux used being borax, or borax and carbonate of soda. Such a mixture is remarkably liquid when in the molten state, and on this account penetrates interstices which ordinary brazing spelter would fail to fill.

Brazing Solder—The composition of ordinary brazing solder ranges within wide limits; the analyses of samples I have examined show a variation from 61 to 33 of copper, and 39 to 67 of zinc. The tin may vary from nil to 14 per cent., and the lead from nil to as much as 3 per cent. Any of such metals may be and are used for brazing, in accordance with the character and requirements of the work to be done. The higher the percentage of copper the higher the melting point, and the higher the percentage of tin the lighter the color. We thus have a very large series of alloys available for very varied requirements. The presence of other metals when in small amounts is often of no consequence in the brazing of brass or copper, though obviously in all cases it is very desirable in important work, such as the brazing of high-pressure steam pipes or where great strength is required, that the composition of the brazing metal shall approach as closely as possible to that of the metal to be joined, as only under such conditions can the maximum strength of the joint be obtained, and it is the non-observance of these conditions which has led to disaster. The skill of the workman is often limited to the fluxing of the solder, and seldom extends to an appreciation of its composition.

When, however, we come to brazing iron and steel the importance of purity is very much greater, and I have found the presence of tin in brazing solder intended for bicycle frames to be very injurious. The explanation is probably to be found in the extraordinary deleterious effect of tin on iron and steel. It is well known that **a very small amount of tin scrap, if allowed to get into a bath of molten steel, will make it very red short, and when brazing solder containing as little as 0.5 per cent. of tin is used for brazing bicycle frames I have found that the joints are very unsatisfactory and unsafe.**

An ingenious method of making a brazed joint is by connecting the two parts to be joined with the terminals of a suitable dynamo. On account of the local resistance the two parts become heated, and if suitable brass wire is wrapped round the tube, in the case of a cycle frame, and the whole surrounded with a reducing gas, such as hydrogen or coal gas, a very perfect joint is obtained without any borax or other fluxing medium.

The reducing gas under such conditions will insure the absence of any oxide of iron or other metal used, and no previous cleaning is required. Such a method of joining has the great advantage that there is no borax to remove from the joint. On account of its great hardness this removal of borax is a serious matter, and much money has been spent on experiments to remove it by pickling and other methods. It is best removed by sand-blasting, the whole frame being so treated, leaving an excellent surface, on account of its roughness, for enameling.

Advantages of Liquid Brazing

Liquid Brazing—Several patents have been taken out for details of apparatus in which a bath of brazing spelter has been kept liquid. The parts to be joined are dipped in the molten metal, the metal being prevented from adhering to the parts that have not to be brazed by applying a coating of blacking to them. **The advantage of this method consists in the fact that less metal is used in making the joint, as so little is lost in applying it, and also the heat is general on the joint instead of being local,** and I have no doubt that on routine work the consumption of gas for heating is less than when blowpipes are use, and of course blast is not required.

A modification of brazing is the use of copper in the form of sheet or wire. Under the Simpson patents tools are thus made in which the cutting part is a small piece of high-speed or other steel, while the shank is mild steel or iron. In making, say, a lathe tool by this process, a bar of square mild steel is taken and a channel planed or milled out on it in which a suitable square piece of high-speed steel fits. The two or three sides being clean, strips of copper are fitted in with a special flux, and the whole highly heated to the fusing point of the copper. After welding, the compound tool is cleaned up and treated for hardening and tempering in the ordinary way. There are some features about this process of building up tools which seem to have considerable merit. First, if ordinary brazing were used, the hardening of many tools implies such a temperature as would often destroy an ordinary brazed point. The zinc would possibly be volatilized, which is not the case when copper alone is used, the temperature of fusion of the copper being so much higher. Secondly, it is conceivable that the weld would be considerably stronger than with an alloy of zinc, because while copper alloys to a considerable extent with iron, the same cannot be said of zinc, which therefore, under the circumstances, would become a deteriorating element. Thirdly, the saving of expensive material, such as alloy steel, must be considerable in the case of heavy machine tools, as only a small portion of metal is ever in actual use. In a sense, therefore, the shank becomes a tool-holder without the disadvantages of the latter in respect to unsteadiness, difficulty of setting, etc. The process lends itself to many interesting applications; thus milling cutters may be made having a core of mild steel instead of tool steel. Hardening and tempering such cutters is a source of much difficulty and loss through distortion and cracking, and if the compound cutters can be so produced the possible economy should be considerable. There is no doubt as to the perfection of the joint, as I have seen pieces of steel joined by the process, which, on splitting, did not part at the weld.

A process has been invented by F. Pich, Berlin, for the hard brazing of cast iron in a smith's hearth. **The patent consists in the decarburization during brazing of the cast iron surfaces to be united, and in bringing at the same time the molten brass solder into close contact with the cast iron surfaces which are decarburized, but without exposure to the air.** For the decarburization of the surfaces copper oxide is used, which is mixed with borax, as a flux, until it has the consistency of a paste. This is applied to the surfaces to be joined, which must first be carefully cleaned. The cast iron pieces are then firmly tied together with wire and heated. The borax first melts, protecting the surfaces from oxidation, and taking up any oxide that may be still clinging to them. It also precludes the attacking of the copper oxide by the oxygen of the air. As the heating proceeds the copper oxide fuses and gives up to the now red-hot surfaces its oxygen, which combines with the graphite of the cast iron forming carbon monoxide and dioxide, while the metallic copper is set free in a very finely divided state. This alloys with the brass solder as it melts when strewn on, and the new alloy combines with the decarburized iron of the surfaces which it is desired to join.

Specimens of cast iron united by this method were prepared and subjected to tensile and breaking tests, and the summary of all the results shows that when the brazing of cast iron pieces is carefully performed according to the details given by Pich, the strength of the pieces so joined is virtually equal to that of the solid material.

Aluminum Soldering Difficulties

As is well known, numerous patents have been taken out, and numerous mysterious mixtures have been advertised for the so-called soldering of aluminum. In nearly every case the result is that, while fairly satisfactory for a short time, the join failed after a time, varying from a few days to some months. One of the most severe tests to which such joins in aluminum can be subjected is that of warm steam. Joins which look well and are apparently mechanically strong, fail rapidly when submitted to this test. In all soldering, it is obvious that the flux used must efficiently clean the surfaces of the metals to be joined, otherwise no alloying of the solder used with the surfaces is possible. In the case of aluminum very few materials adapted for such fluxes are available, the requirement being that they shall absorb oxide of aluminum. Another detail of importance is the great heat conducting of the metal. **A consideration of the results obtained with all the so-called solders of aluminum shows that the metal is so susceptible to electrical action and oxidation that the use of any metal in which aluminum itself does not preponderate is hopeless. The best results have invariably been obtained when the solder was of the same composition as the material to be joined.** This condition involves the principle of autogenous soldering, which will be subsequently dealt with.

The best flux used is a mixture of alkaline aluminum chloride, with the addition of fluorides, such as potassium fluoride or calcium fluoride. When these are mixed in suitable proportions and damped with alcohol, and heated on a strip of aluminum, the surface of the metal is cleaned perfectly. It therefore follows that if two surfaces of aluminum are so cleaned, and an alloy containing a high percentage of aluminum, with such addition of other melted metal as will reduce its melting point slightly below that of pure aluminum, applied with the flux named, that a very satisfactory join will be obtained. The heat such as from a spirit-lamp or bunsen burner must, however, be applied from below the work. I have seen such joins made over a spirit-lamp which stood every test, including that of the steam test.

Difficulties arise from the presence of high percentages of aluminum in alloys in connection with soft soldering. These may be largely overcome by coating them electrically with copper. The following directions for soft soldering their alloys, containing from 5 to 10 per cent. of aluminum, have been issued by an electric smelting company:

"Cleanse well from dirt and grease. Then place the part to be soldered in a strong solution of sulphate of copper, and place in the bath a rod of soft iron, touching the parts to be joined. After a while a copper-like surface will be seen on the metal; remove from the bath, rinse quite clean and brighten the surfaces. The surfaces can then be tinned in the ordinary way."

Autogenous Welding System

The second method of joining metals referred to is that of autogenous fusion or running liquid metal of similar character on to the surfaces to be joined, and in its simplest form is very old. It is illustrated in the case of repairing broken rolls and in lead-burning. It has been a practice for the broken surfaces of rolls to be cut away to give room for the new metal. The whole roll is then heated and hottest possible metal run into the intervening space, with suitable headers to allow of escaping gases.

The application of autogenous welding by acetylene, hydrogen, benzol, petrol or other hydrocarbon vapor to commercial purposes has extended enormously during the past few years, and constructions and work are now possible by the use of such methods, which could not be carried out by any other means; thus repair work of ferrous and non-ferrous metals is now done in every town of importance, and tubes of all sizes are made on a very large scale. For branch pipe construction the process is quite unrivaled. For high-pressure steam pipes the joints after screwing are often welded up, and metal vessels, instead of being made with folded joints, are now made with the blowpipe more cheaply and far more efficiently. Lead burning forms an excellent practice for acetylene welding, as it is fusion welding in the simplest form. It is usually carried out with hydrogen and air, and if the workman can make a good joint with and without a stick of lead, it is a very easy step for him to advance to making one of aluminum or steel, or any metal.

In practice a proportion of four volumes of acetylene to five of oxygen gives much better results than the theoretical two volumes of acetylene to five of oxygen. So important is this detail that blowpipes are now generally constructed to consistently maintain a reducing flame. Such a blowpipe is that of the Drager-Greishiem. In this blowpipe the automatic reducing valves on the cylinders are fitted with gauges, which, instead of being graduated to pressure, are marked with the thickness of the material to be welded. All, therefore, that is necessary is for the workman to adjust the springs on both regulators, so that both gases indicate the same thickness. A simple mechanical mixture is arranged on the blowpipe, making the whole apparatus very practical and convenient.

Characteristic Oxy-Acetylene Flame

A characteristic of the oxy-acetylene flame is that it indicates the correct mixture, for when the acetylene is in excess a small green cap appears over the inner cone of the flame. On reducing the oxygen there is a point at which the cap disappears. The right mixture is just at this point, and the effect is so distinct that when working with acetylene the workman has no excuse for not getting the right proportion.

If temperature were the only consideration, the oxy-acetylene process would be used in all cases in the working of thin metal, but its use requires much greater skill than the lower heat of the oxy-hydrogen flame. Then again, when a fixed acetylene generator is not available, the risk and danger of a portable generator is considerable, and in such cases for oxy-acetylene welding dissolved acetylene only should be used. On the other hand, this is very expensive and the apparatus is heavy, and it therefore follows that the oxy-hydrogen method with its complete portability is very often to be preferred, because hydrogen can be obtained in the usual bottles, and thus forms very convenient plant.

In welding metals other than iron, not only the melting point but the heat conductivity of the metal must be considered. Thus copper, with its high conductivity and its low melting point, can hardly be worked with the oxy-hydrogen flame. Indeed, for the same section as iron it requires a much more powerful oxy-acetylene flame. Brass, bronze, and indeed any metal, may be autogenously welded, and many require much less care than that for aluminium.

The conditions of success which apply to all welding with acetylene or other hydrocarbons are: 1, the use of pure gases; 2, the use of a metal rod of approximately the same composition as that of the work to be joined; 3, the thorough fusion of the inside surfaces before the additional metal is applied; 4, cleanliness of the parts, and when desirable the use of suitable dioxidizing and fluxing powders, such as charcoal and borax, and lastly, the use of a blowpipe capable of complete control in respect to size of flame and proportion of mixture. With extended experience in the autogenous joining of non-ferrous metals, it is to be expected that this method will replace ordinary brazing where quality of work is of the first importance.

It should be noticed that in consequence of the highly local heating action of acetylene, contraction strains are likely to be set up, which may be more serious than those occasioned when the whole work is heated and welded up in the smith's fire in the ordinary way. In the case of cast iron it is very desirable that such strains should be avoided by making the weld first and then reheating the mass as much as possible, and cooling slowly. With respect to steel, it has been repeatedly shown that an acetylene or electric weld should not be hammered while the weld is being made. It is well known that cracks are likely to be made by hammering the metal at a black heat, a temperature occurring quite close to the point of fusion. The work, therefore, should be allowed to cool slowly and then raised to a high temperature in the ordinary way and not by the blowpipe; the weld can in this way be much improved both in shape and strength. A good fusion weld very seldom breaks at the point of welding—indicating, therefore, that this point is stronger than the neighboring metal. I believe this is the explanation of the paradoxical effect noticed with fusion welding, that thick sections never give as high a tensile strength as thin.

Thus 1-6-inch 3 per cent. nicked steel strips gave 97 per cent. strength, 1-4-inch gave 90 per cent., while 1-inch bars broke at 60 per cent. to 70 per cent., with the fracture clear of the weld every time. Again, welded 1-2-inch copper rods drawn down to 3-8 inch in the ordinary way gave regularly 95 to 97 per cent. as compared with the original drawn rod.

Reducing Power of Aluminum

There is an interesting series of processes for the autogenous joining of metals, most of which are patented, which depend on the reducing power of aluminium. Anyone who has seen the application of the Goldschmidt or Thermit process to the joining of the ends of street car rails can hardly fail to be struck by its extreme beauty and simplicity. We have here a small steel foundry not much larger than a silk hat, from which the metal pours in a perfectly liquid state.

As showing the great heat obtainable when aluminium powder is used for welding, it may be mentioned that if a wrought-iron plate 1 inch thick is placed under the crucible, the liquid metal when tapped will burn a hole straight through it, leaving a fairly smooth edge. Experiments show that the heat of the molten metal approaches 3,000 degrees C., the temperature of the Siemens furnace being about 1600 degrees C.

This Thermit process has been applied for the repair of ship's sternposts and other large fractures, and means have been adopted for heating up the fracture surfaces to the proper temperature before pouring in the cementing iron without damaging the clean metallic surfaces. This is done by building up the moulding-box around the fracture in such a way that it may act as a flue or chimney to an outside fire worked with a compressed air-blast, which dries the sand mould and heats up the metal very rapidly. The presence of even a small trace of moisture in the mould gives rise to blowholes in the thermite iron, hence great care must be taken that the mould is as dry as possible. The repair of the sternpost of the German Lloyd steamer *Friedrich der Grosse* was effected in this way.

The only doubtful point in the process is the possible formation of internal fractures or cracks, but it is stated that in all the tests of the results fracture has invariably taken place outside the welding region.

It is very probable that in point of strength most thermite welds are superior to those electrically made, because the volume of heat is greater if not more intense, and, again, there is less risk of the original surfaces being burnt or oxidized. The thermite metal can also be adjusted to carry reducing media, which would quite eliminate any oxidizing influences.

Some Methods of Electric Welding

A third system of autogenous welding is the electric, of which two methods are in use, namely, arc welding and resistance welding.

Arc welding is applied for repairing breakages and filling up flaws in castings, while resistance welding is rapidly being adopted for the working up of metal articles, and it is common to find electric plant in operation for sheet-iron working. Two forms of machines are on the market for this purpose, one known as the spot-welding machine and another for butt-welding. In the spot-welding machine the sheets are joined at spots instead of rivets, hence the name. The electrodes are shaped in accordance with the work to be done, and are put on to the work by pressure effected by a foot-lever, and the current, which is automatically switched on at low potential, welds the parts together at that point. After removing the foot-lever the work can be moved along for welding at a new point.

The entire process is so rapid that an unskilled workman is able to make 1,000 welds per hour on plain sheets, while in the same time an experienced hand could hardly put together a quarter as many rivets. The up-and-down movement of the upper electrode may be performed automatically by means of a motor electrically worked. The electrode then falls and rises at regular adjustable intervals, and the workman only has to move the pieces of work.

This machine may also be applied on water-tight welding. In this case the travel of the work takes place slowly, so that the points of welding lie close together, forming an unbroken seam. The edges of the sheets are completely softened and are pressed together seamlessly. Similarly, when the sheets are not too thick, and irregular shaped sections do not have to be dealt with, the spot-welding machine makes a very satisfactory weld. Thus wheel rims for cycles and motor cars can be joined perfectly by its means, while the advantage of this system for welding handles on covers, or for welding rings on cooking utensils, etc., are conspicuous. In the same way half-stampings, such as kettle spouts, make up to a very satisfactory job with seamless welding.

The last system of joining metals to which I desire to direct attention is the one in which the surfaces are not melted, but only slightly heated.

During recent years the manufacture of compound metals, such as nickel and steel, copper and steel, aluminum and copper, has become of great practical importance, and many beautiful articles are now sold for domestic purposes. The nickel steel, copper steel or nickeled zinc sheets may be obviously produced electrolytically and afterwards rolled down to gauge, allowance being of course made for the ductility of the softer metal. But another method has lately been introduced in which sheets of different metals may be joined perfectly.

The manufacture of aluminium copper sheets illustrates the process, and further is interesting from a metallurgical standpoint. One method with which I am familiar is as follows: **The copper sheet is pickled and cleaned. Aluminium powder is then brushed on by machinery, or by rubbing the surfaces with brushes or rollers of aluminum wire. A sheet of cleaned aluminium is then placed on such a surface, the two are heated and passed through rolls. The union is perfect, and hence the compound sheet may be subjected to stamping, spinning, etc., without any trace of lamination.**

In the same way copper and steel, or almost any two or any number of sheets of different metals, may be compounded. The aluminium acts as a metallic adhesive. While rolling such sheets the top surfaces are often kept oiled to retard oxidation and to obtain better finish.

A second method of making a compound sheet of different metals is that in which an oxide or sulphide of a metal which will alloy with both of the two sheets is taken and mixed with aluminium powder, and the mixture laid evenly between them. The whole is then heated to the fluxing point of the mixture and then rolled, and as the two sheets to be joined receive the full heat of the furnace in which the work is placed, it will be understood that the alloying of the metal from the mixture with the two surfaces of the sheets is very complete.

In another method, where still more heat is used, for the production of compound plate, say, of aluminium and copper, copper or other wire gauze is placed between the sheets and the interstices filled as before with aluminium powder and flux, consisting of alkaline, chloride and fluoride.

On heating the whole and rolling, the surfaces unite as before described, and probably more perfectly, because the gauze retains the flux better during the heating, and so does its work better, and is afterwards squeezed out by the rolls, while in addition there would also be the knitting or dowelling action of the gauze during rolling, which would further tend to hold the sheets together.

The use of such wire gauze would seem to be applicable to certain conditions of brazing, especially when the greatest care is necessary to produce the highest quality of work, such, for instance, as the brazing of steam pipes, to which allusion has already been made.

Factors in Carburetion of Various Automobile Fuels

From a paper by E. J. Stoddard in the September Bulletin of the Society of Automobile Engineers.

I WILL try to digest the important facts relating to carburetion as follows:

By way of laying a foundation for and illustrating what I wish to present for your consideration let us look at our materials in the first place. For our purpose we may say that air is a mixture of

	Oxygen.	Nitrogen.
By volume........	20.81 per cent.	79.19 per cent.
By weight........	23.10 per cent.	76.90 per cent.

We may neglect the other gases as inconsiderable.

But we think the amount of water vapor in the air does make a difference. It has been said that the engine acts quite differently on a rainy day. If the temperature is 62 degrees a cubic foot of air should weigh .0761 and a cubic foot of saturated air .075581. That is, the air is a little over .7 of a per cent. heavier than the mixture. I have figured that only .0119, or a little over 1 per cent. of the air would be displaced. Even with the air at 82 degrees it would be only $\frac{.0733}{.072267} = 1.014 +$, a little over one and four-tenths per cent. heavier than the saturated mixture, and only about .0236 + or a little over 2 per cent. of the air would be displaced.

Gasoline is said to be a mixture of the lighter distillates of petroleum, mainly of the methane or paraffine series, having the general chemical formula C_nH_{2n+c}. The following table contains data relative to some of the liquid distillates from Pennsylvania petroleum, compiled from the books of Redwood and Crew on petroleum.

Name	Chemical Formula	Per Cent. of Carbon	Per Cent. Hydrogen	Boiling Point, F.	Specific Gravity	Vapor Density	
		12064	10365	87			
Pentane ..	C_5H_{12}	83.20	16.71	100	.64	2.538	22430
		9984	60156	143			
Hexane ...	C_6H_{14}	83.68	16.32	158	.676	3.053	159996 air
				165			
Heptane ..	C_7H_{16}	83.90	16.04	210	.718	3.547	
		12204	9820	247			
Octane ...	C_8H_{18}	84.17	15.83	255	.737	3.992	22025
Nonane ...	C_9H_{20}			303	.756	4.8	14792 air

If we assume that the liquid is a mixture of the above-named substances, there is still a good deal of room for variation in the proportions. If we take the heat value of its constituent parts, and my figures are correct, pentane would have a value of 22,430 B.T.U. per pound and octane 22,025, not a very great difference. When we come to figure the quantity of air required, there is apparently a greater difference, 16 pounds of air being required for pentane and 14.79 for octane.

It is desirable in testing carbureters to draw a charge of the mixture from the intake pipe and find out of what it is composed. I have tried taking a given volume of mixture and dissolving out the hydrocarbon with olive oil, noting the diminution of volume. I have not had satisfactory results so far, perhaps because of imperfect apparatus. I believe the chemists use alcohol to dissolve out the heavy hydrocarbons, afterward removing the alcohol vapor with water (Hempel's Gas Analysis). If gasoline vapor is three times as heavy as air, we may estimate roughly the relative volumes of gasoline vapor and air in a 16 to 1 mixture as $\frac{13 \times 1/3}{46 \times 13} = \frac{1}{16 \times 3} = \frac{1}{48}$, or about 2 per cent. Now I think we would want to distinguish a one-tenth variation anyway, and therefore with this method, if it worked perfectly, we would want to distinguish clearly a variation of one-fifth per cent., a fineness of measurement that makes me distrust it. I have thought we might measure the degree of saturation thus: Suppose we put some pure air into a receptacle, introduce sufficient gasoline to saturate it with vapor, and note that the water column rises and stops at 60 inches of water. We know that this is the saturation pressure. Now if we put into a similar vessel the mixture to be estimated and then introduce gasoline as before and note that the water column now rises to 44 degrees instead of 60 we would think that the mixture was $\frac{60 - 44}{60} = \frac{4}{15}$ saturated. It would seem that this was somewhat more hopeful. Now suppose we take a cubic foot of gas from the intake pipe during the operation of the engine. This might weigh .0777 pound and one-sixteenth of it would be about .00486 of a pound. If we take 22,000 B.T.U. as the heat value of gasoline, $22{,}000 \times .00486 = 106.92$ B.T.U., a value that could be easily read to a small fraction of a per cent. Even a much smaller quantity of mixture might be taken. For instance, a gallon, 231 cubic inches, which would contain about 14 B.T.U., is sufficiently large to measure. It seems to me that by this latter method the quantity of gasoline in any mixture may be measured with sufficient accuracy.

Multiple Series Connection Makes Batteries Last; What Is the Cause of Tire Wear? Best Flux for Cast Iron; How to Put on Hub Caps; Curing Squeaky Springs; What to Do When Entering Canada

Shape of Typical Curve

EDITOR THE AUTOMOBILE:—What should be the shape of a horsepower curve? Recently in some brake tests that I made upon a motor upon which I have been experimenting I got a series of results which gave me almost a straight line. Is this correct? Will THE AUTOMOBILE publish a curve which has been reached through actual brake tests on a well-known motor. Such a curve should show at what speed the power falls off when the revolutions per minute get too high.

New York City. INVESTIGATOR.

—This curve for the Packard 48 motor is reproduced at Fig. 1. It shows how the power increases on a straight line practically from 300 to 1,200 revolutions per minute. That means that the power is increasing directly at the motor speed. Above this point the power does not increase as rapidly as does the motor speed and the curve begins to flatten until at 1,700 revolutions per minute it starts to fall off.

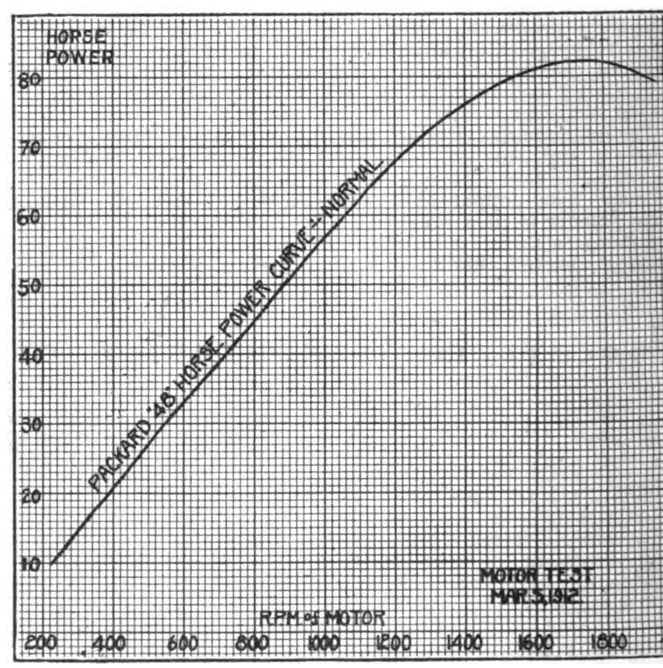

Fig. 1—Characteristic horsepower curve as result of tests on Packard 48 motor

Recommends Multiple-Series

Editor THE AUTOMOBILE:—On page 587 of your September 19 issue you answered a question of C. W. Cauthorn's relative to the number of dry cells to use with a Splitdorf coil. As you have stated, this coil is designed to operate on about 6 volts and therefore not more than five new cells connected in series should be used on it.

I would like to call Mr. Cauthorn's attention to a characteristic of dry cells, which, if taken advantage of, will save him a good deal of money in renewals. It is generally known that if a dry battery is allowed to stand idle for a few hours after hard usage it will "pick up" or "recuperate" to nearly the same current value that it had before. The reason for this is purely chemical—certain reactions within the cell requiring some time to take place. If this time is not allowed, much of the possible service from the battery will be lost. Upon this depends the fact that two sets of cells connected in multiple, as shown in Fig. 5, will give considerably more than twice the service of one set, and three sets so connected, as shown in Fig. 5, will last nearly five times as long as one set.

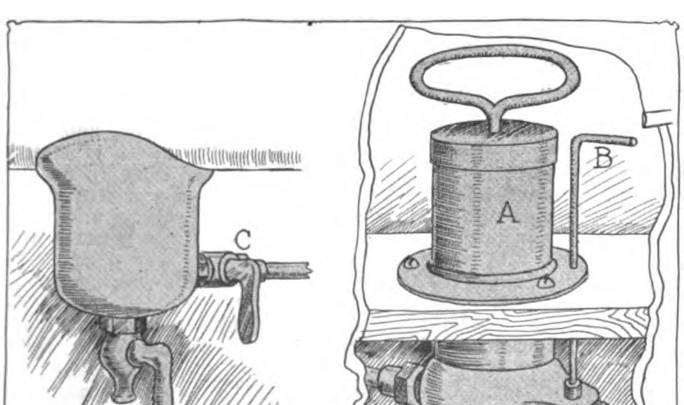

Fig. 2—Oil shut off cocks and auxiliary hand oil pump on the Hudson car

Actual service tests have shown that if one set of five cells in series will run a car approximately 500 miles, two such sets connected in multiple will operate it 1,400 miles and three sets 2,400 miles.

It is obvious then that besides being more reliable, considerable money can be saved by using three sets of cells connected in series-multiple at a time. The gain with four sets is not so marked, and the additional space they take up argues against the use of more than three sets. These can be bought packed in a case with the connections made and spaces filled with waterproofing compound, if desired, at a slightly advanced price.

Cleveland, O. V. A. CLARKE.

What Causes Tires to Wear

Editor THE AUTOMOBILE:—Has any one ever compiled data on the causes of tire casing wear? I think it would be interesting to know why the average tire wears out. Is it due to the negligence of the owner or is it due to the normal wear and tear encountered on an ordinary tour? Can THE AUTOMOBILE tell us anything regarding this important and interesting matter?

New York City. OSCAR TROUTE.

—There have been several independent investigations regarding this matter made by different authorities, but the results have varied considerably owing to the difficulties in obtaining detailed information from a large number of individual casings and tubes. Taking an average of some compilations which have been recently made, it is shown that the percentage of tires that had passed their period of usefulness through normal wear was not in excess of forty for the casings or tubes. This means that 60 per cent. of all the tires have been consigned to the scrap heap because they have suffered neglect or damages which need not have been encountered in ordinary work. It is a fact that many casings have deteriorated to a marked extent before they are ever placed upon the rim. This may be either due to the carelessness of the dealer who handled the tire or the owner who did not take the pains to keep the rubber away from the destructive effects of heat, light, oil and all other agencies to which the tire is susceptible. Taking casing trouble as being the greatest bother to automobilists that now exists, the following percentage table was given some time ago by an authority:

Normal wear	36.0 per cent.
Perforation by nails, etc.	26.5 " "
Under inflation	16.5 " "
Small cuts	5.8 " "
Layers destroyed	5.6 " "
Damaged by oil	3.8 " "
Rusty and dented rims	3.8 " "
Sudden breaking	1.5 " "
Shifting on rim	1.5 " "

This does not take into consideration the factor of overload which the experts of the tire factories state is responsible for the early demise of so many of the tires. That this factor of overloading is important is evidenced by the fact that many of the tire companies have brought out oversize models which fit the regular rims, thus giving a tire that will wear for a considerably longer period. In buying the oversize tires the consumer should use judgment as they are higher in first cost and should the tires he is using on his car regularly be of sufficient size to give satisfaction it is to be doubted if the oversize will make up in additional mileage for the added cost. Many cars of late have been overtired by their makers for the purpose of cutting down on tire trouble for the consumer. On these cars there is no necessity of buying larger tires.

The way for the owner to get the best service from his tires is to weigh the car and then get tires which are recommended by the tire makers for a car of that weight. The practice of weighing the front and rear axle loads is a good one for then the

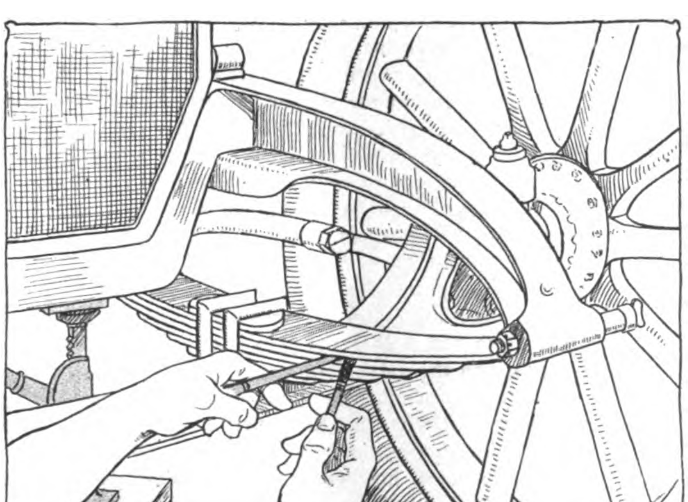

Fig. 4—Showing how to get at the springs of a car to insert graphite

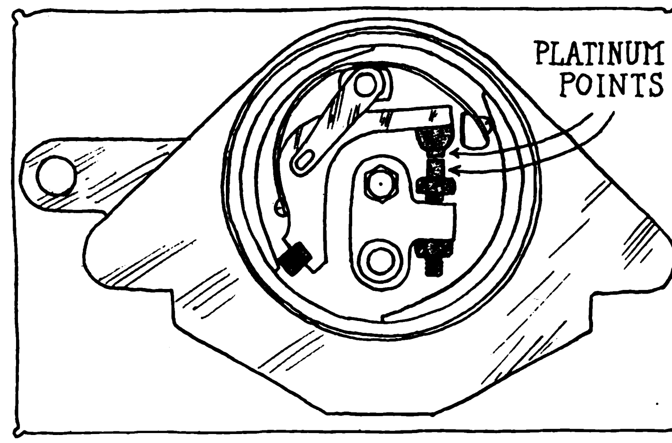

Fig. 3—Breaker box mechanism of the Bosch, showing adjustment points

tire could be designed for the axle carrying the greater load. The practice of taking tires of different sizes for the front and rear axles is not a good one because it is then necessary to carry two complete sets of extra casings when on a tour. Besides the trouble with the carrying of the extra shoes there would be the necessity of having spare tubes for each tire.

Easy Way to Break Hub Caps

Editor THE AUTOMOBILE:—The hub caps on my Hupmobile runabout cost 80 cents apiece. They are light stampings and are very easily breakable by any method whatsoever, but I believe I have discovered the quickest way to run up a fairly good-sized bill for these caps alone. Twice I have attempted to tighten a cap which had a habit of dropping off, so that it would not do so again. I found that owing to the peculiar shape of the cap I could get a good grip on it with my wrench by slipping the latter over the outside flange Fig. 7. A very small amount of pressure exerted this way was sufficient to break the cap. In putting on these caps one should be particular to put the wrench on the nut part of the cap and tighten at this point. Too great a pressure applied at the nut will shear this off also, it must be remembered, and when a hub cap exhibits a tendency to drop off frequently, it should be examined to see if there is not some end thrust upon it which develops this tendency.

New York City. HUPOWNER.

Requirements for Entering Canada

Editor THE AUTOMOBILE:—I am going to take a short trip into Canada. Is it necessary to pay duty when going through the lines or can I make some agreement as to the fact that I am to return within a period of a month bringing the car with me, of course. I know that some such arrangement can be made while taking a car abroad and I would like to know if I am compelled to spend a large sum of money for customs duty in going into Canada.

Malone, N. Y. CHESTER WILKE.

—Automobiles not manufactured in Canada may be admitted under bond or cash deposit for a period of 90 days. This is provided that the owner accompanies the machine and that the owner is not engaged in any automobile business or that the car is not to be used in any business undertaking of any nature during the time that it is within the country. The requirements are as follows:

(a) The automobile shall be reported on form approved in duplicate at the Customs House at the port of importation where a careful examination and appraisal will be made.

(b) An invoice showing the selling price of the automobile will be produced (when practicable) as an aid to the customs collector in determining the value of the machine.

(c) Upon receiving a cash deposit of $25 and a bond executed in Canada in approved form for double the estimated duties,

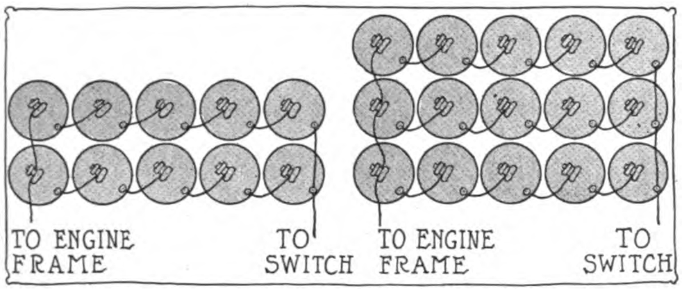

Fig. 5—Battery sets recommended for long endurance by Cleveland man

conditional for the due exportation of the automobile covered thereby within three months of the date of the bond, the collector may grant a permit accordingly (to be indorsed on the duplicate report) for the use of the automobile in Canada for touring purposes.

(d) The bond shall be signed by the importer and by two residents of Canada; or by the importer and by a resident of Canada who has deposited with the collector of the port of entry the general guarantee of an incorporated guarantee company authorized to do business in Canada, and which guarantee is then available as a security in the case; provided:

That the special bond of an incorporated guarantee company authorized to do business in Canada may also be accepted, in a proved form, instead of the bond first herein mentioned, and that the cash deposit of $25 may be dispensed with in any case covered by a special or general guarantee bond.

(e) The bond shall be filed by the collector with the tourist report attached, and the duplicate report shall be handed to the tourist with permit and receipt for deposit indorsed thereon.

(f) The deposit shall be subject to refund by the collector upon return of the permit with proof of the exportation of the automobile within three months of the date of bond. In default of the exportation of the automobile with proof of such exportation to the satisfaction of the collector within three months of the date of importation, the deposit is to be entered as customs duty and the provisions of the bond enforced.

Registration, license tags, temporary importation papers, bonds, etc., can be secured in advance through the Secretary's office so that the tourist will have everything necessary to pass into and tour Canada before he leaves his home city.

Tourists who wish to enter Canada for a period of not more than 7 days can obtain a Customs card at the Customs House at the port of entry and thus avoid the usual Customs formalities. They are not permitted to go beyond the limits of the port of entry and must return to the United States through the same port and must be known to the Customs Collector.

Some Points on Hudson Car

Editor THE AUTOMOBILE:—I am driving a Hudson 33 roadster, 1912, which I have recently purchased second-hand. There are several points about the car which are not clear to me and as I am not a mechanic I do not wish to take anything apart that I am apt to have trouble in putting together again. Among the details with which I am not familiar are the adjustments which are necessary from time to time in the valve and ignition systems and also the lubricating system which includes the use of an auxiliary hand pump which I believe is for the purpose of helping out the regular supply of oil should the car be subjected to hard work as in climbing steep, long hills, etc. Would you please touch a few of the salient features which it is necessary that I understand and tell me how the systems I have mentioned above operate?

New York City. NEW OWNER.

—The adjustments which have to be made on a motor car, even from time to time, are very few. Many cars are run throughout a season without a single change of adjustment in any parts. Regarding your specific inquiries regarding the changes of adjustment necessary in the valve and ignition system, however, a few remarks may be made which will tend to show when these changes are necessary and how to make them.

Taking the valves first, there are two points of wear on a valve. One is where the valve stem strikes the tappet, or, in other words, the bottom of the valve stem and the other is at the point where the valve seats. The wear at these two points is due to different causes, one being the wear of service, while the other is what may be called a deliberate wear. The bottom of the valve stem wears slowly because it continually strikes the tappet in performing the functions for which it is designed. When traveling at high speed, especially if the cam is somewhat square in shape, the movement of the stem takes the form of a sharp blow. In spite of the hard and excellent metal of which the stem is made it will wear away under these repeated blows in the same way that granite will wear away beneath

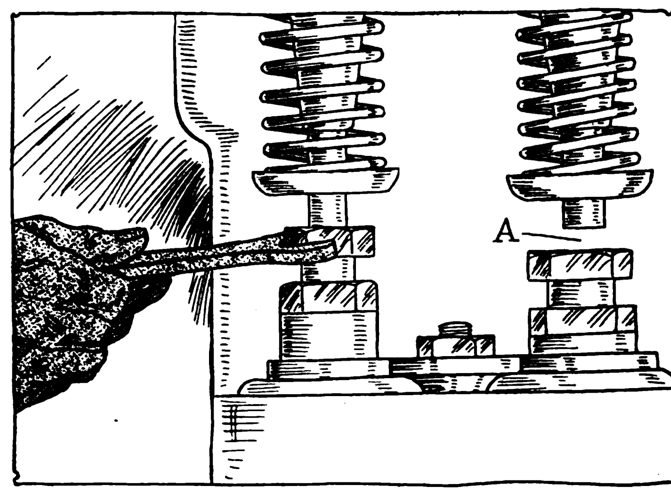

Fig. 6—Method of adjusting tappets on the Hudson 33 roadster model

the repeated drops of water. The wear on the valve at the seat is caused by an entirely different matter. After being subjected to the heat of combustion for a long time the metal around the flame-swept seat will become pitted. It is necessary to grind away the metal of the valve in doing this. Both these sources of wear will tend to equalize each other. As the valves and seat are ground away it will allow the stem to drop lower, while the wear on the stem itself will shorten this part of the valve and equalize the drop due to grinding. Should grinding be necessary very freqnently, or should the stem not wear away rapidly on account of the exceptionally hard metal of which it is composed, the valve stems will need adjustment. On nearly every car made this adjustment is regulated by a nut on the tappet or valve stem. As shown in Fig. 6, a turn of the wrench will make the required adjustment. The motor should be turned over until the valve is entirely down. This can be determined by watching the bottom of the valve stem while the crank is slowly turned until the space at A, Fig. 6, on the valve to be adjusted, is a maximum. The nut should then be turned until the space at A is about .002 inch, or the thickness of a sheet of paper. This adjustment must be made when the motor is cold as the space is only left for the purpose of allowing the valve stem to have room to expand when the motor becomes warm. A good way to test the space is to slip a sheet of thin paper in the space between the tappet and the valve stem and then tighten up on the nut until the paper is just pinched. Then back off the nut a little so it is possible to just withdraw the paper.

Regarding the ignition system, the less you touch it the better. There is one point, however, in the breaker box mechanism that will perhaps require adjustment occasionally. This is shown in Fig. 3, which is a sketch of the breaker box. You will notice on the flywheel of your car a line drawn on the rim with the letters MAG. marked upon it. When this point on the flywheel registers with the pointer on the rear of the motor, the two platinum points should be separating. If the points break too late or too soon, loosen the setscrew on the magneto coupling and turn the magneto shaft by hand until the points are just breaking when the flywheel is in the proper position. Be sure that the order of the spark-plugs is not disarranged. The Hudson car fires in the order 1, 3, 4, 2 counting from the front end of the motor. Batteries are used for starting and these should be tested with a voltmeter occasionally. Six volts is required to adequately meet the needs of the ignition system, while below 4 volts the latter will become inoperative. Another point in regard to the platinum points in the breaker box which should receive attention every few months is that the magneto key furnished with the car should be used to gauge the distance between the points. These should separate the distance indicated by this gauge. As will be noted in the illustration the contact points are fitted with means of adjustment.

The oiling system of the car is not hard to understand. The chain oil supply is carried in the crankcase, while the auxiliary supply is in the tank mounted on the rear of the roadster. The oil is pumped from the crankcase reservoir to a trough-like formation in the crankcase casting. One of these troughs is located beneath each cylinder and as the connecting-rod reaches the bottom of the stroke it plunges into the trough and throws the oil up into the cylinder lubricating them thoroughly besides also sending a spray of oil to the camshaft and other bearings. The pump of which you speak sends an extra supply of oil to the crankcase reservoir to take care of a shortage in supply here or to replenish the supply in case more oil is necessary for heavy work, such as hill-climbing. A is the body of the pump in Fig.

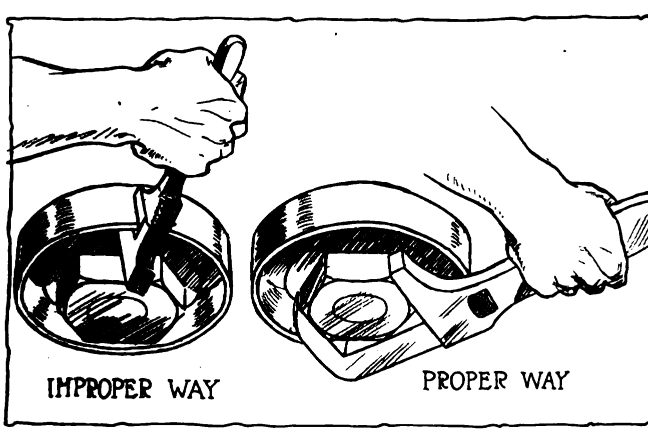

Fig. 7—Two ways of tightening a hub cap with a wrench—bad and good

2 and it is actuated by the handle above it. B is the handle for shutting off the supply from the oil tank. On the bottom of the tank at D is the oil drain, while C is the shut-off from the oil tank to the hand pump.

New Gear Causes Bad Knock

Editor THE AUTOMOBILE:—After having an exhaust cam gear put in my machine, a very bad knock has developed which cannot be stopped by advancing or retarding the spark. While the engine is running idle there is a slight knock which stops instantly if pressure is applied to the shaft which runs magneto and water pump. This seems to indicate that there is play somewhere in timing gears. The exhaust cam gear meshes with magneto gear. When pulling the slightest load there is a very bad knocking and also loss of power. Do you think by putting a new magneto gear in, that it will stop knocking? Or, if not, can you help me in any way to remedy my difficulties?

Garthersburg, Mo. D. B. DIAMOND.

—The trouble is that the two gears do not mesh correctly. The teeth of the two gears should come together as in Fig. 8 while they are probably in bad mesh as shown in Fig. 8. Every time the motor speed changes the two gears which do not properly mesh together come against each other with a sharp impact that is sufficient to produce a heavy rapping sound. This is also the cause of the loss of power. The valve timing will change at every change in relationship between the gear on the end of the crankshaft and the new camshaft gear. At times the valves will not close soon enough and a loss of compression will ensue. A new timing gear that fits will cure the trouble by taking up the lost motion.

Eliminating Bad Spring Squeak

Editor THE AUTOMOBILE:—For some time the left front spring on my car has troubled me by keeping up a continued squeak when traveling over any road that is not as smooth as new asphalt. I have kept the shackles well greased and yet that does not seem to do any good as the noise still continues. I have come to the conclusion that the noise comes from between the leaves of the spring and would like to know if this could possibly be so and how to cure it if it is.

New Haven, Conn. WALTER AMES.

—The answer to the question is simply lubrication. Good graphite, which can be secured from any of the supply houses, is the best lubricant for springs because it will stay in place and will not require renewal for a long time. The method of inserting the graphite between the leaves will be seen in Fig. 4. The car is jacked up under the front member of the frame so that all the weight is taken from the springs. The leaves will then have a tendency to separate. A chisel or any solid piece of metal may be used to still further pry the leaves apart while they are painted with the graphite. If the spring seems to be in rather bad condition it would be well to take it off the clips and remove all but the top leaf, which is held in place by the shackles. These can be left undisturbed as it will be simple to clean this leaf while it is still on the car. Clean the leaves thoroughly with kerosene and then wipe them dry. After this coat them quickly with graphite and reassemble them. This will take the squeak out of the spring and leave it in perfect condition. The springs require this treatment once a season and if it is done in the fall, before the car is put up for the winter, the squeaks which often issue from the springs when the car is taken out for the next summer's season will not be present.

Soldering Cast Iron

Editor THE AUTOMOBILE:—Would you please tell me if there is a flux that is suitable for use with cast iron, such as the waterjacket of a cylinder?

Masontown, Pa. CLARENCE KOEPFE.

—If you have a cracked waterjacket it would be much more satisfactory to take this to a welding company and have a good, careful job done upon it than to trust to simple soldering work. A flux which can be used to solder the waterjacket of a cast-iron cylinder is cut muriatic acid, that is, hydrochloric acid in which zinc has been dissolved. For tinning, use four parts of sal ammoniac solution in water and one part of hot hydrochloric acid. The action can be improved somewhat by sprinkling a little powdered sal ammoniac on the surface. When the welding is done by the oxy-acetylene process a good clean job that you rely upon will result. With the soldering job the chances are that it will start to leak again in a short time.

Kline Adds Coupé Model

Special Body Construction Permits of Change from Coupé to Torpedo Roadster in 10 Minutes

Adoption of Ever-Ready Starter and Rushmore Lighting Dynamo Mark 1913 Line

FOR 1913 the Kline Motor Car Corporation, York, Pa., manufactures the same four chassis models as in 1912, a few minor changes having been made in the way of refinements in promoting silence and ease of mechanical operation and comfort in riding. The company has also brought out a special body type which is practically new to the trade. This is a combination coupé and roadster, the coupé top being removable in 10 minutes, leaving a fully finished torpedo runabout of distinctive appearance. This body is furnished on the 4-40, 6-50 or 6-60 chassis as specified, the only model of the line for which it is not adaptable being the 4-30. These four chassis models constitute Series A, the Kline company having adopted the series system of manufacture for the coming season.

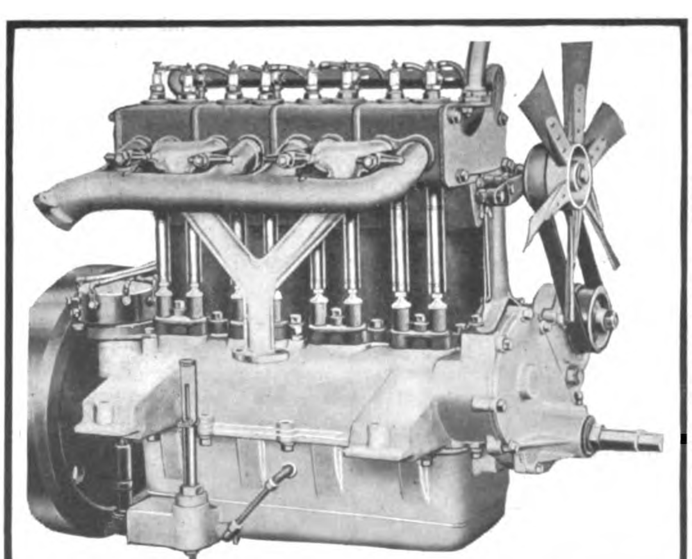

Fig. 2—Right side of Kline 4-30 motor, showing inclosed valves

Mechanical changes in the Klinekars for the coming season are all of a minor nature, the new features being: The inclosing of both intake and exhaust valves on all motors; the addition of a Rushmore dynamo for the electric lighting system; the adoption of the Ever-Ready automatic mechanical self-starter; some slight modifications in the sizes of springs and tires; use of cork inserts in the clutch instead of the spring inserts used in the 1912 cars; an auxiliary spring construction has also been adopted in the rear. A three-way valve connecting the gasoline tank with the motor is regulated from the side of the car, rendering it unnecessary to crawl under the car to change the fuel connections. All bodies for the 1913 cars are made in the Kline shops and are of combination steel and wood instead of semi-aluminum as in 1912.

There is no change in any of the motors outside of inclosing the valves. The horsepower of all motors is calculated at 1,200 revolutions per minute, except the 4-30, which is taken at 1,100 revolutions per minute. Motor dimensions are as follows:

Model	Cylinders	Bore	Stroke	Horsepower
6-60	6	4¼	5½	60
6-50	6	4 3/32	5	50
4-40	4	4¼	5½	40
4-30	4	4	4½	30

All motors are of the long-stroke, water-cooled type and are constructed on the separable enbloc system, the cylinders being cast single or double according to the model. Thus any cylinder may be removed and placed without disturbing the others, it being possible to take out the cylinders separately without removing the motor from the car, or the cylinders can be removed as a unit. Should a new cylinder be needed, it can be substituted for the old one without disturbing the rest of the motor. As each cylinder is opened at either end it is possible to obtain a large and well-gauged water space between the cylinder and the waterjacket. After the cylinders have been machined, they are bolted together with six bolts made of special stock designed to resist rust. These run through the waterjackets, the joints being made tight by paper gaskets, while the opening between the cylinders does away with water pipe connections between them, as shown in the accompanying illustrations of the various motors. As the water enters at the forward end of the motor and is forced out of the waterjacket of the rear cylinder up to the radiator, moreover, this has the advantage of insuring free circulation. Contrary to the general application of the enbloc system, there is a bearing between each cylinder, designed to render the motor much more rigid while at the same time making the construction lighter. Thus, in the case of the six-cylinder motors, the crankshaft has seven bearings, and in the four-cylinder motors five crankshaft bearings are used.

Close-grained gray iron of specially selected stock is used for the cylinders of all motors. Before the cylinders are assembled in the motors, each one is subjected to a severe hydraulic test under high pressure. If any defects or flaws exist this will bring them out and the cylinder is rejected.

In grinding the cylinders, every precaution possible is observed to insure accuracy in every case. Specially selected gray iron is also used for pistons and piston rings. These are ground on both diameters and sides and are made interchangeable. Piston pins are of large diameter and are hardened and ground. Positive lubrication of the pins is secured by making them hollow.

A feature of the 1913 cars is the fact that all valves are inclosed, as shown in the accompanying illustrations of the various motors. The valve casings are of aluminum, entirely dustproof and easily removable. All valves are interchangeable. The heads of the valves are of nickel steel and are of large diameter. Integral stems, of carbon steel accurately ground, are used. The valves are operated by a drop-forged camshaft with cams keyed and pinned. They are case-hardened and ground accurately to size. The camshafts are housed in the crankcase. The push rods used are of the sliding type with large bearing surfaces, the adjusting nuts being drilled and fiber inserted. This, of course, renders the rods silent in operation and provides a sliding contact on the cam practically without friction. The whole construction tends to insure positiveness and silence in the valve action.

All motors are mounted on a three-point suspension, except the 4-30, which is mounted on a subframe.

The crankshaft used in all motors is of special carbon steel, drop-forged and double heat-treated, all beaing surfaces being ground to exact size. All crankshaft bearings are of Parson's white brass and all are adjustable.

Connecting-rods are of drop-forged nickel steel. Crank pin bearings are bushed with Parson's white brass, while the piston pin bearings are bushed with Cramp's special bronze.

A special aluminum casting is used for the crankcase, the forward supporting arms being cast integral on all models, with the exception of the 4-30, which, being mounted on a subframe, requires different construction. The half-time gearcase forms an integral casting with the engine base and entirely incloses the gears, insuring protection from grime and dust. The bottom section of the crankcase contains an oil reservoir and is easily removed for the purpose of making adjustments or inspecting the crankshaft, connecting-rods, or main bearings.

Two separate systems of ignition are used, the first consisting of dry batteries and a single-unit coil on the dash with a switch on the steering column (except on the 4-30), with high-tension distributor and separate spark-plugs, while the second comprises a Bosch high-tension magneto with a separate set of spark-plugs.

The method of supporting and driving the magneto is shown in the illustration of the 4-40 motor, Fig. 4, the base plate of the instrument being attached to the left side of the crankcase, the same shaft driving the water pump and fan. A positive universal coupling forms a direct connection between the gear-driven pump shaft and the magneto. The distributer is located between the cylinders, as can be seen in the same illustration of the 4-40 motor, where it is shown between the magneto and the water pump. It is driven by spiral gears from the time shaft with a vertical shaft running in bronze bearings. The distributer is inclosed in a dustproof hard-rubber cover. It has but one adjustment and but one point of contact for either the four or six-cylinder motors.

In advancing or retarding the spark the central post is the only movement, thus doing away with the primary or secondary wire breaking at the terminals. The contact points are of aluminum and require very little attention.

The splash system is used for the lubrication of all motors, the oil being carried in the lower part of the crankcase, which has

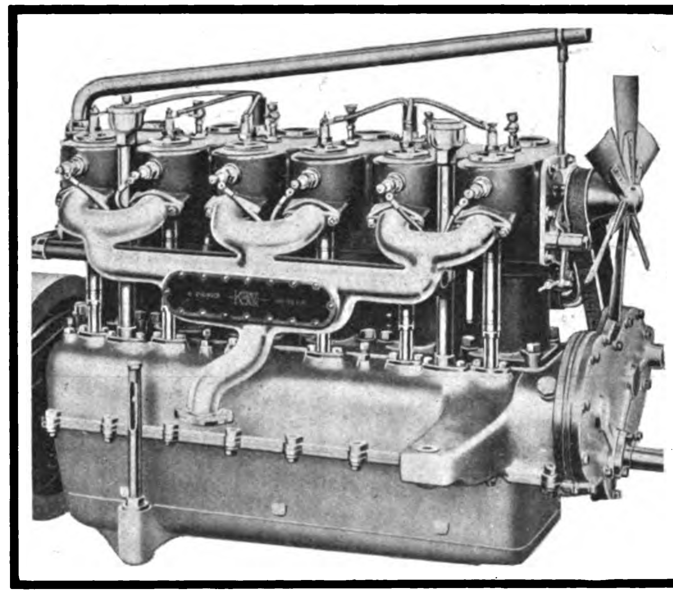

Fig. 3—Motor of 6-50 model with intake manifold and oil level

a capacity of about 2 gallons, and which is divided into four or six troughs, depending upon the number of cylinders of the motor. These divisions consist of the horizontal partition which forms the bottom in the lower half of the crankcase, together with the vertical partitions designed to keep the oil from running to one end of the crankcase when the car is on a grade. The partitions insure ample lubrication under all conditions, provided, of course, that the proper oil level is maintained in the crankcase. The splash system is of the constant level type and is readily adjustable by levels inserted in the side of the crankcase. These levels are shown in the illustrations of the 4-30 and 6-50 motors, Figs. 2 and 3, respectively. They have a micrometer adjustment and the level can be raised or lowered, according to the lubrication requirements of the motor. The oil is supplied to the crankcase reservoir through a filler tube mounted on the side of the crankcase, that on the 6-60 being shown in Fig. 5. This tube is equipped with a cap and filtering screen to prevent foreign matter from getting into the crankcase.

A gear-driven oil pump delivers the oil from the base reservoir

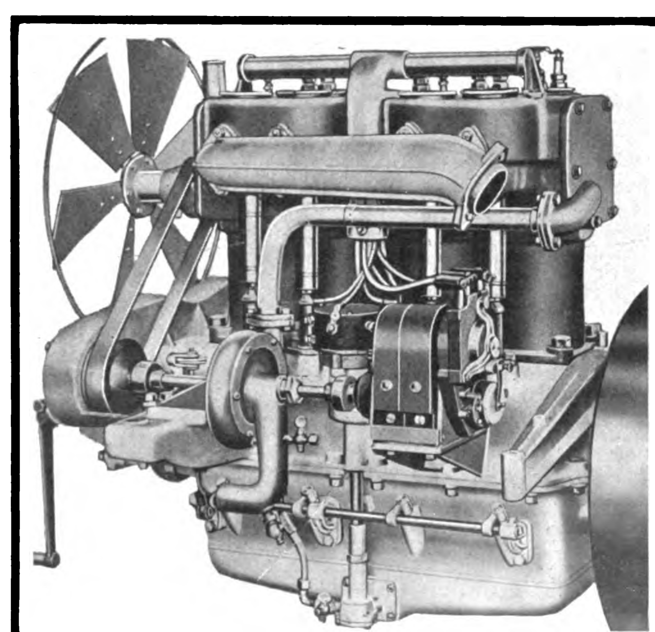

Fig. 4—Exhaust side of 4-40, showing fan, pump and magneto mounting

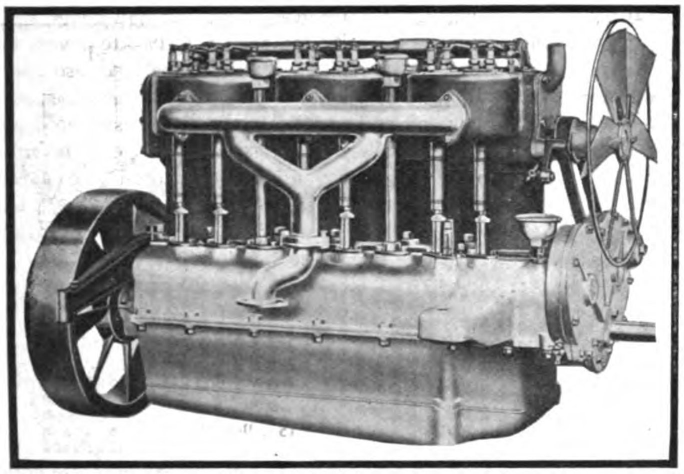

Fig. 5—Bringing out clean design of intake side of the Kline 6-60 motor

to a sight-feed on the dashboard. All the oil passing through the lubrication system of the motor must go through this sight-feed in full view of the driver, who is thus enabled to tell exactly the condition of the oiling system. From the sight-feed the oil is led to the crankcase where it enters the distributing pipe leading to the splash troughs in the upper part of the crankcase.

The steering gear, cardan joint and differential are packed in grease. The transmission gears run in heavy oil.

The carbureter used is of the automatic float-feed type and of special design to secure the greatest efficiency with the Kline type of motor.

Cooling of the motor is effected by means of a positive, gear-driven centrifugal pump forcing the water from the radiator up through the waterjackets and back to the radiator. The radiator is of foreign design, being of the flat tube, cellular type, of large capacity and substantial construction. The pump case is bolted to the crankcase, insuring permanent alignment. The auxiliary cooling system consists of a ball-bearing fan bolted to the forward end of the motor and driven from the pump shaft by means of a belt which may be readily adjusted to the proper tension.

The clutch is of the leather-faced inverted cone type with cork inserts, the leather used for the facing being of the non-burning variety. The clutch is provided with a ball thrust contained in the dustproof housing. A heavy spring released through the action of a yoke acting on a ball thrust ring holds the clutch in engagement. As soon as the clutch is disengaged, its rotation is stopped by a clutch brake. This tends to render gear-changing noiseless. The clutch pedal is compounded so that a slight pressure of the foot is sufficient to throw out.

A special feature of the Klinekar is the design of the double universal joint between the clutch and transmission, which instead of sliding to release the clutch, as in common practice, has an arm or spider mounted on the main shaft and connected in the clutch with blocks and pins. This promotes easy engagement. The joint is fitted with a metal greaseproof covering and is so constructed that it may be lifted out after removing the bolts which hold it in place, thereby giving free access to both clutch and transmission without further complication.

The Rushmore dynamo, driven by a silent chain from a gear on the main drive shaft just in front of the gearbox, as shown in Fig. 1, is mounted on an extension of the subframe supporting the gearbox.

The transmission is of the sliding gear selective type. It has four speeds forward and one reverse, with direct drive on third, being geared up on fourth speed. All speeds are obtained by single lever from the right side through an H-quadrant. The gears and shaft used are of heat-treated alloy steel. The bearings are imported and are of the annular ball variety. When changing gears, a sliding movement to either right or left engages one of the gear-shifting levers which operates the gear selected and automatically locks the rest. Gears are 6-pitch with .875-inch to 1.125-inch face, turned from solid bars of alloy steel and machined on the pitch line to within .003 inch, producing silence and ease of operation.

The driveshaft connecting the transmission with the rear axle is fitted with two universal joints, as shown in Fig. 1. These are automatically lubricated, the front one from the transmission and the rear one from the differential, and are protected from water, dust and dirt by steel covers. A slip joint is provided at the end of the shaft, being arranged so that it lies practically horizontal, thus preventing end thrust and wear on the joints.

The rear axle on all models is of the floating type, the bevel gears, differential and live axle being contained in a one-piece pressed steel housing except on the model 4-30, on which it is divided in the center. All moving parts of the differential and rear axle run on non-adjustable ball and roller bearings. The large differential and small bevel gears and bearings may be lifted directly out of the axle housing without disturbing any adjustments, except on the model 4-30, which requires only the separation of the two parts of the housing.

Two sets of brakes, both of the expanding type, are operated on drums on the rear axle by means of cams. Each set works through an equalizer and both are inclosed so as to be dustproof, except the 4-30 model, on which the service brakes are of the internal-expanding type, while the emergency brakes are external-contracting. This model has the expanding brake entirely inclosed in the drum and the contracting brake inclosed on the inner side.

The adjustments for taking up wear in the brakes are on the outside of the brake drums. To tighten the brakes, the locking nut is released and the adjustment bolt is turned to the right. This bolt is integral with the cam operating the brake and by throwing the cam on an angle increases the opening between the brake bands and consequently increases the outer diameter of the band. On the 4-30 the adjustment is made by means of turnbuckles on the brake rods.

The front axle is an I-beam drop-forging, the spring seats being forged integral with the axle.

Control is by means of spark and throttle levers located on a sector on top of the steering wheel and an accelerator pedal on the front floorboard. The spark and throttle sector does not move with the steering wheel. The gas and spark are regulated through gears located at the bottom of the steering gear housing and connected to levers for operating the carbureter, dis-

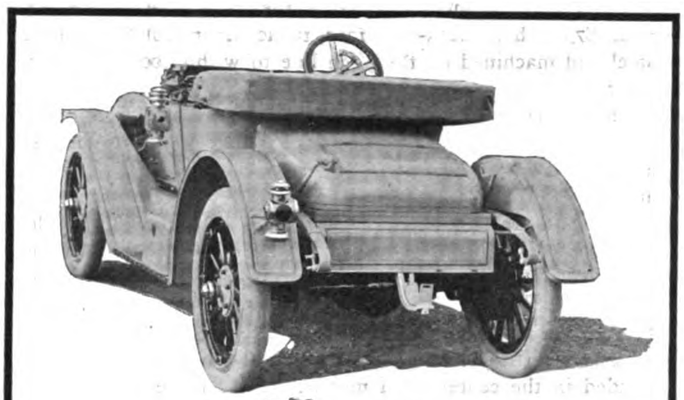

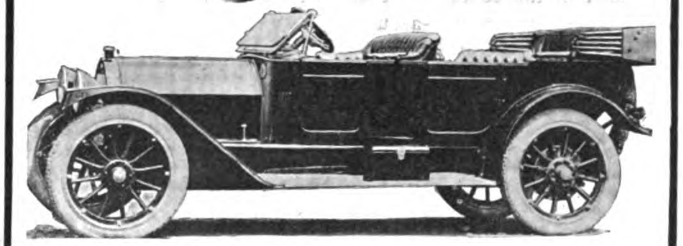

Fig. 8—Kline 6-60 runabout with baggage compartment
Fig. 9—Kline 6-60 model with foredoor touring body

tributer and magneto. The steering column is mounted on the right frame member and is supported by bearings in the dashboard. The walnut steering wheel is 18 inches in diameter. Steering is effected by a semi-irreversible worm and gear fitted with ball bearings to take up lost motion.

The frame is of heat-treated pressed steel, channel section with a subframe to carry the transmission, and, on the 4-30, another subframe to carry the motor. The main frame is narrowed in front to provide for turning the car in a small radius and has a kick-up over the rear axle to allow for spring clearance and to keep the center of gravity as low as possible, thus increasing the safety factor. Clearance on all models is 11 inches, except on the 6-50 and 4-30, on which it is 10 inches.

The spring suspension of the 1913 Kline has a novel feature in the shape of an auxiliary rear spring, which is shown in Fig. 10. This consists of a short, heavy spring which does not come into service except under an extra-heavy load or extremely severe road shock. Then it tends to resist the flexure of the main spring and thus reduces the jar on entire car.

Front springs on all models are semi-elliptic in form, the three-quarters scroll elliptic type being used on the rear, the only exception to this being the 6-60 and 6-50 Meteor special speed car, on which semi-elliptic springs are used all around. The front springs on all models are 36.5 inches, while the rear springs are 47 inches, except in the case of the Meteor, which has 50-inch rear springs.

The wheelbase of the 6-60 has been increased 2 inches over 1912. Wheelbases of the various models are as follows:

6-60	132
6-50	126
Meteor	110
4-40	118
4-30	115

Wheels on all models are of the wood artillery type, selected second grove hickory being used.

The tire dimensions on the various models for 1913 are as follows:

Model	Front	Rear
6-60	37 x 5	37 x 5
6-50	36 x 4.5	36 x 4.5
4-40	36 x 4	36 x 4
4-30	34 x 4	34 x 4

The Meteor is equipped with 36 by 4.5 tires all around for the 6-60 chassis and with 36 by 4 for the 6-50. Tread is the standard 56 inches with an option of 60 inches for Southern trade.

Combination steel and wood bodies of flush-side design are used in the 1913 cars instead of semi-aluminum. The 6-60 is furnished in touring car, toy tonneau, runabout and coupé roadster style, the passenger capacity ranging from two to seven, and the road speed from 55 to 65 miles an hour. The 6-50 also comes in these styles, as does the 4-40. The 4-30 is furnished as a touring car, toy tonneau and roadster only, the passenger capacity ranging from two to five and the speed from 50 to 60 miles per hour. Limousines, berlines and other closed and special body constructions are built to order. The Meteor is a special two-passenger creation mounted on the 6-60, 6-50 or 4-40 chassis, capable of 65 to 70 miles per hour.

Gravity fuel feed is used on all models, the capacity being as follows:

Model	Touring	Toy Tonneau	Roadster
6-60	19 gallons	17 gallons	26 gallons
6-50	19 gallons	17 gallons	26 gallons
Meteor			26 gallons
4-40	18 gallons	17 gallons	26 gallons
4-30	16 gallons	15 gallons	26 gallons
Coupé			32 gallons

An addition to the 1913 line of the Kline company is the coupé roadster illustrated in Figs. 6 and 7. Fig. 6 shows the canopy top in position, making the car a coupé, while Fig. 7 shows the top removed, leaving a comfortable, commodious roadster of the torpedo type. The mechanical specifications of this car are the same as the other 4-40, 6-50 or 6-60 models, as this is simply a special body mounted on the regular chassis. The detachable coupé top is mounted on the parapet of the roadster so cleverly that the joint is invisible, giving it the appearance of a one-piece body. The top has two large doors, one on each side, and the windows are made in either plain or Colonial style, the latter being shown in Fig. 6. The front glass is adjustable and the windows may be lowered to any height desired. With the top mounted, two large doors are used, for which smaller doors are substituted when the car is used as a roadster. The operation of detaching the top requires only 10 minutes, it being held by seven bolts. The interior of the coupé affords the same degree of luxury in appointment as a limousine and is fully equipped. When the top is detached and the small doors are bolted in place, the car presents an entirely different appearance, as shown in Fig. 7.

The equipment on all cars except the 4-30 includes: Semi-duquesne silk mohair top, side curtains and dusthood; adjustable clear vision shield; improved tire irons; Firestone universal detachable demountable rims; Rushmore dynamo, silent chain drive, with two electric headlights, 25 candlepower each, also sidelights, tail light and gauge lamp on the dash; automatic mechanical Ever-Ready self-starter; speedometer, horn, foot rail, coat rail, tire repair kit, pump, jack and complete set of tools. Black and nickel finish is employed throughout.

The equipment of the 4-30 is the same except that the self-starter is optional, the Ever-Ready mechanical type or the Prest-o-Lite acetylene starter being furnished as desired, there being a difference in price depending on the starter selected.

A $1,000 British Car

"THE motor trade in this country has taken many years to come to the front, although today the best British cars are the best cars in the market. To turn to the manufacture of rubbish, from which no lasting reputation can be built up, is to cast away the fruits of long endeavor. We hope and believe that British manufacturers will have the good sense to stick to a class of work in which they, at the present time, excel."

This sums up the opinion of engineering England on the present agitation of bringing out a $1,000 British car to compete in the British Empire with the low-priced American machines. This extract from an editorial in the current issue of **Internal Combustion Engineering** is emphatic, it is certain, there is not any ambiguity in it, and it is straight from the shoulder. While coming from the highest motor car engineering authority in Great Britain it expresses a sane survey of the situation from the engineer's viewpoint, penned as it was by one who has traveled through America, knows the enormous buying possibilities of this country and is also entirely familiar with the manufacturing methods necessary for the production of such a car.

Speaking further on the subject editorially:

"Any creator of cheap-car schemes must steadfastly keep before him the immensely important fact that the American maker has 100,000,000 of people at home and many more millions just over his frontiers. Here in the British Isles not only is there a much smaller population, but a smaller percentage of the population are possible, or probable, buyers of cars, because greater distances, lesser value of space and a higher average earning ability prevail in the United States. And above all the American car in America only costs half or less than half its European price, if price be reckoned as a percentage of earnings. One thousand dollars is approximately equal to £200 on rates of exchange, but $1,000 is as easy to earn in America as £100 in England, and it is earned. This means that the American market is not only twice the size of ours—in proportion with the population—but four times as great. We lay special emphasis on this aspect of the matter as it is seldom realized. **What it means, is that to have as good a business proposition in proportion to the population here as the $1,000 car in America, the identical vehicle would have to be sold at from $400 to $500, obviously utterly impossible."**

This is sound reasoning, which could be carried further, namely that a British factory would have to entirely re-vamp its method of manufacture before production of a cheap car would be possible in the face of the prices of American cars in Europe. The British factory is not equipped with the intricate jig systems of America; a year ago in plants turning out over 2,000 cars a year it was difficult to find half a dozen jigs in the entire factory. Hand labor was relied upon everywhere. Parts were removed to be fitted and refitted again and again before they were finally assembled. Such practices could not exist with the $1,000 car. To bring out a cheap car would alone be a big problem, but this task would assume enormous proportions when it coupled with it an entire revision of manufacturing methods.

In commenting on the possibilities of a cheap British car outselling a cheap American car in the British colonial possessions, such as Canada, Australia, South Africa and parts of South America, the editorial goes on to say: "It is easy, too, to talk glibly of the colonial markets, but there it is not so easy to sell British cars, except those of the highest reputation. Our citizens overseas know the cheap American car, and the good British, but the cheap British machine is unknown and would therefore be regarded with suspicion. It must also not be forgotten that an American maker has always this free-trade island—the British Isles—as a dumping ground, so that a slight overestimation of output can be corrected easily. We here have no similar land to take our own surplus with open arms."

This aspect of the colonial trade is a true one, but goes further in that the British subject in Canada realizes the value of close proximity to the American factory for spare parts, so that in case of breakage there is not an expensive cable toll and a 6-day boat trip, meaning a delay of perhaps 10 days, but the possibility of having the spare part reach him within 1 or 2 days at the utmost. This is strong argument for the United States car in America and chiefly for the Canadian market.

Gathering of the first General Automobile Sales Association in the auditorium of the Claypool Hotel, Indianapolis, Ind.

General Automobile Sales Association Is Formed as Result of Indianapolis Convention

New Organization Aims to Bring Together the Automobile Manufacturer, Dealer and Advertising Man—Keynote in Resolution Perpetuating the Association Which States That Helping the Dealer Benefits the Whole Industry

INDIANAPOLIS, IND., Oct. 9—The General Automobile Sales Association, which claims Indianapolis as its birthplace, brought its first convention to a close this afternoon after having staged a remarkably successful 2-day meeting of dealers, manufacturers and advertising representatives. In the automobile industry, the newly-born association is unique in its scope and purposes, for it brings together the dealer who sells the cars, the manufacturer who makes them and the advertising agent who creates the demand for them. All must work in perfect harmony for best results, and it is for a better understanding of one another that such a gathering was proposed.

Homer McKee, of the Cole company, is the originator of the idea, although J. J. Cole made the first meeting possible by lending what financial assistance was necessary. And to Francis L. Wurzburg, general manager of the Class Journal Company, belongs the credit for its perpetuation. His resolution, proposed and adopted along towards the end of today's session, strikes the keynote when it states that "in helping the dealer, the whole industry is benefited." Incorporated in the resolution is a list of fourteen representative figures in the industry who have been selected to put the organization on a firm and lasting foundation, and whose very participation in its future affairs assure it of a healthy and rapid growth. The resolution follows:

"Whereas, we, the charter members of this, the first automobile retail convention, are of the opinion that an organized national movement in behalf of the retail dealers will be of great benefit to the industry, be it

"Resolved, that we hereby constitute ourselves the nucleus of such an organization and pledge ourselves to its perpetuation.

"And be it resolved that the next meeting be held in Detroit in 1913 at a date to be later determined.

"And be it resolved that the following men be appointed as a committee in charge to serve for one year:

"J. J. Cole, Indianapolis; Homer McKee, Indianapolis; H. M. Swetland, New York; E. LeRoy Pelletier, Detroit; John C. Wetmore, New York; Hugh Chalmers, Detroit; Roy D. Chapin, Detroit; William Boyd, Chicago; Carl Page, New York; C. B. Mears, Cleveland; J. L. Mahin, Chicago; H. L. Stratton, New York; J. G. Monahan, Indianapolis; F. B. Stearns, Cleveland."

Unlike many a great undertaking which has had humble beginnings, the General Automobile Sales Association, which was so named on the suggestion of J. J. Cole, received anything but a small start. Long ago manufacturers in other branches of industry realized the advantages to be gained from helping the dealer in just this

Heard at the First General Automobile Sales Association Convention at Indianapolis

"The idea of helping the dealer in all his problems is worthy of all the effort we can muster."—J. J. Cole, president Cole Motor Car Company.

"A good dealer can hold up a poor car a good while, but a poor dealer cannot uphold a good car very long." —H. O. Smith, president Premier Motor Manufactuirng Company.

"If we can ever get a co-ordination between advertising and sales, there is nothing we cannot do."—E. LeRoy Pelletier, Flanders Interests.

"The automobile industry is one of the great, strong, red-blooded businesses of to-day."—C. A. Bookwalter, president Cheltenham-Ætna Press.

"Individuality means everything in business."—W. D. Nesbit, Mahin Advertising Company.

"When you sell a man an automobile, you do him a great benefit."—Elbert Hubbard.

"By service is meant the education as to the proper use of an article, its speedy adjustment and quick parts replacement."—H. G. DuPree, Remy Electric Company.

"Advertising, instead of detracting from a salesman, multiplies his services many times."—W. H. Boyd, Curtis Publishing Company.

"There will be no more automobile departments in the daily newspapers when races, reliability runs, endurance contests and other motor car competitions cease to be carried on. Manufacturers should support them." —J. C. Wetmore, New York Evening Mail.

way, and it marks the beginning of additional prosperity for the great automobile industry of this country and Canada when such a method of promoting the sale of motor cars is adopted. Not only has the industry welcomed the idea openly and eagerly, but without exception every figure of note in this great business who attended the 2-day meeting was enthusiastically in favor of it and congratulated the Indianapolis men for conceiving it.

Some of the more striking high-lights that developed during the sessions in the delivery of the addresses were the following:

J. G. Jones, of the Alexander Hamilton Institute, New York City, in speaking on Headwork in Salesmanship gave some sound advice to dealers and salesmen: "Since automobile manufacturers are building cars along scientific lines," he said, "the salesmen should sell them along the same lines. There are fourteen qualifications for a good salesman. They are: Natural qualifications, prime condition, personality, ambition, honesty, courage, acquired qualifications, confidence, enthusiasm, earnestness, application, preparedness, observation, self-analysis."

"How to Use Advertising in the Retail Game," by J. L. Mahin, of the Mahin Advertising Company, Chicago, was one of the best addresses of the convention. Mr. Mahin pointed out the many phases and kinks for the edification of the dealer and laid special emphasis on the fact that service for the customer is the major point for the salesman to keep in mind. Mr. Mahin's address is on pages 794 and 795.

S. A. Seiberling, president of the Goodyear Tire & Rubber Company, Akron, O., delivered a masterly talk on the future of the industry. "The automobile industry has written one of the most spectacular pages in the history of the world," he said. For the coming year he predicted the following:

"At this rate 10 years from now the automobile business and its allied interests will have a value more than four times greater than that of the great Pennsylvania Railroad system. And when we shall have developed and taken advantage of our roads and highways by using automobiles on them, the automobile industry will be worth more than the entire railroad interests of the country. The dealer is the medium for this great growth.

"But," continued Mr. Seiberling, "the dealer of the past had an entirely different problem from that with which the dealer of the future will have to cope. Cars must henceforth be *sold*, whereas in the past they have been *bought*. Service in the future must begin when the car is sold. The dealers in each community have problems which are local to that territory, and these must be evolved by co-operation."

H. L. Liebricht, of the Export Advertising Company, said of the possibilities of extending foreign motor car trade. "In foreign countries all realize that the medium-priced American car has no equal. But the greatest drawback to the sale of American cars abroad is this question of service. The European manufacturer sells more cars in South America than does the maker from this country simply because the buyers can get their cars repaired reasonably and quickly. There are many openings for American garages where American cars are understood. Ninety-five per cent. of the chauffeurs abroad are Italian, Swiss or German, and these men do not understand the American car. They cannot repair it. Consequently, there is much demand for the American chauffeur. There is an opportunity for many a young American in this business, therefore, in foreign lands. In all foreign countries new roads are being built, which broadens the field for cars. Last year Venezuela appropriated $285,000 for good roads, and she will set aside $400,000 for the same purpose for the coming year. The foreign field is unlimited."

"Advertising instead of detracting in any way from the salesman aims at multiplying his services many times over," was the keynote of W. H. Boyd's message to the convention. Mr. Boyd, continuing, said: "The whole type and standard of salesmanship is improving. Today a man can be a good man and still sell goods. The forces and influences which are put into the salesman's hands are a far greater asset today than any personal qualifications which he may possess. Here is where the sound manufacturing organization and advertising come in."

Mr. Boyd also touched upon the actual and potential demand for advertising. "Your advertising must not only convince the man who buys a car, but it must make converts to your line of all those with whom he comes in contact before the sale is made. Many of these may never buy a car, but they have an influence upon the man who does. If public sentiment is in favor of a particular car, it will sell, for one is proud to own something which others admire."

The inadequate advertising fund was decried by Mr. Boyd, who added "that to make a car known it must be hammered into the people incessantly. One big advertisement in a national publication followed by none at all is of little value. The article must be kept constantly before the public. Before signing up

Co-ordination of Sales and Advertising

Extracts from an address by E. Le Roy Pelletier before the First General Automobile Sales Association in Convention at Indianapolis, Ind., October 8 and 9

TO knock your competitor will never get you anywhere. Personally. I most admire the man who gives me the strongest competition. We are all in business for the same purpose, and every man is entitled to a share of it in proportion to his ability. If we were asked to pick out the best car made today, we could not do it, for they are all good, and to run down the products of other makers to a prospect is to jar his confidence in the product as a whole.

When the time comes when we get a perfect co-ordination between the advertising and sales ends of the industry, there is nothing which the industry cannot do. Just because a man was not in the market for a car 2 months ago is no reason why it is useless for the agent to call upon him today. Prospects are born in a night. When the automobile dealer is enjoying himself in the evening, his advertising is still working for him, hammering home the need of every man for a car. And seated at the library table, the man who is thinking of a car reads the advertisement and becomes convinced and enthused.

There is not a very large percentage of good salesmanship in the automobile business. Motor car salesmen would do well to emulate the cash register and adding machine salesmen, for these men can bring back only one of two things—the order or the burial certificate of the prospective purchaser.

This convention is an excellent idea, and being such it cannot fail. I predict a much greater attendance of dealers and manufacturers another year. But the main lesson for every dealer to gain from the present session is to go back home and organize another little convention of the dealers in his community, and to talk over with them the subjects which have been discussed here.

Price cutting should cease. The whole world is a disorganized organization working against the little community of automobile dealers, and the latter are very foolish to cut one another's throats, making their ranks just that much smaller to cope with the greater outside army.

How to Secure the Newspapers' Aid

Excerpts from an address by John C. Wetmore before the First General Automobile Sales Association

THE dealer is the man behind the gun. The whole success of the industry depends upon the gunner. He sells 80 per cent of the cars made—the small dealer, not the branch manager.

I am proud of what the newspapers of this country have done for the automobile. The automobile was bound to arrive at its present state of perfection sooner or later, but through the aid of the press it has arrived 5 years ahead of time. The dealer should follow several tips as to how to get the best results from his newspapers in his home city.

In putting publicity in the newspapers, the dealers should use the right kind of stuff—that which has a news value. Boost the man who boosts you; put your advertising in the paper which supports automobiles for this is the paper which is read by the class of people whom you wish to reach. Create a field of optimism and don't knock. Create a desire in the minds of the buying public to own motor cars—don't point out all the faults of the machine.

The automobile departments of the newspapers must have something to talk about—they must have real news—else they cannot survive. When there are no more races, motor car contests and hill-climbs, then there will be no more newspaper support. It is up to the makers to enter these things to furnish news for the press and to keep automobile news alive.

with any car maker the dealer should assure himself of the maker's consistent and national advertising campaign. For this reason every dealer should become a student of advertising."

"There are two distinct types of salesmen whom we come in contact with every day," continued Mr. Boyd. "One is the personal salesman, the man who has brilliant qualities as a salesman, who has his own methods and has perfect confidence in himself; and that is a good type. But there is another type that I would call the scientific salesman, were it not for the fact that that word scientific has been used so much that it is becoming stale and has lost to a large extent its original force. But I would call the salesman I have in mind the 'social'—not the 'sociable.' That is the salesman who represents the organization with the buyer; the man who does not depend upon his own brilliant qualities of personal salesmanship, but the man who depends upon the force and influences which have been created for him to use, who knows how to shape this force and influence for his own individual purposes.

"The forces and influences that are put in our hands as salesmen are far greater and far more effective than any personal qualities which we will be able to exercise, no matter how brilliant we may be.

"That naturally brings me to the subject of advertising and what it represents, and especially what it represents to you salesmen who have back of you a manufacturer who appreciates to the full extent the value of advertising and knows how to use it in such a way as to put the greatest possible dynamic influence and power in your hands to use.

"I want to emphasize the essential difference between what is the natural and potential demand of advertising. When an advertisement or a series of advertisements appears in a magazine, immediately it arouses curiosity and interest on the part of people who are interested in the product, and it develops immediately a certain amount of tangible evidence of its presence. A few people, perhaps several thousand people, will send in a direct answer to that advertisement and ask for a catalog or information of some kind about the product. Many other people will go into the dealer's store in their respective communities and ask for the article advertised. I am speaking now, of course, of publicity advertising which is intended to stimulate the sale of merchandise through local dealers all over the country. But whatever may be the tangible evidence of that advertisement, or that advertising, it is only a very small fractional part of the real value of the advertisement and the potential value of the advertisement, which has been sown broadcast among the multitude of people who read the advertisement. Without any attempt at accuracy, if the tangible direct value of an advertisement is measured, we will say, by 10 per cent, the potential value of the advertisement must be equal to at least 90 per cent.

"What is this potential power of advertising with which we are concerned, and which is the most vital thing that will come before this convention?

"That advertising in order to realize its greatest value must touch and influence directly not only the people who are interested in the purchase of an article, but all the people who may influence those who actually do purchase the article.

"So it is up to you dealers to study the advertising just as carefully as you study the mechanism of a car, and be sure that you have got the kind of advertising that is going to educate every man, woman and child in your community as to the value of the car."

H. G. DuPree, of the Remy Electric Company, Anderson, Ind., spoke on the topic of service, asserting that the accessory maker must have service for his customers as well as the car maker. The automobile today is sold in competition with almost everything else, for people must give up other luxuries in order to afford the machine. Service for the customer is essential. It might be argued that service implies that something is going to happen to the product, but people who become so delighted with the results of quick repair and so on that they loose sight entirely of this thought. Courtesy, dispatch, kindly interest and diplomatic conversation are the chief essentials to successful service.

In introducing Elbert Hubbard to the convention Mr. Nesbit stated that individuality means everything in business. Hubbard is individual—he is eccentric and unique. Mr. Hubbard interspersed his humorous talk with words of motor car wisdom. When you sell a man an automobile you do him a favor, he said, for you give him a chance to get out into the great out-of-doors. He made a plea for good roads, and for Fisher's project of a transcontinental stone road, saying that every manufacturer should set aside 1 per cent. of his gross income each year for the proposed highway. Mr. Hubbard's address will appear in next week's issue of THE AUTOMOBILE.

The Scientific Selling of Motor Cars

Extracts from an address by C. F. Kettering before the First General Automobile Sales Association in Convention at Indianapolis, Ind., October 8 and 9

EVERY business is confronted with the selling problem and the automobile industry is not any exception. There is no other means of transportation today which can rival the motor car as a solver of the problem of the carrying of persons and things from one point to another. For this reason, the automobile has passed the experimental and the merely pleasure stage and is a permanent fixture. A good dealer can hold up a poor car a good while, but a poor dealer cannot uphold even a good car very long. To increase sales, educate the salesmen. There is no influence for their betterment which surpasses such a gathering as this. There are few things in the automobile business today which are worse than the practice of taking used cars in trade for new ones for more than such cars are worth. The used car should be taken in at a figure which will allow for its quick re-sale.

Does the dealer broaden the industry by trading in cars at such prohibitive figures that it is impossible for him to get rid of them again? The interests of the manufacturer and dealer are identical. The manufacturer is closely interested in the dealer, for the latter is a part of the selling organization. If the dealer is devoid of prosperity it reflects upon the car maker.

Starting as a luxury, the motor car today is a practical proposition. It is one of the keys to the high cost of living, for it makes it possible for the farmer to get to town with his wares oftener, for the city business man to live in the suburbs, and in the commercial field it is conducive to lower transportation cost. It is most important for the dealer to select the best selling line of commercial cars for his territory. That line which sells best in one community is not necessarily most popular in another. The dealer should have explicit confidence in the line which he sells, for he cannot enthuse his prospects unless he himself is enthusiastic. The first question which some realers ask is, "What is the discount?" A low cash selling basis and a long discount do not go together.

Development of the Automobile Industry

Excerpts from an address by H. O. Smith before the First General Automobile Sales Association

IN this day and time, automobiles have become so common that we of the superior knowledge of their workings have slipped somewhat away from the calling to the attention of those who do not know them so well what really wonderful pieces of mechanism they are. There are many thousands of people who still look upon them as experiments, and it is these whom we must interest.

The salesman who is alert will relate to the passive prospect the story of the development of a gear, a rubber tire, a carbureter or any other parts of the car in a way to incite his admiration for the supreme efforts which have been necessary to bring about such perfect-runnning machines. If he complains of the troubles which are experienced with tires, point out to him how bad it would be if there were no such things as pneumatics. We marvel at the great and powerful mechanism of the locomotive, yet we pass with a glance the automobile, which is a far greater thing. Do not say to the buyer of a car that he *must* oil this or that, but point out to him the disastrous results of not doing so. Such concrete examples as this will teach the man how to take care of his car, where mere directions as to what to do and what not to do would not be heeded. By getting him to appreciate the mechanical reasons for doing *this* and not doing *that* you stimulate his interest and make him a satisfied purchaser.

How To Use Advertising in the Retail Field

Substance of the Address Delivered by J. L. Mahin Before the First Annual Convention of the General Automobile Sales Association at Indianapolis —Service for the Customer a Big Advertising Factor

SERVICE—Sometimes we salesmen get a little bit confused in our viewpoint as to whom we are actually serving. **Do we actually serve the man who pays us the money, or the man who takes the product of our sales and consumes it?** The keynote of the talks yesterday all seemed to be along the line that the consumer, the man who took the automobile off the market, was really the man who was to be served.

There is no question that the manufacturer up to date has done his duty in that direction. Nobody could listen to what Mr. Kettering said yesterday about the wonderful scientific and mechanical problems that had been overcome in the production of a motor car, placed in the hands of people who do not have to spend a lifetime of study and experiment in getting satisfactory service, but appreciates that fact. **The successful manufacturer to-day is the man that is looking out to give service to the man who pays the money.**

I believe in salesmanship. To me salesmanship gives a man positively the best opportunity for expressing the force which God Almighty has put into him. Salesmanship is the ability to get other people to accept your viewpoint as to the value of the thing that you have to present to him. That is really all that salesmanship is. **It is the power and ability to get others to accept your estimate of the value of the thing that you are connected with or that you have anything to do with.**

On this question of salesmanship does the dealer render service? And if he renders service, to whom does the best part of his work go in the form of service? Up to date in many quarters there has been an impression that the dealer was working for the manufacturer; but the question, it seems to me, for you gentlemen to seriously consider is: **Can the dealer render 100 per cent. of efficiency in service to the automobile user? Can he? If he can, it does seem to me that the solution of the thirteen problems that were on the list that was sent to me, which will be brought out in this convention, will be comparatively easy.**

The manufacturer recognizes that the dealer who best serves the consumer is the best dealer for him. **The dealer who can serve the buyer, give the buyer the most intelligent and efficient use out of the car that he buys, is the best dealer for the manufacturer.** That being true, why is not that dealer the best dealer for the dealer himself? And is it possible for the dealer to earn every cent of the money that he gets on a car in actual service to the buyer? I believe that it is; and I believe it so strongly that I have an order in on a car absolutely on that basis to-day. I believe that the dealer who makes his legitimate commission off from the sale of my car is going to earn his money. I propose as a committee of one to see that he does anyhow, and I believe that he is going to do it. I believe that that car is going to be worth more to me than it possibly could have been if I had gotten the agent's discount and not have the service that I intend to have and have already received through that dealer.

Now what can the dealer do for the consumer? Certainly in as complicated a piece of mechanism as a motor car, notwithstanding the wonderful foolproof qualities that brains and skill and experimentation on the part of the manufacturer have put into it, certainly in a motor car as complicated as it is the buyer cannot learn too much about it; he cannot know too much about it to get full efficiency out of it.

The manufacturer cannot meet the buyer face to face. He cannot size the buyer up as a man and see what he reveals in his countenance or in his manner, as to his special fitness to handle a motor car, or his viewpoint toward things in general. **The manufacturer cannot get that delicate point of contact. The dealer is the only one who can get that contact, and when a car is properly and intelligently used it saves trouble with the car.** Who is to put the owner of the car in the mental attitude by which he can save that trouble except the dealer? And how can the dealer do that unless he not only knows the car, its powers and its limitations, but also he knows human nature, and knows what the man who buys that car is likely to do to it or not do to it, and keeps him in the proper mental frame of mind toward the car, its functions, its care and attention? Isn't it reasonable to assume that if the dealer takes the attitude with a man, after he has sold him a car, as was stated here yesterday,—that you are going to have tire trouble, but you would have nothing but trouble if you did not have tires; tires overcome trouble; without them there would be no motor car—and if you educate the buyer to the old fundamental principle of life that prevails everywhere, namely, that anything which is worth having is worth working for; that you cannot get full, efficient, satisfactory service out of the car unless you properly use it, unless you give thought and work to the use of it; get the buyer in full appreciation of the responsibility that he possesses as one in possession of the car—I say, isn't it reasonable to assume that if the dealer puts the buyer in possession of these ideas and into this attitude, isn't the life of the car going to be longer? Won't it give greater satisfaction, greater mileage? Isn't it going to be possible to take care of the car so that it will be worth more than it would be if it were indifferently or carelessly handled?

If that is true, there is the dealer's opportunity and the dealer's responsibility.

Now, I have said a good many times before that salesmanship has two primary qualities. No successful salesman that I know but what has the ability to be both plausible and sincere. What is plausibility but the ability to size up the man you want to sell something to, and present what you have to him so that it appeals to his viewpoint, his standpoint? To do this you have to know human nature. You must know the circumstances of the buyer. You have got to look at the thing from his viewpoint before you can be plausible. If you are plausible, if you fit what you have into the scheme of life and the every-day experiences of the buyer you have got him coming your way; he is yours; he belongs to you. You have given him the best demonstration of the power of salesmanship. **Plausibility is adapting what you have to the viewpoint of the other man.**

Service is really all you get out of an automobile. You can have all sorts of equipment on your automobile, but when you want it, and it isn't fit to run, what good does it do you? It is like money in the bank which the banker will loan you **when you don't need it.** The time you want it is when you need it, and really that is all that any buyer gets out of an automobile, service when he needs it. And isn't it possible for the dealer to take the same viewpoint toward his function in the sale, service to automobile buyers so that he can honestly and conscientiously feel that so far as the automobile buyer is concerned the money that he, the dealer, gets is the best invested portion of the whole transaction? If that is true, gentlemen, if that can be made true—and I honestly believe it can be made true because that is a fundamental principle that is borne out by every successful salesman that I ever met—it is worthy of your serious consideration. I never met a successful salesman yet, a really successful salesman, a man who could sell anything and knew he could do it, but who could add the cost of his salesmanship to the cost of the article that he was selling and make that thing that much more valuable by that amount.

If that can be done in the automobile business by the dealer getting that idea in his mind, that the services he renders the buyer, the man who buys the automobile, that is the best portion of the service that these buyers can get and a lot of these other problems will adjust themselves.

The first problem; how to dig up new prospects: **The best way to dig up prospects is to have a satisfied customer boosting for you. There is nothing that beats it. The voluntary service of a satisfied buyer will bring you more of the**

best kind of prospects than anything else that I know. The best manufacturers to-day are using the best advertising mediums, the best advertising ability, the best engineering ability, and all of that service is being given to the dealer. All the dealer has to do is to simply discriminate and use ordinary, every-day common sense and judgment in tying up with the manufacturer that gives him all of the other facilities for service which the dealer himself is not in a position to render. That is only a matter of decision and choice on the part of the dealer.

The manufacturer wants the good dealer a whole lot more than the good dealer wants a good manufacturer, as a rule—in other words, I firmly believe that there are more good manufacturers than dealers available; so it is up to the dealer to simply exercise his choice, you see, as to the concern that he is going to tie up with, and the fellow that has not mastered engineering service and advertising problems needs that service more.

How to deal with women: A woman does not want to ride in a car that does not look like something and that does not give service. She wants a serviceable, presentable car. A car where your customers are your boosters, where your customers are saying good words for you, you get the best class of people as your clientele, it does seem to me that right on that point alone there is a strong force at work.

Now to organize and maintain a money-making sales organization. **The best money-making sales organization is the sales organization where the salesman earns all he gets in service to the buyer. All the rest of it is then just velvet; what he does for you or sells for you is velvet. But he will never get that thought in his mind unless you put it there; talk to him about it.**

How to prevent frittering away profits on free repairs: The better way indeed to prevent frittering away of profits on free repairs after you have sold the car is to have demonstrated to the buyer and have him accept his responsibility in the care of that car. What better way is there? After you have shown him what he has to do to get full service a good start is made. Don't show him in a negative way. Don't say, "Don't do this, that or the other thing," but say to him, "You must put this oil in here, and do this and do the other to get the highest possible service," and you get him to do that, and then if he comes in and wants you to make repairs you ask him, "How did that happen? Didn't you do so and so?" "Yes, I did that." "Well, don't you remember I told you about that very thing?" Now, isn"t that man in a better position and more likely to be fair with you and not to demand unreasonable things than he would be if you had never told him those things? Isn't he in a better position to not demand unreasonable things from you?

How to dispose of second-hand cars: If the dealer believes himself that the price he gets on the sale of a new car he earns in service to the buyer he is not going to give up part of that in taking a loss on a second-hand car. He cannot consistently be honest with himself and take a loss on a second-hand car when he has given full value to the man who bought the car in the first place, can he? I see one of you men shaking your head. That doesn't scare me at all. I have heads shaken at me so many times that I don't mind it. We have got to aim high. We have got to have an ideal to strive for and we have got to have a margin of safety—all of those things. But I will come right back again: If you can get yourself, Mr. Dealer, to believe that you earn in service to the man who buys your car all of the money you make out of the car, if you really believe it, you are not going to be so keen to take his second-hand car at a price that will lose you money, and it will help a long ways to get yourself into the proper mental attitude.

You can never ask anybody or expect anybody to believe what you don't believe and get away with it for any length of time, I don't care how plausible you are. The salesman who lasts is the man who is sincere. The man who is not afraid of the lost sale on the wrong basis will eventually win and you cannot do something in this world and get a reputation for doing something without it costs you something; and one of the things it will cost you will be a lost sale now and then to a man who wants the unreasonable thing and who puts you in the attitude of not being consistent if you do the unreasonable thing that he has wanted you to do. You have got to take the stand, but you will win in the long run.

There isn't any better philosophy than Mr. Hubbard preached last night—that you win in this world by indirection. You don't always win the thing that you set your heart on, but the fundamental principle that you put into your work, that you stick to, attracts to you somebody else to take the place of the lost one.

I could go on with all these thirteen arguments, but I have very much exceeded my time. However, I will just say a word about the sincerity that is back of salesmanship—the ability to take the loss of a sale and to smile and go back again.

I am a believer in the salesmanship that is expressed in the philosophy, **that the man who gets the most turndowns makes the most sales because he makes the greatest number of calls.** That has been my experience in salesmanship. I have not found any easy, royal road to su cess. I don't know any way to catch many fish by sitting down and waiting for the fish to come. The best method of fishing to-day is going along the stream and casting the fly in everywhere and the fellow who does that all day brings home more fish than the one who sits down and waits for the time to be ripe or the sun to be just right and the wind in the right direction and waits for the fish to come to him.

The business of selling automobiles is working upon so many complex things in human nature, the emotions, the sentiments, the sympathies of life—they are all somehow entwined in the automobile. The man who rides in the automobile for purely sentimental reasons, to give himself relaxation, to give his family greater enjoyment, is contributing to a cause in the matter of good roads that will unquestionably be one of the greatest economic developments and forces for good that this country could possibly accomplish. And a business that gives a man an opportunity to do all those things is a mighty good business to be in and it seems to me it is a business that a man ought to be proud to be in. An automobile dealer has the opportunity; he comes in contact with human nature in all of its phases. He is dealing with the manufacturer. He comes in contact with the biggest brains and the most courageous dispositions that it is possible to find in this country. He meets the men who do things in a big way. And in meeting his customers, the car buyers, he meets every kind of human being and the man who can sell motor cars—and the time is coming if it is not here when motor cars **must be sold** rather than simply **supplied**—is the man who certainly is to be envied for his position in the world.

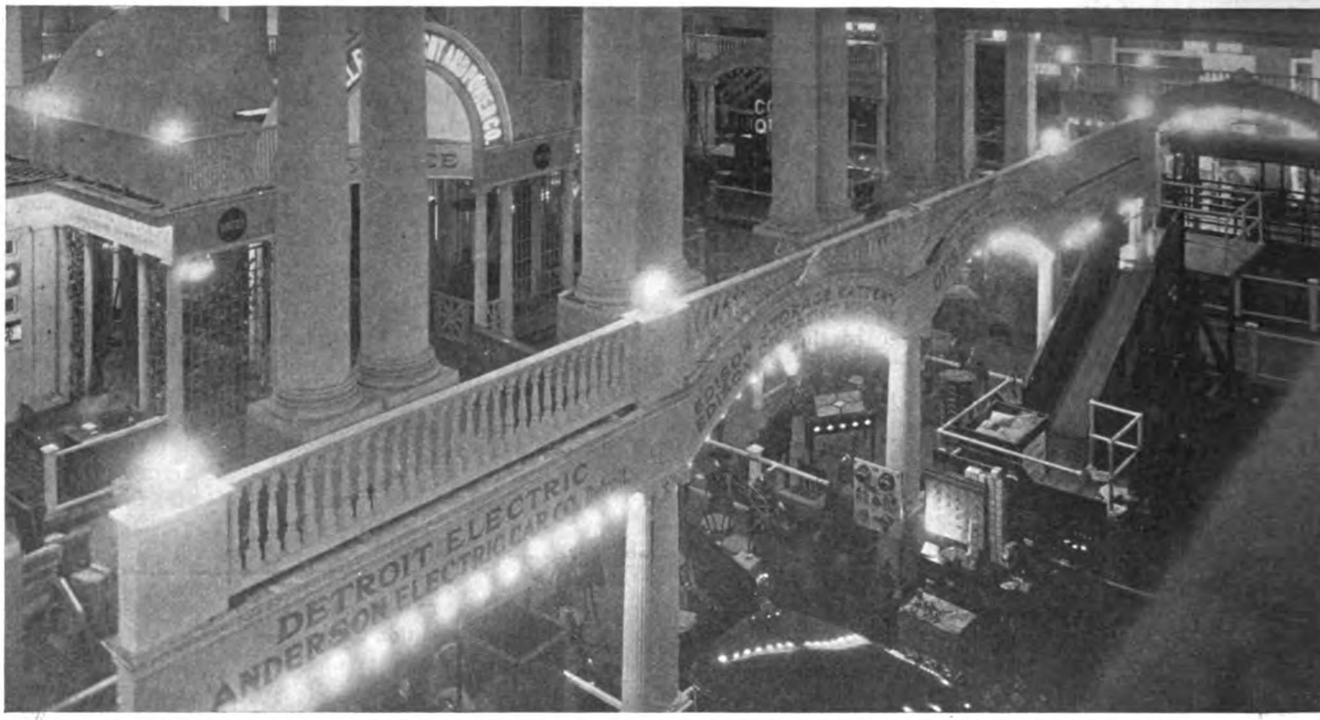
Now, it is possible for every man in every community to have leadership of some kind, and leadership as an automobile dealer, it seems to me, is a very enviable thing from the standpoint of a man's own self-respect. He has got to do more things well to be a successful automobile dealer than almost anything else I know. And in doing more things, and doing them all well, what is he doing to himself? Isn't he being true to the purpose that God Almighty put us into this world for, and that is, finding out all the hidden forces and resources we have within ourselves and using them with a beneficial purpose for those with whom we come in contact?

Automobile Men Enter Insurance Field

In an effort to bring order out of the present chaos pertaining to automobile insurance and to inject an element of competition that will work for more reasonable rates, the National Motor Indemnity Company and the National Motor Insurance Company have been chartered at Albany. The former concern will insure against automobile collisions, property damage and liability and the latter will cover fire, explosion and marine hazards. The managements will be identical and the policies issued will be contained in one document if convenient and losses will be handled through one adjustment department.

A number of prominent men in the automobile industry are named as among the incorporators of the companies, among whom are the following: William E. Metzger, A. G. Batchelder, Hugh Chalmers, Thomas Henderson, Albert C. Pope, Alfred Reeves, S. A. Miles, Winfred J. Foss, Edwin B. Jackson, A. E. Maltbie, George W. Hipple and Chester I. Campbell. William B. Joyce, president of the National Surety Company, will be chairman of the executive committee of the new insurance organization.

The companies will be affiliated with the Motor Union Insurance Company, of Great Britain, which has an intimate connection with the Motor Union, the big organization of automobile owners of Britain that corresponds with the American Automobile Association in the United States.



Interior view of Electrical Exposition, held now at New York Grand Central Palace, where eighteen models of electric automobiles are exhibited

Electric Car Men in Third Convention

More Than 150 Members of Electric Vehicle Association of America Meet in Boston —Capitalization of $500,000,000 in the Automobile World Represented— Standard Charging Plug and Lamp Socket Adopted

BOSTON, Oct. 12—The feature of the week was the big convention of the Electric Vehicle Association of America, which was held here the past few days, the association representing a capitalization of $500,000,000 in the automobile world. It was the third convention of the association and there were present more than 150 members. President William H. Blood, Jr., of Chicago, called the convention to order Tuesday morning, saying among other things:

"A few years ago electric vehicles were not largely used and the public was unaquainted with their true value. The vehicle manufacturers were not making large sales and their factory and selling costs were necessarily high. As few electric vehicles were being marketed the makers of batteries were making correspondingly few batteries. Central stations with comparatively high rates for current were hindering rather than helping the introduction of electric vehicles. All of these interests awoke at about the same time, joined hands and formed this association with the result that the use of the electric vehicle has increased marvelously and its adoption is becoming more general. It is proper, I believe, to call your attention to the comparison between gas and electricity. Only a few years ago gasoline was a by-product. When the automobile industry started, the ruling price was 10 cents a gallon. This price has constantly climbed to 14, 16, 18 and 20 cents, and even to as high as 25 cents in some localities. The garage owners are probably justified in opposing this rise, for the wholesale price is being advanced constantly, and the ultimate consumer, as usual, will pay the bill. On the other hand, the rates charged for electricity are constantly on the decline. The price of electricity used for charging batteries in the first electric vehicles was at the rate of 20 cents per kilowatt hour; a 15-cent rate soon followed, and for a number of years a rate of about 10 cents or thereabouts has been common. Today the user who charges his own single vehicle gets rates varying from 8 or 9 cents down to 4 or 5 cents per kilowatt hour, while the larger user, in certain localities, pays between 2 and 3 cents. The entire tendency is downward."

Reports were presented by committees on operating expenses, rates and charging stations, publicity, insurance, standardizations, etc. C. E. Michel then read a paper "Where We Stand Today" presenting some interesting facts and figures relative to the growth of the electric vehicle business. He said: "In St. Louis our revenue from charging during the first 6 months of 1912 increased at the rate of $1,000 a month or nearly 37 per cent. more than the previous year. It is estimated by Mr. Williams, of the Edison company, of New York, that the number of electrics in use in New York has increased 35 per cent. in the year ending June 1, 1912. Mr. Jones, of the Commonwealth Edison Company, of Chicago, estimates that in June, 1912, there were 200 electric vehicles under order but undelivered to Chicago business houses. One electric truck man sold single-handed $981,000 worth of trucks during the 1911 season and he did not make an apology for a single one of them.

Dr. M. Ekstromer, of Denver, in his paper on the Electric Vehicle in Denver, made the surprising announcement that in his city there is one electric pleasure vehicle to every 217 inhabitants, or more per capita than in any other city in the United States.

Street and Traffic Conditions As Related to the Electric Vehicle, was the topic prepared by R. McAllister Lloyd. In it was suggested the need of dividing streets to provide a surface for motor traffic. It said: "As commercial vehicles drawn by horses have always been greater in number than pleasure vehicles, and as they are all destined to become motorized, accidents are likely to increase unless radical measures are taken to limit the speed of motor traffic. Up to the present time the electric vehicle for both passenger and commercial use has maintained a reputation for sane speed and ease of manipulation, but there seems to be a growing tendency for salesmen to advocate higher speeds, and if no protest is raised we shall find within the next few years the entire traffic of our streets speeded up to the pace set by the taxicabs. From an engineering standpoint it is perfectly practicable to increase the average speed of the electric vehicles, wagons and trucks, about 50 per cent., but I question the advisability of doing so. Is it not wiser to stick to the speeds now prevailing in the operation of electric trucks and advocate them for all methods of propulsion, not because electricity is inherently slower than gasoline, but because the interests of humanity are conserved by so doing?"

The forenoon session ended with the members discussing the papers. After luncheon they were taken for a drive through the historic sections of the Bay State. At the evening session there was an election of officers resulting as follows: Arthur Williams, president; F. W. Smith, vice-president; Harvey Robinson, secretary; Day Baker, treasurer; William H. Blood, Jr., P. D. Wagoner, G. N. Kelley, and E. S. Mansfield, executive officers for 3 years and William G. Bee for 1 year to fill an unexpired term. Papers were then presented as follows: Frank W. Smith on The National Co-operative Advertising Campaign of the Electric Vehicle Association of America; Dr. Harold Pender and H. F. Thompson, on Notes on the Cost of Motor Trucking; and Bruce Ford, on Some Recent Developments in the Lead Battery for Electric Vehicles.

The second day's session was called to order by the new president, Arthur Williams. Ex-President Blood took the floor and declared that the members who were refusing business were making a mistake and he further contended that every manufacturer of electric vehicles should have ample capital to increase his plant to meet orders. Stephen G. Thompson then delivered a talk on The Future of the Electric Vehicle in the East. He said among other things: "The industry is steadily gaining ground in its proportion to the total number of commercial vehicles in use. The reason for this is not far to seek, in that the market for commercial power wagons is found to be in those states that are the most densely populated. In New York, Pennsylvania, Illinois, California, Ohio, Massachusetts, Michigan and New Jersey, with a total population of nearly 40,000,000 people, more than 20,000 commercial vehicles are in daily operation, these states leading all the others in rank of population in cities of 25,000 inhabitants and more. Logically, therefore, the future of the electric vehicle lies in the East, this being the section of the densest population and hence of the most extensive street freight movement."

E. S. Foljambe presented a paper on the progress of the commercial vehicle in America with especial reference to the electric truck. He said: "The production of commercial vehicles has now reached the stage where the number in use will probably be doubled in 1 year. Taking the 30,000 commercial vehicles in use in 1912 as a basis it is safe to estimate that the production of these vehicles will exceed 40,000 during next year, more than doubling in 1 year the total number of trucks in daily use. It is impossible to ascertain the exact number of electric vehicles which have been produced, but estimates place the number of electric trucks between 7,000 and 8,000." He then advocated more advertising by the makers stating that much of the success of the gasoline cars was due to this feature. R. E. Russell then read a paper on Electric Vehicle Battery Charging Apparatus that was illustrated by different forms of appliances for this purpose.

Alexander Churchward opened the afternoon session with a paper on The Standardization of the Electric Vehicle. He stated that the speed of such vehicles had been increased from year to year because of the demand of the owners for faster machines. He said that he believed that a speed of 25 miles an hour was too high for a machine capable of easy control by a woman or child where the brake strain is 56 per cent. greater than at 20 miles an hour. He said that the manufacturers should agree on a standard maximum speed. This should apply, also to the commercial vehicles. Carl H. Clark then read a paper on The Electric Vehicle from an Insurance Standpoint, in which he brought out the fact that much caution and care is being taken now in wiring such vehicles, reducing the possibilities of fire in the trucks now being manufactured to a minor degree. Harold H. Smith then read a paper on The Edison Storage Battery in Service.

The convention then adopted a standard plug for charging, and also a standard bayonet lamp socket to be used in the future on all electric vehicles constructed. The convention also recommended that a flat rate be charged for garaging and a kilowatt hour charge for current be used in the future. The convention ended with a theater party in the evening. Many of the members remained here throughout th week attending the Electric Show now going on in Mechanics' Building.

New York Electrical Exposition Larger Than Ever

THE Electrical Exposition of 1912 opened at the Grand Central Palace on October 9 and will continue until October 19. In its general scope it is larger and more complete than any of its predecessors, but in the way of automobile trucks and pleasure cars the representation is not so large as has graced a number of former shows.

Ten companies are exhibiting. One company failed to receive its show car in time for installation. The exhibitors are as follows:

Anderson Electric Car Company, Detroit: Detroit electric pleasure cars.

Atlantic Vehicle Company, Newark: Two models of trucks.

Baker Vehicle Company, Cleveland: Pleasure cars and 2-ton trucks.

Champion Electric Vehicle Company, New York: 750-pound wagon and 1-ton truck.

Buffalo Electric Vehicle Company: Buffalo electrics.

General Motors Truck Company, Pontiac, Mich.: Model 5-ton truck.

General Vehicle Company, Long Island City: Trucks of assorted sizes.

The Lansden Company, Newark: Municipal and commercial trucks.

The Studebaker Corporation, Detroit: Assorted trucks.

Ward Motor Vehicle Company, New York: 1,000-pound wagon and 1-ton truck.

All told there are ten models of pleasure automobiles representing the Anderson, Baker and Buffalo companies. The line of trucks is more complete, consisting of eighteen models made by eight companies.

An important feature of the exhibition is the testing track that has been established on the third floor. The three companies showing pleasure cars have one or more of their cars assigned to the testing floor and running demonstrations are given at each session. In connection with this feature of the show there has been installed a treadmill arrangement upon which novices can be schooled in the first principles of operation.

The attendance on opening day was excellent, it being estimated at well over 5,000 and all of the automobile exhibitors were kept busy explaining the qualities of their wares.

While storage batteries were in evidence and many designs adapted for automobile uses were exhibited, an inspection of this department of the show brought out the fact that the line of 1913 products is practically identical with what the makers offered for the year of 1912. No improvements to speak of have been made in lead batteries, and the same refers to the non-sulphuric type of accumulators. The exhibitors of batteries were: Edison Storage Battery Company, Orange, N. J.; Gould Storage Battery Company, New York City; Philadelphia Storage Battery Company, Philadelphia, Pa.; Electric Storage Battery Company, Philadelphia, Pa.

Other exhibits of interest to automobile engineers and owners were the lighting equipments of the Wagner Electric Manufacturing Company, St. Louis, Mo., and the Universal Electric Welding Company, Long Island City, N. Y.

Investigation of Relative Costs

What will probably prove a most important factor in the impartial and scientific calculation of delivery costs is the investigation now being carried on by the Massachusetts Institute of Technology of the relative costs of horse, gasoline and electric delivery service. Findings of these researches have been published from time to time within the last 6 months, and while absolutely conclusive and satisfactory for the engineer and technical man, the results have not yet reached the stage where the public at large appreciates their importance.

At the Electrical Exposition and Automobile Show of 1912, as part of an engineering exhibit showing facts of interest in regard to central station service, certain figures given out by the technology researchers are presented in graphic form. An effective color scheme is also employed to carry home to the average spectator the essential facts of delivery service cost, whether by horse, gasoline truck or electric vehicle service.

In comparing the cost of gasoline and electric vehicle delivery, a 10,000-pound truck is used as the standard and the cost is divided under three headings, fixed charges, maintenance and operating, designated by three colors, and reckoned in cents per mile of travel. Thus for the electric vehicle the fixed charge is 10 cents, the maintenance 15, and operating 22, making a sum total of 47. For the 10,000-pound gasoline truck, the sum total is 61, of which 17 is assigned as fixed charge, 18 for maintenance, and 26 comes under the heading of operating.

Horse delivery is calculated on a basis of cost in cents per trip, for a two-horse wagon. This, however, includes the cost of three horses, allowed as necessary to keep a two-horse team in daily working condition. Here the fixed charge becomes a little more than 1 cent a trip, the maintenance drops below that sum, while the operating cost rises to 6 cents per trip. This chart, however, does not attempt to show the comparative amount of territory covered by the horse team in contrast to the trucks.

In another group of charts, the subject of package delivery is taken separately. Here the cost is reckoned in cents per mile with a 1,000-pound gasoline and electric wagon respectively. The same divisions of fixed charges, maintenance and operating costs are continued. In package delivery service, one learns that the fixed charge in cents per mile for a ½-ton gasoline wagon is 6.5, maintenance is 4.5 and operating cost about 20. For the same weight electric truck, the fixed charge is 5 cents, maintenance 4.5 and operating about 14. With a horse-drawn wagon, allowing two horses for daily work, the cost in cents per delivery comes under 8 cents, and is divided into 1 cent for fixed charge, 3 cents for maintenance and 6 cents for operating. Here again no attempt is made to compare the amount of territory which the motor trucks would cover in excess of that traversed by a one-horse team.

70,000 at St. Louis Show

Record Attendance Marks Most Successful Automobile Exhibition Ever Held in the Mound City

Automobiles, Trucks and Accessories Worth $1,000,000 on View—200 Cars Sold Outright

ST. LOUIS, Oct. 14—With a record attendance reaching a grand total of approximately 70,000 the most successful show ever held in this city closed tonight. It was given by the St. Louis Automobile Manufacturers and Dealers' Association. The $1,000,000 display of pleasure cars, trucks and commercial vehicles, accessories and tires attracted visitors from all parts of the Middle West.

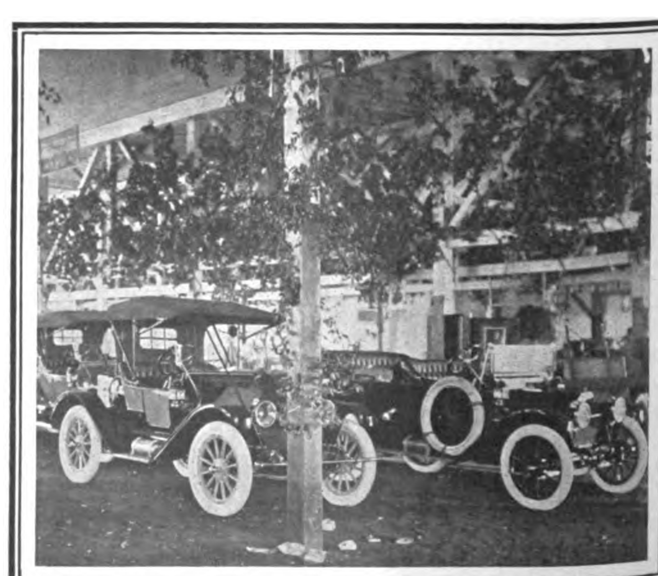
The exhibits included 300 1913 models of seventy makes of pleasure cars and more than sixty models of commercial vehicles were displayed.

As a business getter for the exhibitors the show has been unsurpassed. The public repaid the exhibitors for their expenditure of money, time and effort. It is estimated that 200 machines were sold outright and 3,500 prospects were acquired.

Estimates as to the amount of business that will be done in this city in the next year ranged from $9,000,000 to $15,000,000. Counting the sales which will probably be made in the St. Louis territory by St. Louis agents or sub-agents the amount of business has been estimated as high as $200,000,000. This estimate was made by one of the largest distributors of the St. Louis territory and included the larger part of Missouri, Illinois, Texas and a part of the south and southwestern states.

Negroes Lead as Alabama Chauffeurs

MONTGOMERY, ALA., Oct. 14—Only 36 per cent. of the licensed automobile drivers in this state are white. Negroes seem to have an established place in this field. This is the result of the lower wage for which they will accept the service. The average age of chauffeurs is 22 years, but two men in the state having licenses who are over 30 years of age. The average height among the 3,224 men holding licenses is 5 feet 9 inches. The average weight is 160 pounds. In order to enforce the state automobile tax more thoroughly this year every police officer in the state has been made a deputy collector of automobile licenses.



Partial view of the St. Louis, Mo., automobile show

Contest News of the Week

Twelve Entries in Phoenix and San Diego Road Races—Chicago Athletes Win Team Match Series

Disbrow Lowers Track Record at Springfield, Ill., by 2 Seconds—Also Beats 2-Mile Mark

PHOENIX, ARIZ., Oct. 14—Entries for the Desert road race closed last week with an even dozen contenders named. The list includes the following: Three Cadillacs, Buick, Franklin, two Americans, Schacht, Simplex, Hupmobile, National and Mercedes.

The Automobile Club of Southern California guaranteed only ten entries and the list leaves a margin of two contestants on the right side.

In addition to the Los Angeles cars there will be a division from San Diego, sanction for which has been given by the American Automobile Association. Under its terms the San Diego club agrees to secure at least eight entries.

The start of both divisions will be on Saturday, October 26. The Los Angeles cars will follow a route made up of certain sections used in former races but will not go to San Diego as it did last year. The San Diegans will follow a route through the southern part of San Diego and Imperial counties, skirting the Mexican line in places. The two routes join a few miles west of Yuma, where the night control has been established.

The cars will be ferried across the Colorado at Yuma and the start to Phoenix will take place the following morning. In order to smooth out any possible friction in the arrangements, the A. A. A. has ordered its Arizona representative to take charge of the contest at Yuma. Under his instructions, this official will line up the Los Angeles cars on the eastern side of the river at 5 o'clock in the morning and will start the column ahead of the San Diegans. The latter contenders will start 5 minutes after the last of the Los Angeles cars is sent away.

From Yuma to Phoenix it is likely that a wild race will ensue between the representatives of the two California cities despite the rough roads and shifting sands.

Athletes Beat Motorists in Tour

CHICAGO, Oct. 14—Winding up the 1912 series of team matches, the Chicago Athletic Association's representatives decisively defeated the Chicago Automobile Club in the fall run for the Allen S. Ray and Carleton White trophies, making the sixth victory for the Cherry Circle in the seven times the two clubs have clashed. Nine of the C. A. A.'s ten cars were perfect, while the C. A. C. had four of its ten penalized. A new scheme was tried in the run of Saturday—that of giving 5 points credit to a team for each perfect score it turned in. As the C. A. A. only had 13 points against it and was credited with 45 for nine perfect scores it won the match with a mark of 32 plus. On the other side, the C. A. C. had 263 points against it and only 30 points credit, so its score was 233 minus. Because of having the best total the C. A. A. won the Ray trophy and because of having the greater number of perfect scores it added the White cup to its already large collection.

The run was a 1-day affair instead of the usual 2, the noon control being located at the Hazelden farm of George Ade, the playwright, at Brook, Ind., a distance of 90 miles. Threatening weather the night before, when it rained hard, kept down the size of the field and so only twenty cars went to the tape. But those who did drive had a most enjoyable outing, for the sun shone, the roads dried up and it was a joy ride both ways. At Ade's the Daughters of Ruth served the luncheon and at the finish the losing team paid for the dinner at the South Shore Country Club.

Penalties exacted were mostly for stalled motors but in the case of A. M. Robbins, who got the maximum penalty of 250 points, broken shock absorbers brought on penalization that put the C. A. C. out of the running completely. It took Robbins so long to complete the repairs on the accessories that he was just reaching the noon control as the last car pulled out on the return journey.

Local Records Go at Springfield

SPRINGFIELD, ILL., Oct. 12—Two local mile track records were broken here today at the motor races held in connection with the state fair in progress this week. Louis Disbrow, driving the Simplex Zip, lowered by 2 seconds the track record for the mile of 53 1-5 seconds held by Barney Oldfield in the Blitzen Benz. Disbrow also lowered Kirscher's record for the 2 miles on this track. These were two of the nine events of the meet which were witnessed by 25,000 people. Summaries follow:

Car	Driver	Time
5-MILE—CARS 231-300 CU. IN.		
Case	Nikrent	5:34.75
White	Ulbrecht	
5-MILE—CARS 301-450 CU. IN.		
Case	Endicott	5:10
Interstate	Madden	
Stutz	Luttrell	
1 MILE AGAINST TIME		
Simplex	Disbrow	:51.20

Paraffin Carbureter Tests

Stewart-Morris Instrument Gives Excellent Results with That Fuel on 2,000-Mile R.A.C. Trial

THE following account of the R. A. C. tests made upon the Stewart-Morris paraffin carbureter is based upon an article appearing in *The Motor* (London).

The Stewart-Morris paraffin carbureter is controlled by the Stewart Precision Carbureter Company, Ltd., London, and tests on a 27.3-horsepower Pathfinder car fitted with one of these carbureters, and running on paraffin have been made recently. This is the same car which has been through the 2,000 miles R. A. C. test.

The design of the carbureter is such that while intrinsically only a single instrument, it serves a dual purpose, insomuch as one may start up for simplicity's sake with petrol, and when the engine has warmed, the petrol tap is turned off and paraffin takes the place of the more expensive fluid. There is no need for any adjustment or attention to the carbureter, beyond merely turning off the tap which cuts off the petrol supply when the engine is warm, the said tap being part of a three-way cock, so that either of the liquids may be passed to the carbureter or both cut off, according to the requirements of the case.

A basic differentiation from ordinary practice is that the suction of the engine conveyed through the ordinary induction pipe has no effect whatsoever on the delivery of the fuel from the jet and is not really intended to suck up the fuel from the jet orifice. At the base of the sectional drawing is seen a T union through which the fuel enters the circular chamber R. In the center of this circular chamber is a light rod, connected to the plunger Q, which, working in the cylinder constitutes a dashpot control. Following the small central rod up the center of the cylinder, it will be seen that it passes, at the point O, through a hole in the center of the cap P. This light rod is tapered in construction so as to constitute a tapered needle valve. It will be seen, therefore, that if we assume the presence of paraffin in the chamber R, under a certain pressure, there being no other means of escape for it, it will be sprayed out in an atomized form round the orifice surrounding the needle valve, and it will also be understood that as the needle valve rises or falls so the orifice surrounding it is increased or decreased, the action being entirely automatic. With this paraffin carbureter, the fuel is delivered under a pressure of some 4 pounds to 5 pounds to the square inch, and it is this pressure which causes the spraying of the fuel from the jet, and not the suction of the engine. The description of the operation of atomized paraffin from the pipe D follows. On the left is an opening C, through which the air which mixes with the paraffin to constitute the explosive mixture is drawn. From D the pipe runs to the exhaust manifold, enters into it, passes through a certain length of it, and on making its exit is connected again to the pipe E, situated just above D on the body of the carbureter. In this way the fuel and air are carried in a gasified state to the vaporizer, are carried bodily through the vaporizer, and come back again to the body of the carbureter as a fixed gas. Having, then, a properly mixed gas at the pipe E and entering into the space marked F, the mixing chamber. At the top of the mixing chamber is a plain valve marked J, which is accurately weighted, and in the base of the said valve there are a number of slots, so that when it is raised from its seating B, through the medium of the suction of the engine, the gas in the mixing chamber can pass through to the induction pipe in the ordinary way. The needle valve is also connected to this valve at the top, so that as the valve rises according to the suction of the engine, so the needle valve is moved in synchronized correlation, thus automatically delivering the correct proportion of fuel. To the left of the mixing chamber F is an auxiliary air-inlet valve, the control of which is effected through a link connection with the throttle valve, and this supplies a sufficient quantity of air to insure a correct mixture up to about 70 per cent. of the full power of the engine, after which a still further supply of air is allowed to enter, the control being effected either by hand or by means of the throttle-controlling mechanism.

It is, of course, the question of the extra air which is always the main feature likely to cause trouble in the design and production of a paraffin carbureter, but in the case of the new Stewart-Morris design the arrangement appears to be quite satisfactory. The suggestion has been advanced that the suction of the engine would have an effect upon the flow of the fuel, as the main air supply is drawn past the orifice through which it issues, but the orifice in question is so minute, and the pressure within so great in comparison with the suctional effort, that one may practically neglect its action. The other illustration shows the method of fitting the carbureter, and the comparative simplicity of the vaporizing media adopted, while in general dimensions the size of the carbureter itself is by no means out of the ordinary.

The R. A. C. Certificate

Certificate of Performance, No. 355, in a 2000 Miles Trial of a Stewart-Morris Paraffin Carbureter (Under the Open Competition Rules of the R. A. C.) August 30 to September 11, 1912.

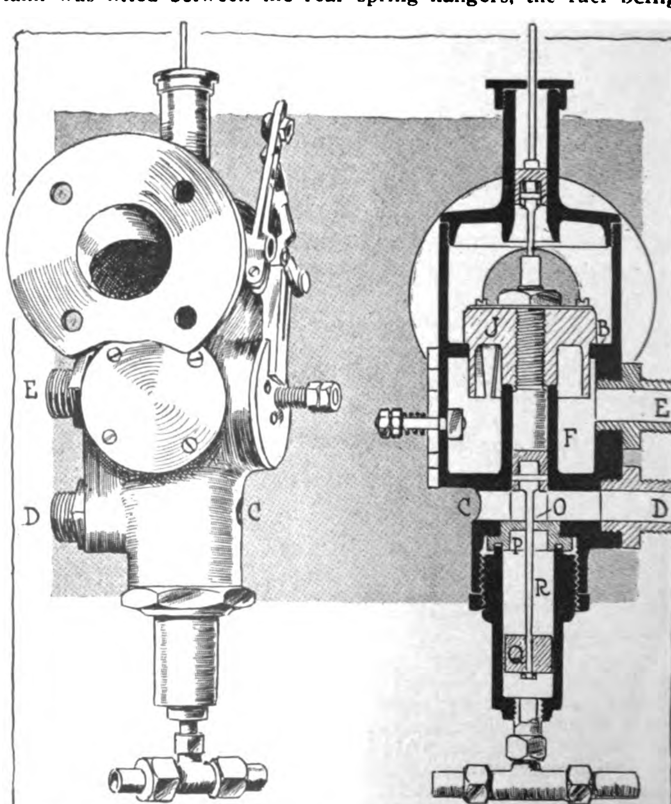
This is to certify that a Stewart-Morris paraffin carbureter was entered for trial by Messrs. The Stewart Precision Carbureter Co., Ltd., of 199, Piccadilly, London, W.

The weight of the carbureter, not including the vaporizer within the exhaust manifolds, but including the pipes leading thereto, was 9 lb.

The carbureter was fitted to a 27.3 h.p. R.A.C. rating "Pathfinder" car. The following are the particulars of the car:

Weight (front axle)	1507 pounds
Weight (back axle)	1963 pounds
Total weight	3470 pounds
Average weight of load during trial	356 pounds
Average total running weight	3826 pounds
Bore and stroke of engine	105 millimeters, 133 millimeters
Number of cylinders	4
Gear ratio on top gear	3.7 to 1
Size of tires	34 inches by 4 inches
Wind area of body	14.8 square feet

The carbureter was fitted in the usual place. The paraffin tank was fitted between the rear spring hangers, the fuel being



Section of Stewart-Morris paraffin carbureter lifted to the carbureter by pressure. The petrol for starting was carried in a small tank in the boot, the same pressure system being used for both fuels. Petrol and paraffin pipes led to a three-way cock on the heel-board, thence to the carbureter. The pressure was not sustained automatically, but by means of a hand pump. The pressure was not kept constant, but was usually between 5 and 6 pounds per square inch. It was increased when approaching any considerable hill, and was put up to 7 pounds per square inch up Sunrising Hill.

The control was by throttle and cold air lever. The latter was not used much, on an average about three times a day.

On some occasions when the engine was started on petrol a device was employed which allowed petrol to be injected into the induction pipe.

The paraffin oil was an oil marketed by Messrs. Carless, Capel and Leonard, as "Phœbus" oil. Its specific gravity was .807 at 13 degrees C.

The following is a synopsis of the ways in which the engine was started during the trial:

The engine was started direct on paraffin twenty-three times, the longest stop after which this was done being 17 minutes. On four occasions unsuccessful attempts were made to start on paraffin direct.

On nine occasions the engine was started on paraffin, petrol having previously been injected into the induction pipe, the longest stop after which this was done being 45 minutes.

The engine was started on petrol twenty-one times, the shortest period after which the fuel was changed to paraffin was 10 seconds, the longest being 4 minutes 20 seconds. The variation in this time appeared to be dependent on the duration of the previous stop. On six occasions the engine stopped when the change of fuel was made, being subsequently restarted on paraffin.

The total distance covered during the trial was 2003.3 miles, 1001.0 miles being run upon the road upon the club's six standard routes, and 1002.3 miles upon Brooklands track.

Road Trial.—The average speed (running time only) was 19.8 miles per hour. The quantity of paraffin used was 47.88 gallons, being a consumption of 20.91 miles per gallon or 35.70 ton miles per gallon. 1.05 gallons of petrol were used during the road portion of the trial.

Brooklands Tests.—The 1002.3 miles upon the track were covered at an approximately constant speed of 35 miles per hour. The paraffin consumed was 46.41 gallons, being a consumption of 21.59 miles per gallon or 36.88 ton miles per gallon. 0.76 gallons of petrol were used during the track portion of the trial.

Slow Engine Speed Test.—The engine was run idle for 10 minutes on paraffin at an average speed of 352 revolutions per minute. The speed during this time was very regular, and no misfiring was apparent. At the end of this period the throttle was opened to its fullest extent as quickly as possible, the ignition at the same time being advanced more slowly. The engine accelerated regularly without hesitation or misfiring.

Slow Car Speed Test.—The car was driven on paraffin, on top gear for 1.5 mile at 6.14 miles per hour, the speed being kept as constant as possible. The car was then accelerated, 39.2 miles per hour being attained in 51 seconds. The engine fired regularly during the slow running except during the last 200 yards, when there was occasional misfiring.

Consumption Tests.—The following tests of the consumption of paraffin were taken:

Speed Miles per hour	Consumption Miles per gallon	Ton-mile per gallon
10.6	23.12	39.43
14.9	23.81	40.66
20.1	26.69	45.58
25.2	27.19	46.44
30.45	23.94	40.89
35.8	17.45	29.81

Hill Test.—The car was timed up the test hill, the speed being 11.16 miles per hour. The weight of the car and load in this test was 3,557 pounds.

Condition After Trial.—At the conclusion of the trial the cylinders of the engine were removed. There was a somewhat considerable amount of deposit upon the piston heads of No. 1 and No. 4 cylinders, while that on the piston heads of No. 2 and No. 3 cylinders was not so great. The cylinder heads and valve ports had slight deposit, but were somewhat sooty. The valves had no deposit, but were somewhat sooty. The sparking plugs were somewhat sooty. The engine showed signs of over-lubrication.

General Remarks.—Throughout the trial there was no misfiring with the exception of that mentioned above in the slow car speed test. During the trial 1 minute and 1 4-5 seconds was taken to check the adjusting nuts of the taper needle. With this exception no work was done upon the carbureter or upon the engine. The fuel pressure was at that time 4.5 pounds.

The temperature of the cooling water was taken at midday each day, and was found to vary between 94°C. and 96°C.

Throughout the trial the engine was stopped by turning off the fuel supply and not by switching off.

Harking Back a Decade

What the Motoring Publications of 10 Years Ago Had To Say on Live Matters of the Day

FROM *The Automobile and Motor Review*, October 11, 1902: The Peerless racing car that appeared recently at Brighton Beach was the first 1903 model to be introduced in New York. The motor has two cylinders, 4 1-2 inches in bore by 5 1-2 inches stroke. It is equipped with sliding gears in the transmission in place of the small individual clutches formerly used.

Word comes from Paris that William K. Vanderbilt, Jr., is now backing the manufacturing operations of Leon Bolee, the French constructor, who is engaged in building a small number of automobiles of the Daimler-Mercedes type intended for the American market and listed at $6,000 each.

In the recent British reliability trials, the honors in the steam division must be accorded White 29, a 6-horsepower car driven by Mr. White himself. The car finished with a clean score, being credited with the maximum number of points, 1,800, for the whole test.

The hilly and roughly paved streets of Baltimore are probably accountable for the lack of progress that has been made in that city by the automobile so far. There are only about seventy automobiles owned in the city.

California and the whole Pacific Coast has shown a wide interest in the automobile. The Golden State Automobile Company is preparing to manufacture an 8-horsepower car at San José. The motor will be of the double-opposed type and the transmission will be by rawhide pinion and iron gears, so that it will be noiseless.

Exports from New York for the week ended October 4 amounted to $4,000. This is a considerable falling off from recent weeks.

At the Republican convention at Saratoga September 24, a plank for the platform of the party in the State of New York was adopted urging the construction and maintenance of good roads.

The annual reliability run of the Automobile Club of America started from New York on Wednesday last and will be completed next week. Additional entries were received, bringing the total number to seventy-nine. Tuesday was spent in weighing the cars. A full report of the run will appear in next week's issue.

Frederick H. Elliott, secretary of the Automobile Club of Syracuse, will soon resume his work of organizing a New York state association of automobile clubs. The object of the state body will be to prevent hostile legislation. In speaking of the persecution to which automobilists are frequently subjected, Mr. Elliott said: "There are very few persons, either peace officers or plain citizens who are capable of telling how fast an automobile is going. Consequently testimony based upon conclusions of witnesses incapable of judging the facts must be unreliable."

Informal applications for space at the Chicago show, which will be held in February, number fourteen. The diagrams will be issued next week and allotments will be made October 15.

The Peerless Motor Company, of Cleveland, has filed incorporation papers in West Virginia. The capitalization is placed at $300,000. I. M. Blanchard, L. H. Kittredge, John McGregor, Jr., F. A. Quail and G. B. Slidell, of Cleveland, are incorporators.

H. Ward Leonard, formerly third vice-president of the National Association of Automobile Manufacturers, has been elected first vice-president to succeed A. L. Riker. Frederic Martin Lande was chosen second vice-president. Charles Clifton was made third vice-president. Harry Unwin was made secretary and Windsor T. White has been elected a director.

Disco Electric Starter

Two-Unit System Including Motor, Generator and Storage Battery Adopted in Addition to Acetylene Type

THE new Disco starter is of the electric type. For some time the Ignition Starter Company, of Detroit, Mich., has been well known for its activities in the acetylene starter field and it is with great interest that the construction of the new device may be noted because it is the first time that a concern which has been devoted to the acetylene starter has included one of he rival type in its line. Both types of starter will be carried in future by this concern which has recently improved its acetylene product and brought it out under the name of the 1913 model Disco.

A two-unit system is used for starting, lighting and ignition. The system is complete in that no other electric apparatus is necessary when the entire Disco system is employed. All the electric functions throughout the car are taken care of and the system is made automatic as near as it is possible for an electric starting, lighting and ignition system to be. The apparatus consists primarily of a dynamo, a motor and a storage battery. Suitable connections and electric devices for automatically regulating these three principal units form the remainder of the system.

The electric motor has no other purpose than to start the motor. It is mounted on the side of the crankcase and connected by gearing to the flywheel. The amount of reduction between the motor and the flywheel depends upon the size of the motor to be started and the compression pressure against which the motor has to pull. In the test motor at the Disco works, which has a bore of 4 7-8 inches and a stroke of 6 inches, with a compression pressure of 75 pounds, the total reduction between the motor and the flywheel is twenty to one. On a motor of lower compression or smaller size, the reduction would not have to be so great. The ratio of reduction is variable as is the method of mounting the starting motor upon the structure of the crankcase of the automobile motor. To take the motor the flywheel will have to be geared in the same manner as is common with the electric systems now found on the market.

The amount of current consumed by the motor when starting the engine will vary with the motor upon which the starting system is applied. On the larger six or four-cylinder motors the amperage which will be drawn when starting the motor will be much higher than in the smaller type. For instance with a motor of 4 1-2 inches bore and 5 1-2 inches stroke having a compression pressure of 60 pounds which is common in ordinary touring practice the motor will draw 65 amperes when spinning the flywheel at the rate of 120 revolutions per minute. On a heavier motor the amperage will rise considerably as may be expected from the added effort necessary in producing the turning moment on the geared periphery of the flywheel. To take an example of a heavier motor the current required with a bore of 4 7-8 inches and a stroke of 6 inches is 90 amperes when turning the flywheel 110 revolutions per minute. In the latter case the gear reduction was twenty to one as mentioned above which gave a speed of 2,200 revolutions per minute to the starting motor.

It must be remembered when estimating the current required with an electric starting motor that everything depends upon how stiff the motor is, whether it is to be started dead cold or whether the motor has just been stopped after a long run. Carburetion difficulties under adverse climatic conditions will necessitate a longer spinning of the motor than when everything is favorable for a quick start. No compression release is required with the Disco electric system which is powerful enough to start the motor against full compression.

The voltage question is another upon which the makers of electric starters do not seem to agree. The Disco system works entirely at 12 volts. This is a very practical voltage in that the lighting system is readily handled with it. The ignition system which generally works at 6 volts through the primary circuit can also be adequately taken care of by a 12-volt system. The starting motor is made only in the 12-volt size. It is series wound and can be connected by any means desired to the flywheel of the large motor. The electric starting motor is illustrated in Figs. 1 and 2. The latter illustration shows the plan view with the only two wires required in its operation while the elevation is given in Fig. 1.

The generator is entirely automatic in its action. It is cut into the storage battery when the motor speed has reached a point that approximates a rate of 7 miles per hour of the vehicle when running on direct, at a reduction of about three to one to the driving wheels. Below this speed there is no connection between the battery and the dynamo so that there is no possibility of the storage battery discharging back through the generator when the car is standing at the curb. The current for the lamps and the ignition, if the motor is running idle, is furnished at this time by the storage battery. The charging curve of the dynamo commences at a 7-mile an hour vehicle speed and continues to rise until it reaches a maximum at about 15 miles per hour. At this point it starts to flatten, the slope of the curve gradually becoming more slight and at 25 miles an hour it drops off. The charging curve can be varied, however, and can be made to suit conditions by the manufacturers who adapt the system to the vehicle upon which it is to be placed.

The switch which automatically cuts the generator into the battery circuit and out again when it does not produce a sufficient current to charge the storage battery, is regulated entirely by armature reaction and not by the actual speed of the motor except that the latter will govern the reaction. By this means, however, the tendency for the switch to be continually cutting in and out when the speed of the vehicle closely approximates 7 miles per hour, is obviated to a large extent.

The batteries are carried in the usual manner beneath the frame of the car. A voltage of 12 is required and this condition can be filled by a battery which will be light and yet have a sufficient current capacity to light the lamps for a long time, when the motor is not running. The ignition feature is optional and may be added to the starting system if desired by the purchaser. When the ignition feature of the Disco electric system is omitted it will not in any way interfere with the other units which are connected up in the same manner as they would have been had the wiring been taken from the storage battery.

The Disco people have not brought out this starting system suddenly. They have been working upon it vigorously during the past year and were among the first to recognize the commercial value of a high grade electric starting and lighting system. The units have been carefully refined and it will no doubt be one of the highest priced outfits upon the American market at the present time.

British Retain Tax Rating

Committee Appointed by the Treasury Finds Present Horsepower Taxing System Satisfactory

LONDON, ENG., Oct. 11—The committee appointed by the treasury in order to investigate the horsepower rating of automobiles has now issued its report. The committee was appointed on December 6, 1911, with the following reference:

To consider the provisional regulations which have been made under section 86 (2) of the finance (1909-10) act for determining the horsepower of motor cars, and to report whether any amendments are desirable, with special reference to the equitable treatment of steam cars and electric cars.

The committee has held a number of meetings, and has had before it seventeen witnesses representing manufacturers, and the various institutions and societies in connection with the motor car industry. The main point to be considered by the committee related to the effect of stroke bore ratio, a topic which has been much discussed in recent years by various societies and institutions concerned in the manufacture of motor cars. For example, according to one formula put forward by the Society of Automobile Engineers based upon a large number of engines, the power of an engine of which the bore and stroke are equal should be 33 per cent. less than an engine of similar bore in which the ratio of stroke to bore is 2 to 1. The recommendation of the committee, after hearing the whole of the evidence, is that the present rating now enforced be retained as regards the taxation of motor vehicles. The committee believes that the majority of those interested in the manufacture of motor cars are in favor of this course, not only because the method of rating is substantially fair as between one car and another, but also because any change of system would lead to a great deal of inconvenience to persons who have made arrangements for manufacturing or dealing in cars in classes suggested by the present system. In view of the fact that an engine with a longer stroke consumes more gasoline by reason of developing more power, therefore this engine pays an additional tax on gasoline.

With regard to old cars, a number of witnesses represented that the horsepower of cars made a number of years ago was considerably less than that of modern cars of the same rating. A grievance is undoubtedly felt by many owners by reason of the high tax on a car of little value. The committee however, has not considered it within its province to make any recommendation as to the taxation of cars which have depreciated in value in the ordinary way.

Steam cars have hitherto been taxed in the same manner as the petrol car, that is the steam engine in a car is taken as equal to that of the petrol engine having equal cylinder area, and where the engine is double acting the rating is correspondingly increased. Since the real horsepower is independent of the engine dimensions, and depends solely on the boiler, the regulations now in force are obviously incorrect. The committee recommends that in regard to steam cars 3 square feet of heating surface should be taken as equivalent to 2 square inches of piston area, which may be regarded as giving 1 horsepower in a gas engine.

The number of electric motor cars is comparatively small, and are all used in this country for one kind of service, namely, town work. Most of these vehicles are fitted with motors rating at 8 horsepower, and as the result of experiments carried out by the committee it is found that at 20 miles per hour about 7 1-2 horsepower has been used. They are of the opinion that these cars can be described with sufficient accuracy as exceeding 6 1-2 but not exceeding 12 horsepower, and recommend that the regulations dealing with them be amended accordingly.

The substance of recommendations of the committee is most conveniently summarized in the form of the following regulations for the determination of horsepower, which might, in the opinion of the committee, take the place of the provisional regulations now in force:

1. For the purpose of these regulations the horsepower of any motor car deriving its motive power wholly from an internal combustion engine worked by a cylinder or cylinders shall be taken to be:

(a) in the case of a single cylinder engine the horsepower attributed to the cylinder of the engine;
(b) in the case of an engine having two or more cylinders the sum of the horsepowers attributable to the separate cylinders.

2. The horsepower attributable to any cylinder of an internal combustion engine shall be deemed to be equal to the square of the internal diameter of such cylinder measured in inches divided by a numeral.

(a) in the case of a single-acting cylinder having a single piston, the numeral used as divisor shall be 2.5;
(b) in the case of a single-acting cylinder having two pistons, the numeral used as divisor shall be 1.6.

3. The horsepower of any motor car deriving its power wholly from a steam engine shall be taken to be proportional to the effective heating surface of the boiler supplying steam to such an engine, at the rate of 1 horsepower for every 3 square feet in such effective heating surface, and the effective heating surface shall be taken to be:

(a) in the case of a boiler having horizontal or approximately horizontal tubes, the whole of the surface of the tubes which is exposed to the flame or hot gases;
(b) in the case of a boiler having vertical or approximately vertical tubes, half of that surface of the tubes which is exposed to the flame or hot gases.

4. Any motor car deriving its motive power from an electric motor or motors shall be deemed to be of a horsepower exceeding 6 1-2 but not exceeding 12.

5. In measuring cylinders and boilers, and in calculating horsepower, fractions of inches and feet and fractions of a unit of horsepower are to be taken into account.

6. Where it appears that in consequence of the exceptional design or construction of the engine of any motor car the horsepower as calculated under the preceding rules is substantially less than the average power which the engine would develop in continuous use on the road if there were no restrictions on speed other than those imposed by the car itself, then such average power shall be taken as the power.

EDMONTON, ALTA., Oct. 14—Statistics compiled from government reports show that in comparison to population Alberta has more automobiles than any other province in the Dominion of Canada, there being 300 cars or one to every 124 persons, estimating the population at 374,663. Manitoba is second, having one car to every 152 persons of its population of 445,614, while British Columbia has third place, reporting one automobile for every 165 persons of a population of 392,480.

Saskatchewan is fourth. It has 2,537 cars, or one for each 194 persons of its population of 492,432. Ontario has the largest number of cars reporting 7,338, or one for each 344 of a population of 2,523,208. Nova Scotia has the smallest number of automobiles, there being one to each 852 of its population, which is placed at 492,338. New Brunswick with a population of 351,889 has 594 automobiles.

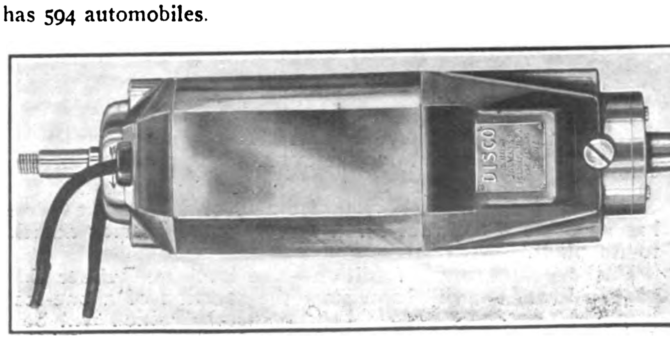

Fig. 2—Plan view of Disco electric starting-motor

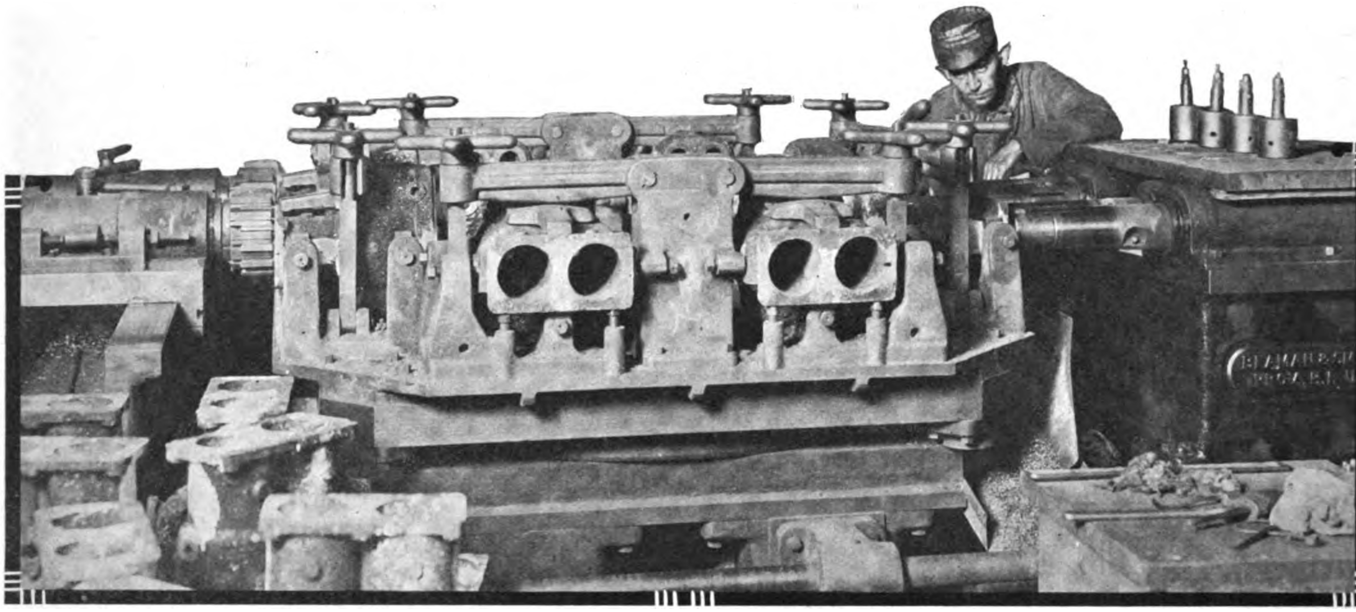
Factory Miscellany



Machine built especially for use in the shops of the Packard Motor Car Company, Detroit, Mich., for boring and milling cylinders

Made specially for the Packard shops, the machine shown in the above illustration is more than justifying the expense which must necessarily be connected with the design and manufacture of a special machine. The particular work which this large machine takes care of is the boring and milling of cylinders. The large turntable which holds the work in its proper place takes eight cylinder castings at a time, that is to say, sixteen individual cylinders. This machine completely mills, bores and faces eight complete cylinder castings in 10 minutes. It can be operated steadily throughout a working day and during that time will turn out 60 complete jobs. The machine is operated by two men, one of whom takes care of the setting up of the work, while the other operates the mechanism connected with the machine. The latter operation consists in changing cutters and stopping and starting the mechanism after each new job is ready for the milling and boring operation. The lubrication and general care of the machine can also be taken care of by the second man, while the man who sets up the work can do this so rapidly that it does not interfere in any way with the steady manipulation of the machine. When this machine finishes its work a quick shift is made to a second milling table where ports, intakes and exhaust openings are milled to gauge. Altogether the arrangement is a great time-saving factor.

MERCHANTS Visit Kissel Factory—The Milwaukee Merchants and Manufacturers' Association recently made a pilgrimage to the main plant of the Kissel Motor Car Company, Hartford, Wis. As the company is about to establish a branch factory in Milwaukee, Wis., the visit was of particular interest to the business men who made the trip. Twenty-four cars met the party at the station and took them to the company's plant, where they were able to observe the building of automobiles at the height of the busy season. The accompanying photograph shows the party assembled before the factory.

Jackson's Factory Plans—The Jackson Motor Car Company, Jackson, Mich., contemplates erecting a branch factory, to cost approximately $200,000.

Planning Krit Addition—The Krit Motor Car Company, Detroit, Mich., is having plans prepared for the erection of an addition to the company's plant.

Rauch & Lang's Addition—The Rauch & Lang Carriage Company, Cleveland, O., builder of electric automobiles, will erect a large addition to its plant.

Prest-O-Lite Enlarges—The Prest-O-Lite Company, Minneapolis, Minn., has bought property 80 feet by 336 feet in St. Paul, Minn., for $8,000, and will enlarge.

Julian Company Builds—The Julian Motor Company, Syracuse, N. Y., has commenced construction of its new plant for the manufacture of automobile engines and marine motors.

Detroit Company's Plant—The Parish Manufacturing Company, Detroit, Mich., manufacturer of automobile frames, has awarded a contract for the erection of a brick addition to its plant.

Buckeye Company's Addition—The Buckeye Rubber Company, Akron, O., will soon start the erection of a one-story brick and concrete addition to its factory, which will be 40 feet by 120 feet.

Moon's 1912 Additions—In the past season many additions were made to the factory of the Moon Motor Car Company, St. Louis, Mo., increasing its capacity 65 per cent. Further additions are now being made and a very great amount of new machinery is being installed.

Walloff Establishes Plant—The Walloff Motor Truck Company, Minneapolis, Minn., in consideration of receiving a free site and free gas, has undertaken to establish a plant at Redcliff, Alta., for the manufacture of motor trucks and automobiles. The main building will be 60 feet by 150 feet.

Willard Company Buys—The Willard Storage Battery Company, Cleveland, O., has purchased the real estate and three-story brick and stone building formerly occupied by the Frost Wire Fence Company of that city. The building affords the company 50,000 additional square feet of space.

Vinot's Montreal Plant—A site has been selected in the east end of Montreal, Can., by the Vinot Car Company of Canada, and it is expected that it will be possible to turn out the finished product in the spring. The local company has a working agreement with the Vinot Car Company of France and will be helped materially through this connection.

Ford's Scientific Management—Revolutionary steps along the line of scientific management of its factory are being taken by the Ford Motor Company, Detroit, Mich. It is striving to eliminate every waste motion of its employees and all superfluous space in its buildings. Its latest move toward that end is the abandonment to a large extent of its storerooms.

Ford's Walkerville Progress—The Ford Motor Company, Walkerville, Ont., has more than doubled its production each year since 1909. The plant is being greatly enlarged. A big gas producer engine is being installed, the machine shop is being increased and every other department is being increased in proportion. This is being done to take care of the estimated production of 15,000 cars for the coming year.

Calendar of Coming Automobile Events

Shows, Conventions, Etc.

Jan. 2-10	New York City, Importers' Salon, Hotel Astor, Importers' Automobile Alliance.
Jan. 4-11	Cleveland, O., Annual Automobile Show.
Jan. 4-11	Montreal, Que., Montreal Motor Show, Drill Hall and 65th Regiment Armory.
Jan. 11-25	New York City, Thirteenth Annual Show, Madison Square Garden and Grand Central Palace, Automobile Board of Trade.
Jan. 20-25	Philadelphia, Pa., Annual Automobile Show.
Jan. 25-Feb. 1	Montreal, Que., Automobile Exhibition, R. M. Jaffray, Manager.
Jan. 27-Feb. 1	Detroit, Mich., Annual Automobile Show.
Jan. 27-Feb. 1	Scranton, Pa., Annual Automobile Show, Hugh B. Andrews.
Feb. 1-8	Chicago, Ill., Annual Automobile Show.
Feb. 10-15	Minneapolis, Minn., Annual Automobile Show.
Feb. 11-15	Ottawa, Ont., Annual Automobile Show.
Feb. 17-22	Kansas City, Kan., Annual Automobile Show.
Feb. 24-Mar. 1	Cincinnati, O., Annual Show, Music Hall, Cincinnati Automobile Dealers' Association.
Feb. 24-Mar. 1	Omaha, Neb., Annual Automobile Show.
Feb. 24-Mar. 1	St. Louis, Mo., Annual Automobile Show.
March 3-8	Pittsburgh, Pa., Annual Automobile Show.
March 8-15	Boston, Mass., Annual Automobile Show.
March 17-22	Buffalo, N. Y., Annual Automobile Show.
March 19-26	Boston, Mass., Annual Truck Show.
March 24-29	Indianapolis, Ind., Annual Automobile Show.

Race Meets, Runs, Hill Climbs, Etc.

Oct. 19	Track, Brighton Beach, N. Y., Motor Dealers' Exhibit Company.
Oct. 19	Salem, N. H., Track Races, Rockingham Park.
Oct. 19	Narberth, Pa., Track Races.
Oct. 19	Fort Smith, Ark., Ft. Smith-Van Buren Automobile Club.
Oct. 21-25	Reliability Run, Chicago Motor Club.
Oct. 24-26-27	Track—San Antonio, Tex., San Antonio Auto Club.
Oct. 26	Track—York, Pa., York Motor Club.
Oct. 26-28	Los Angeles to Phoenix Road Race, Maricopa Auto Club.
Oct. 31	Track—Phoenix, Ariz., Maricopa Auto Club.

Proposed Contests

Oct. 19	Hartford, Conn., Races, E. W. Powell.
Oct. 26	Track—White Plains, N. Y., Geo. T. Long.
Nov. 3-5-6	Track—Shreveport, La., Shreveport Auto Club.
Nov. 15-16	Track—Richmond, Va., Richmond Automobile Club.
Nov. 28	Road Race—Visalia, Cal., W. H. Lipton.

Kelly Enlarges Plant—The Kelly Motor Truck Company, New York City, has been refinanced with a capital stock of $4,000,000, which means the enlargement of its plant.

Packard Building Addition—The Packard Motor Car Company, Detroit, Mich., is erecting a new factory building at its plant on Harper street and the Boulevard.

Mathiesen Company's Plant—The Mathiesen Spring Cushion Wheel Company, San Antonio, Tex., will install a plant at that city for the manufacture of spring cushion automobile wheels.

Plans Accessory Factory—The Ernest Lee Machine Company, Cleveland, O., has plans for an automobile accessory factory to cost $15 000. It is to be one story high, of brick and 100 feet by 320 feet.

Cheverlot's Flint Addition—The Cheverlot Motor Company, Detroit, Mich., has secured a site in Flint, Mich., and will erect a factory for the manufacturing of automobile bodies, to cost $50,000.

Hall's $17,000 Addition—The C. M. Hall Lamp Company, Detroit, manufacturer of automobile lamps, has taken out a building permit covering the erection of a two-story addition to its plant to cost $17,000.

Ross & Young's Plant—The Ross & Young Machine Company, Detroit, Mich., has acquired a site 100 feet by 200 feet, and will, it is stated, erect a new factory. The company manufactures automobile engines.

Wheel Company's Factory—The Ideal Steel Wheel Company, Cincinnati, O., makers of a new automobile wheel, will close a deal for a factory within a very short time. The transaction will involve about $30,000.

Oakland Makes 11,500 Cars—The Oakland Motor Car Company, Pontiac, Mich., plans to make 11,500 cars for 1913, necessitating a number of factory additions. A total of 300,000 square feet of space will be added.

Poppenberg's Seven-Story Building—The Poppenberg Motor Car Company, Buffalo, N. Y., has completed plans for the construction of a seven-story building at the corner of Main and Carlton streets, that city.

Building New Car—A. G. Bayerline has secured manufacturing space in the plant of the King Motor Car Company, Detroit, Mich., where he is at work on the car which he will shortly introduce to the automobile world.

Electric Company Starts—The new factory building and sales branch of the Buffalo, N. Y., Electric Vehicle Company were formally opened recently. Electric roadsters and coupés equipped with wire wheels were on exhibition.

U. S. Tire Company Busy—All of the United States Tire Company's plants will be operated during the coming winter on full summer schedule. This means that they will be run night and day, three shifts of workmen being employed.

General Vehicle Builds—The General Vehicle Company, Long Island, N. Y., manufacturers of automobiles, is receiving bids for the construction of a new factory, to be six stories high and 327 feet by 75 feet. The estimated cost is $50,000.

Factory in Hyde Park—The Lenox Motor Car Company, Boston, Mass., has increased its business so that it has outgrown its present quarters in Boston, and so a factory has been secured at Hyde Park, Mass., in which to build the product, the Boston plant being used as a service station for Lenox owners.

Inaugurate 9-Hour Workday—The Aluminum Castings Company has inaugurated a 9-hour workday schedule at its Manitowoc, Wis., plant, which is devoted to the manufacture of castings for the automobile industry. The wage schedule has been changed so that employees receive wages equal to a 10-hour workday rate.

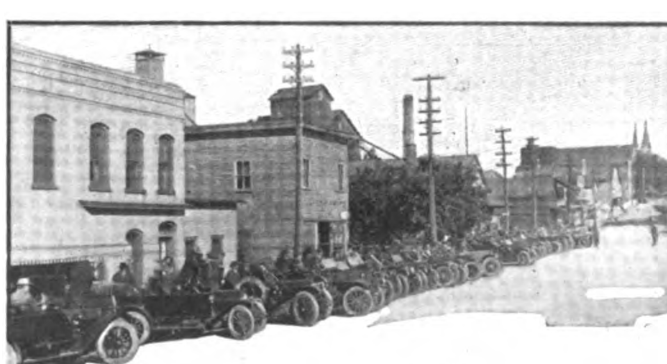
Tire Factory in St. Louis—A rubber tire manufacturing plant, to be a new industry in St. Louis, Mo., soon will be started. The concern, to be known as the St. Louis Tire and Rubber Company, will be organized in the near future. It will be capitalized at $150,000. A site for the plant already has been chosen and work will be begun as soon as possible.

Marathon's New Factory—The Marathon Tire & Rubber Company, Cuyahoga Falls, O., was recently organized for the manufacture of tires, inner tubes and a general line of rubber goods. A building is now under construction which will be 65 feet by 300 feet, and machinery will be installed as soon as possible with the expectation of beginning operations November 1.

Buy Axle Works—Thomas Walker and Superintendent Weiss, of the Weston-Mott Company, Detroit, Mich., and other associates have bought the Flint Axle Works and the firm name will be changed to the Walker-Weiss Axle Works. They will enlarge the facilities of the plant for the manufacture of automobile axles.

Rands Buy Factory—The Rands Manufacturing Company, Detroit, Mich., maker of automobile equipment, has purchased from the Pfauder Realty Company, Rochester, N. Y., the plant located at Fort and St. Antoine streets. The plant is about two-thirds the size of the fa tory now occupied by the company and will be operated as an addition to the present plant. The very latest equipment will be installed in the factory.

KisselKar Adds Plant—The Kissel Motor Car Company, of Hartford, Wis., has acquired the former Romadka trunk works on Center street, between Thirty-first and Thirty-second streets, Milwaukee, Wis., and is now converting the plant into a motor car factory which will serve as a branch of the big KisselKar works in Hartford. The Romadka Bros. Company, up to the time of its failure last spring, owned and operated one of the largest trunk and bag manufa tories in the United States, having more than 200,000 square feet of floor. Frank J. Edwards, manager for the Kissel company, states that it is proposed to use the Milwaukee branch for the production of two complete Kisselkar models.



Visit of the Milwaukee Merchants and Manufacturers Association to the plant of the Kissel Motor Car Company, Hartford, Wis.

The Chinese are beginning to yield to the lure of the American automobile. Two Overland cars arriving at Tientsin

AMERICAN Cars Abroad—Automobiles built in the United States are being shipped into every civilized country of the world. Even inhabitants of the Celestial Kingdom are becoming converts to the American machine and numbers are driving about in them at the present time. The above photograph shows the arrival of two Overland cars at Tientsin, China.

The Rittenhouse-Winterson Company, Baltimore, Md., has moved to new and larger quarters at 602 Water street.

Prest-o-Lite in Toronto—The Prest-o-Lite Company, Indianapolis, Ind., has opened a branch in Toronto, Ont.

Elmer Resigns—H. A. Elmer, president and general manager of the Grant Motor Car Company, Indianapolis, Ind., has resigned. His future plans have not yet been divulged.

Salisbury Pathfinder Manager—H. G. Salisbury, for the past few months sales manager of the Pathfinder Motor Car Company, Los Angeles, Cal., has been appointed general manager of that concern.

Baltimore's City Garage—Mayor Preston of Baltimore, Md., and the other city officials are working on a plan to establish a central city garage for storing all motor vehicles used by the municipality.

Imperial's Frisco Branch—The Imperial Automobile Company is the latest motor car manufacturer to establish a factory branch in San Francisco, Cal. G. A. Troutt will take over the Imperial interests for the entire Pacific Coast.

Purchase Tire Branch—Fred L. Harveycutter and Thornton Chesley have purchased the branch business of the Kelly-Springfield Tire Company, Washington, D. C., and will conduct it under the name of the Kelly-Springfield Tire Company.

Waite Manages Reeve Company—H. C. Waite, formerly factory manager of the G. & J. Tire Company, Indianapolis, Ind., has been appointed general manager of the Reeve Company, Providence, R. I., which concern is another subsidiary of the U. S. Rubber Goods Company.

Ordinance Strictly Enforced—The police department of Columbus, O., has issued notice that the ordinance recently enacted by the City Council providing that all automobiles must come to a full stop while passing street cars discharging passengers will be strictly enforced.

Maxwell in Toronto—The Maxwell-Stoddard Ontario Company is one of the new firms entering the automobile field in Toronto, Ont. This concern, which is the Ontario distributer for the United States Motor Company, handles the Maxwell and Stoddard-Dayton cars in Ontario.

Baltimore's Show Appointments—Messrs. John S. Bridges, Thomas G. Young, Joel G. Nassauer and Secretary H. M. Luzius has been appointed by the Automobile Club of Maryland as committee to make arrangements for the annual automobile show to be held this winter in Baltimore, Md.

Nurse Receives Automobile—The gift of an automobile tc Miss Florence Charters, visiting district nurse for the Hospital for Sick Children, Albany, N. Y., permits her to make from twenty-five to thirty daily trips, whereas by street car and walking she could visit only twelve patients a day.

Hoosier Elect Officers—Officers have been elected for the Hoosier Motor Club, Indianapolis, Ind., for the ensuing year as follows: James L. Gavin, president; Joseph R. Raub, treasurer, and W. S. Gilbreath, secretary. George Ade, the humorist, and Harold Taylor have been elected honorary members of the club.

Tire Regulations Extended—The regulations of the Treasury Department of April 22, 1912, providing for the allowance of drawback on tire treads known as Woodworth's treads, manufactured by the Leather Tire Goods Company, Niagara Falls, N. Y., in various sizes, have been extended to cover tire treads 26 by 2½, manufactured by the same company, with the use of imported hard rivets.

Boston Club Needs New Quarters—The members of the Massachusetts Automobile Club, Boston, Mass., the oldest motor organization in the Bay State, are trying to decide what to do about new quarters. The club has outgrown its present building on Boylston street and because of lack of room there is a long waiting list of prominent motorists who would like to join the club and use the garage, which is regarded as a model of its kind.

Essenkay in Houston—The Essenkay Sales Company has established an office in Houston, Tex., with H. H. Hassel as manager.

Road Bureau Established—A bureau of information has been established in Tacoma, Wash., and it is proving of great value to the touring public.

Establishes Milwaukee Auto Mart—The Auto Mart of Chicago, Ill., has established a branch at Milwaukee, Wis., with headquarters at 301-303 Watkins building.

Establishes Repair Shop—F. O. Morse has established a salesroom, garage and repair shop at 386 Brady street, Milwaukee, Wis., and will be distributor for the Crawford.

Studebaker's Mail Car—The Studebaker Corporation, South Bend, Ind., has put a test car on trial in collecting mail in Minneapolis, Minn. Services are to be given free for 60 days.

Alabama's Road Delegates—With the assembling of over 1000 delegates in Birmingham, Ala., last week at the state good roads convention, this state claims to be first in the South in good roads activity.

Lozier in St. Louis—The St. Louis Lozier Company, St. Louis, Mo., organized to take the agency for the Lozier line in that territory, has opened salesrooms in that city. Nelson S. Gottshall is in charge.

Stearns Shipments Increased—Statistics taken in July, August and September, 1912, show the shipments of the F. B. Stearns Company, Cleveland, O., to have increased 100 per cent. over the preceding year.

Does Wisconsin Business—The Galena-Signal Oil Company, a Pennsylvania corporation, capitalized at $10,000,000, has filed articles and a statement to do business in Wisconsin. The local interest is given at $10,775.

Clemens Enters Retail Business—J. Stanley Clemens, for a long time manager of the Portland, Ore., branch of Chanclor & Lyons, accessory dealers, has resigned and will enter the retail automobile business in Portland.

Ohio Affairs—The Ohio Motor Car Company, Cincinnati, O., for which a receiver was recently appointed, is being operated under the jurisdiction of the court. Every indication points to the fact that the company will be reorganized at an early date.

Changes in U. S. Tire—The following changes will take place in the United States Tire Company, Tacoma, Wash.: H. A. Farr will become manager of the Seattle branch October 1; C. H. Mayer will be promoted to the managership of the Portland, Ore., branch.

Promoting Highway Construction—An association has been formed at Lemmon, S. D., to promote construction of a highway from the twin cities to Yellowstone Park, a continuation of the Parmley road which is being built from Aberdeen to Mobridge.

Form Tire Partnership—A Weisskopf, state agent for the O'Neil Tire Protector Company, Milwaukee, Wis., and Oscar L. Bland, a well-known accessory and car man, have formed a partnership and established a general accessory and supply store in that city.

San Benito's Registration—It is claimed that no community in the United States has a greater number of automobiles for its population than San Benito, Tex. The population of San Benito is little more than 3,000 and the number of automobiles owned by the people there is 127.

Loomis Leaves Truck Business—F. L. Loomis, of Minneapolis, Minn., has left the truck manufacturing business and is looking for a line of trucks and pleasure cars. T. F. Robinson will continue the former business, which was the Robinson-Loomis Motor Truck Company, building the Gopher truck.

Alabama Receives $64,489—With the completion of Alabama's fiscal year, October 1, it is found that $64,489 was paid into the state's treasury for automobile licenses. The expense of operating the department was $9,673.35. About half of the remainder, $24,434.90, was devoted to the improvement of roads.

Fire in Specialty House—The Aluminum Specialty Company, Sixth and York streets, Manitowoc, Wis., sustained a loss by fire last week when a back fire in a gasoline engine which was being primed for starting, ignited a gasoline container, causing an explosion. The resulting fire caused only a slight inconvenience.

Error Corrected—In a recent issue an item appeared stating that the residents of Glens Falls, N. Y., addressed a petition to Governor Dix protesting against the acceptance of the new state road between Lake George and Glens Falls, and that the state executive had given assurance that the road would not be accepted until investigated. This was an error as a resident of Glens Falls states that the road had already been accepted without the Governor's knowledge.

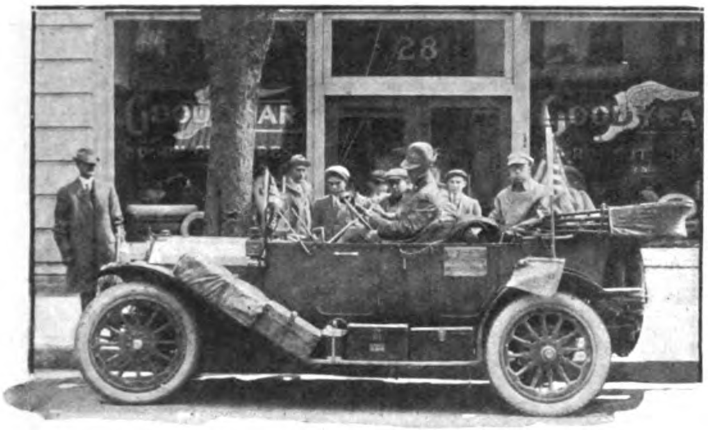
COMMERCIAL CARS

Place	Car	Agent
Boston, Mass	Atlantic	C. D. Daly
Toronto, Can	Lippard-Stewart	W. T. Butler
Vancouver, B. C.	Dayton	O. J. Fox

This car, an Overland, dashed over a 50-foot embankment at Houston, Tex., and sustained only a slight bend in one front fender. The machine was hoisted to the street with a derrick, refilled with gasoline and driven to the salesroom



A. L. Westgard in his official Pathfinder car starting from the New York branch of the Goodyear Tire & Rubber Company on his Midland Trail through Philadelphia, Reading, Harrisburg, Chambersburg, Pittsburgh, Columbus and Dayton to Indianapolis; thence to St. Louis

Forsyth with Thomas—R. L. Forsyth has been appointed sales manager of the Thomas Flyer Company, San Francisco, Cal.

Hyde with Empire—Harlow Hyde, late of the Cole Motor Car Company, Indianapolis, Ind., has been made advertising manager of the Empire Automobile Company, Indianapolis.

Denniston District Manager—E. E. Denniston has been appointed by the Stewart Motor Corporation, Buffalo, N. Y., manager for the district covering the states of Illinois, Iowa and Missouri.

New Atlanta Swinehart Manager—A. L. Talbott has been appointed manager of the Atlanta, Ga., branch of the Swinehart Tire & Rubber Company, Akron, O., succeeding C. E. Homes, who has resigned.

MacNab with Marion—M. D. MacNab has resigned as general manager of the United Motor Chicago Company, Chicago, Ill., to become vice-president of the Marion Motor Car Company, Indianapolis, Ind.

Delegates in Automobiles—No feature of the Tri-State Good Roads meeting at Mammoth Cave, Ky., was more of a success than the idea of inducing the delegates to come in automobiles. The Nashville, Tenn., delegation occupied thirty-two cars.

Carnahan District Manager—A. T. Carnahan, of the Swinehart Tire & Rubber Company, Akron, O., has been appointed district manager in charge of Ohio, West Virginia, Kentucky, western New York, western Pennsylvania and eastern Michigan.

Aid Association Formed—The employees of the Standard Tire & Rubber Company of Boston, Mass., have formed an association called the Standard Tire & Rubber Company Mutual Aid Association for the benefit of its members when they are ill and in need.

Wilby's Canadian Tour—Thomas W. Wilby and F. V. Haney, the two transcontinental motorists, who left Halifax, Nova Scotia, on August 27 for Victoria, B. C., in search of an all-Canadian highway from coast to coast, had covered 4,000 miles of the trip and had reached Nelson, B. C.

Organize Insurance Company—A number of automobile owners of Eugene, Ore., have organized a mutual insurance company known as the Oregon Automobile Mutual Fire Association. The object is for mutual protection and relief of the members against loss by fire.

Sells 2,010 Cars—On October 1 the Ford Motor Company closed its fiscal year. The Northwest branch at Seattle, Wash., under the management of R. P. Rice, handled a total of 2,010 machines during the 12 months beginning October 1, 1911, compared with 875 cars sold in 1911.

Baltimore Motorists Indignant—Baltimore, Md., motorists are indignant at the proposed scheme of Mayor Preston to pass an ordinance imposing a local license on automobiles. They declare it would be triple taxation, as they now pay the highest registration fee of any state in the Union, and in addition they pay personal tax on their cars up to their fullest value.

Bosch Prizes Awarded—The Bosch Magneto Company, New York City, has distributed its prizes to the Vanderbilt Cup and the Grand Prize winners whose cars were Bosch-equipped. De Palmo, winner of the Vanderbilt, received $200, while Bragg, winner of the Grand Prize, received $500. Second and third places were awarded $100 and $50, respectively, in the Vanderbilt Cup, while second place in the Grand Prize received $200.

Sales in Australia—Canadian motor cars are having a large sale in Australia. About a tenth of the cars in use in the commonwealth are of Canadian make. The Canadian trade commissioner in Australia reports that in Victoria there are registered 447 cars of Canadian make. New South Wales has 376, South Australia 203 and 75 in Tasmania. One hundred additional cars have just arrived from Montreal, Que. The competition, he reports, is very keen.

Dallas Has Motordrome—Dallas is to have the largest motordrome in the world. The contract for the same was closed recently and calls for an expenditure of more than $40,000. The track will be a .25-mile saucer around which will be placed thousands of seats for the public. The company backing the enterprise is composed of such men as Louis Nicolaus, Edward Magnus, E. L. Winterman, J. S. Arthur, Louis Nolker and A. E. Koener, of St. Louis, Mo.

Automobile Ordinance Modified—The Chicago, Ill., ordinance which prohibits automobiles passing street cars which have stopped at crossings to take on or let off passengers has been modified by the City Council which recently amended the regulations so as to include all vehicles. A test case had been threatened by motorists who claimed class legislation and the city fathers, rather than risk having the law wiped off the books, made the change, which, it is thought, will make the clause ironclad.

Indianapolis Patrol Mileage—An interesting report of the mileage of motor cars used in the Indianapolis, Ind. police department during 1911 has just been filed with the board of public safety by Martin J. Hyland, chief of police. The two Packard patrol wagons covered 23,868 miles in 7,249 runs, carrying 9,139 prisoners to the police headquarters, 1,804 prisoners to the workhouse and 165 prisoners to the woman's prison. The Premier touring car used for emergency runs made 1,978 runs, carrying 401 prisoners and making a total to 12,542.1 miles. The total cost of gasoline, oil and maintaining the three machines, exclusive of the drivers' salaries, was $3,927.60.

Automobile Incorporations

AUTOMOBILES AND PARTS

Canal Dover, O.—S. Toomey Company; capital, $60,000; to manufacture and sell automobiles. Incorporators: R. I. Toomey, S. J. Brister, Theodore Williams, M. C. Toomey, Oliver Toomey.

Cleburne, Tex.—Cleburne Motor Car Manufacturing Company; capital, $10,000; to manufacture automobiles. Incorporators: H. E. Luck, W. P. Ball, Brown Douglas.

Detroit, Mich.—Detroit Motor Chassis Company; capital, $25,000; to manufacture automobile chassis. Incorporators: J. Kinucan, J. L. Stringer, William P. Culver.

Elyria, O.—Elyria Auto Sales Company; capital, $10,000; to sell automobiles. Incorporators: W. C. Bennett, F. S. Bates, Correl Smith, J. J. Dillon.

Jackson, Tenn.—Jackson Motor Car Company; capital, $5,000; to manufacture automobiles. Incorporators: H. C. Gillespie, H. D. Canfield, E. L. Bowne, W. H. Weakley, W. C. Sandifeur.

Morgantown, W. Va.—City Automobile Company; capital, $4,800; to manufacture automobiles. Incorporators: J. Leonard Yates, B. S. Dearing, N. B. Yost, Margaret Smith, Cora B. Dearing.

New York City.—Auto Bankers, Inc.; capital, $5,000; to sell automobiles on credit. Incorporators: Clyde E. Block, J. Lester Fierman, Samuel W. Schwartz.

New York City.—R. H. Conty & Company; capital, $2,500; to manufacture and sell motors, parts, etc. Incorporators: R. Henry Conty, M. Conty, Emil Frankel.

New York City.—Grant Six Company; capital, $15,000; to engage in the automobile business, etc. Incorporators: Clarence P. Hulst, William G. Miller, James B. Speyer.

New York City.—Kammer Automobile Company; capital, $10,000; to engage in the automobile business. Incorporators: Max A. Kammer, Frances Kammer, William Magsamen.

Rock Hill, S. C.—McFadden Auto Company; capital, $3,500; to manufacture automobiles. Incorporators: V. B. McFadden, D. B. McFadden.

GARAGES AND ACCESSORIES

Detroit, Mich.—Merralls Starter Company; capital, $150,000; to manufacture gasoline engine starters and other automobile accessories. Incorporators: William A. Merralls, Robert S. Neely, Harlow B. Lowland.

Goldsboro, N. C.—Blackburn Garage & Motor Supply Company; capital, $25,000; to conduct a garage and deal in accessories. Incorporators: H. C. Smith, M. M. Allen.

Hopkinsville, Ky.—Hopkinsville Cadillac Company; capital, $10,000; to conduct a general automobile and garage business. Incorporators: R. E. Cooper, T. W. Blakey, Odie Davis, Richard Levell, E. G. Peterson.

Jefferson City, Mo.—Shackelford Garage Company; capital, $2,000; to engage in the garage business. Incorporators: Addison Shackelford, L. E. Shock, Paul Gee.

Shell Road to Be Restored—The shell road around Mobile Bay, Mobile, Ala., the most famous driveway in Alabama, is to be restored.

Forsyth Salesman Thomas—R. L. Forsyth has been appointed sales manager of the Thomas Flyer Company of San Francisco, Cal.

Van Deusen Resigns—Walter H. Van Deusen, assistant general sales manager of the Abbott Motor Company, Detroit, Mich., resigned Oct. 1.

New Service Station—The Pope Hartford Company, Boston, Mass., has leased a large building on Heywood street, Cambridge, for use as a service station.

Stevens Transferred to Denver—Sam A. Stevens, representative of the Rauch & Lang Electric Company, has been transferred to the Denver branch of the company's business.

Construct Municipal Garage—The Rochester, N. Y., common council adopted last week an ordinance authorizing the construction of a municipal garage and stable to cost $30,000.

Shanks Made Sales Manager—The Kelly Motor Truck Company, Springfield, O., announces the appointment of Charles B. Shanks, formerly of the Winton, as sales manager.

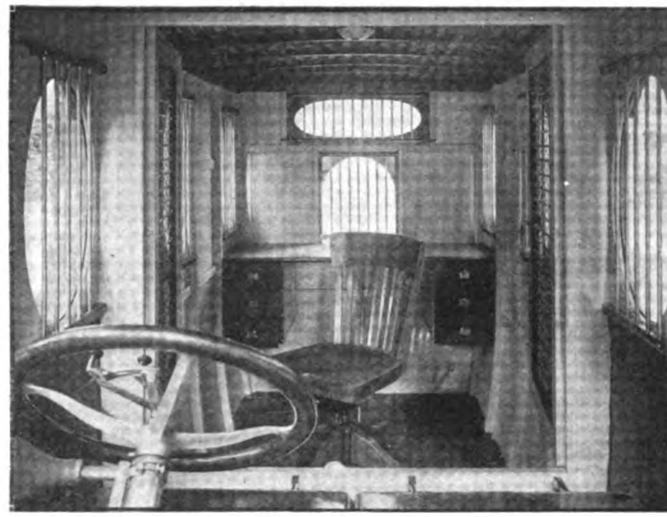
Federal Opens Frisco Branch—The Federal Rubber & Manufacturing Company will shortly open a factory branch in San Francisco, Cal., which will be in charge of L. L. Rettig.

Hickman Representing Stevens-Duryea—S. E. Hickman has been appointed by the Stevens-Duryea Company special representative for the Buffalo, N. Y., territory, with offices in the Hotel Lafayette.

Budd with Sanford—J. G. Budd, manager of the Victor Motor Truck Company, Buffalo, N. Y., has resigned to become general sales manager of the Sanford Motor Truck Company, Syracuse, N. Y.

Hall President Salisbury Company—Frederick P. Hall has been elected president of the Salisbury Wheel & Manufacturing Company, Jamestown, N. Y., succeeding Scott M. Penfield, who becomes sales manager and vice-president.

Martin Manager Buick—Robert H. Martin has been appointed manager of the Buick Motor Company's branch, Washington, D. C., succeeding T. S. Johnston, who has been made Eastern sales manager of the Republic Motor Company.



Interior of the bank on wheels now used by the city paymaster of Detroit, Mich. It is fitted up inside like a regular office which can be locked securely to prevent robbers from reaching the money. It is mounted on a Cartercar chassis

Dallas to Get Big Motordrome—A contract for a $40,000 motordrome to be built in the city of Dallas, Tex., has just been closed. The track will be one-quarter mile long and built as a saucer around whose circumference the grandstand will be arranged.

Northwestern Cole Company Formed—The Northwestern Cole Motor Company, 219 Sixth street, Minneapolis, Minn., has been formed to handle the northwest distributing business of the Cole Motor Car Company of Indianapolis, Ind. H. P. Wood is president and general manager.

Midland Changes—J. D. Beebe has been appointed general manager of the Midland Motor Company, Moline, Ill., succeeding Frank B. Wood. F. A. Padgett has been made sales manager. The company will build a 60-horsepower, six-cylinder car which will be fitted with a Wisconsin motor.

Gamble Company's New Quarters—The Gamble Motor Car Company, Toledo, O., is constructing a new building which together with its old quarters will increase its establishment to the size of one-fourth city block. The new construction will be of brick and steel, the floors being made of concrete.

Ford Joins Goodyear—J. A. Ford, of the Cleveland, O., Mechanical Rubber Company, has resigned his position as superintendent to join the forces of the Goodyear Tire & Rubber Company, Akron, O., where he has accepted a position in the experimental department in connection with mechanical goods.

Buffalo Boulevard Opened—The Buffalo-Niagara Falls boulevard, which the Buffalo, N. Y., Automobile Club was instrumental in constructing, will be officially opened for traffic November 15. Sixteen feet of the road is of brick and 16 of improved earth road, the boulevard being 32 feet wide along the entire course.

Highway Engineer Appointed—Owing to the large amount of good roads construction now in progress in Louisiana, a state highway engineer has been appointed, W. E. Atkinson, who will be at the service of all parishes to indicate proper methods of road construction and to see that roads once built are properly protected.

Federal's San Francisco Branch—The Federal Rubber & Manufacturing Company, Milwaukee, Wis., will open a branch in San Francisco, Cal., in the near future. It will be a general distributing depot for the entire Pacific Coast. E. L. Rettig, manager of the solid tire department of the Diamond Rubber Company's branch in that city, has been appointed manager of the new Federal establishment.

Apperson's Annual Meeting—The annual meeting of the stockholders of the Apperson Brothers Automobile Company was held in the offices of the company at Kokomo, Ind., Tuesday, October 8. Elmer Apperson, Edgar Apperson and T. E. Jarrard were elected as directors for the ensuing year. Later, at a meeting of the board of directors, officers were elected as follows: President and general manager, Elmer Apperson; vice-president, T. E. Jarrard; secretary-treasurer, Edgar Apperson.

Automobile Incorporations

MUSKEGON, MICH.—W. W. Butterfield & Company; capital, $10,000; to manufacture a self-starting device for automobiles.

NEW YORK CITY.—Automobile Information Publishing Company; capital, $10,000; to print and publish automobile trade lists. Incorporators: Albert F. Britton, Robert B. Johnston, Freeman C. Britton.

NEW YORK CITY.—Central Park Garage Company; capital, $500; to engage in the garage business. Incorporators: William E. Young, George J. Johnstone, Charles A. Frueauff.

NEW YORK CITY.—Motometer Company; capital, $5,000; to manufacture devices for automobiles, etc. Incorporators: George H. Townsend, Harrison H. Boyce, Frederick J. Moses.

NEW YORK CITY.—Never Skid Manufacturing Company; capital, $50,000; to manufacture non-skid devices for automobiles, tires, etc. Incorporators: Daniel E. Wing, George L. Lewis, Charles H. Stanton.

NEW YORK CITY.—Perfection Automobile Body Company; capital, $15,000; to manufacture and sell automobile bodies and appliances. Incorporators: William H. Mendel, William H. Mendel, Jr., James V. Simpson.

NEW ORLEANS, LA.—Ezeride Filler Company; capital, $1,000,000; to manufacture a tire filler. Incorporators: Ruffin R. Barrow, Gordon S. Orme, John H. Fulton, J. F. Anderson, Daniel D. Curran, Harry H. Osborn, J. Blanc.

SHERBROOKE, QUE.—Canada Tire Filler Company; capital, $150,000; to manufacture a tire filler.

ST. LOUIS, MO.—Auto Products Company of America; capital, $25,000; to manufacture, buy, sell and deal in chemicals, polishes, compounds, cements and automobile accessories. Incorporators: Warren W. Smoot, Eugene B. Stinde.

ST. LOUIS, MO.—St. Louis Motor Transportation Company; capital, $25,000; to conduct a transportation business. Incorporators: William R. Busch, Frank J. Busch, Knox Taussig.

YOUNGSTOWN, O.—Youngstown Taxi-Cab Company; capital, $10,000; to operate and maintain a taxicab business together with a garage. Incorporators: David Friedman, Sadie Friedman, Harris Friedman, Helen Friedman, Bert Friedman.

CHANGES OF NAME AND CAPITAL

CANTON, O.—Knight Tire & Rubber Company; increase of capital from $500,000 to $1,500,000.

CLEVELAND, O.—Cadillac Automobile Company; name changed to Cleveland Cadillac Company.

DETROIT, MICH.—M. & P. Electric Vehicle Company; increase of capital from $50,000 to $100,000.

JACKSON, MICH.—Clarke-Carter Automobile Company; name changed to Cutting Motor Car Company.

MUSKEGON, MICH.—Continental Motor Manufacturing Company; increase of capital from $500,000 to $2,400,000.

NEW YORK CITY.—Wrights' Garage; capital, $2,000; to engage in the garage business. Incorporators: William R. Dickie, Earl D. Wright, Elizabeth D. Wright.

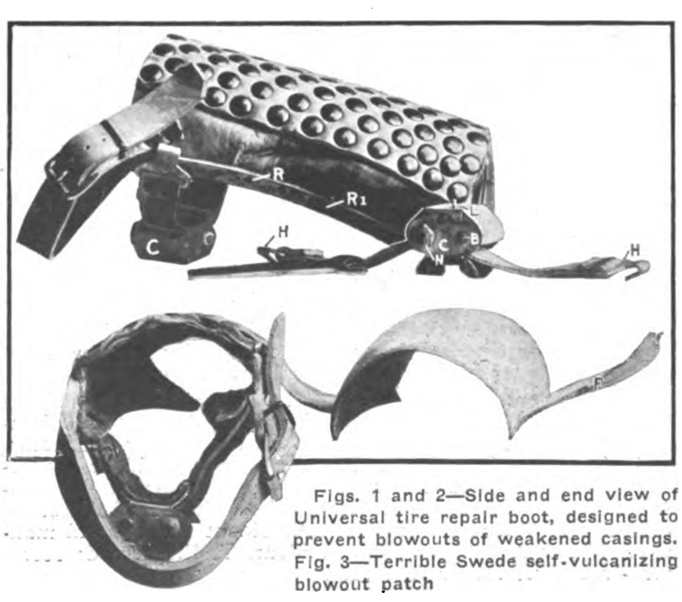
Universal Tire Repair Boot; Star Plug Switch; Automatic Valve Grinder; Wink Anti-Back-Kick Crank; Terrible Swede Tire Patch; Sound Intensifier for Hunting Noises; Rexo Vibrator Signal

Universal Blowout Preventer

ON the strength of the fact that one ounce of prevention is better than nine pounds of cure, the Universal Tire Protector Company, Angola, Ind., has brought out a repair boot by means of which threatening blowouts may be prevented. The Universal boot, Figs. 1 and 2, consists of two layers of specially tanned chrome-leather which are secured together by rivets R passing through a malleable iron rim R. The process of tanning the leather renders it so soft and pliable that the two layers easily adapt themselves to the shape of the casing onto which the shoe is applied. The method of securing the shoe to the casing is by means of three straps of the same leather as the boot itself. One of these straps has its two sections fixed to the bead portions of the boot and may be drawn tight by a buckle attached to one end of the strap. The other two straps are also made in halves which are held together by the connecting part C, Fig. 1. The latter is pierced by two bolts B, the heads of which are shaped as nuts N. The bolts carry ratchet wheels which are engaged by pawls secured to the inside casing of the part C. The pawls may be lifted out of engagement with the ratchets by pressing the end of the levers L secured to them and projecting through the casing C. When the nut is turned it winds up the strap half attached to it, both bolts being adapted for this work so that any desired tension put on the straps the hook ends H of which engage the rims R of the boot. The Universal boot is made for tires of 2.5, 3, 3.5, 4, 4.5 and 5 inches section and in the following lengths: 9, 12, 15 and 18 inches. It is furnished either with plain or studded tread, the latter type being designed for use in connection with non-skid tires.

Star Spark-Plug Switch

An accessory by means of which fouled spark-plugs may be easily located is made by the Star Motor Device Company, 1900 Broadway, New York City, is shown in Fig. 7. The switch or tester comprises three parts which are securely fixed together and one tester is permanently attached to each spark-plug through a slot which is punched in the sheet metal part of the device. This slot fits around the top end of the binding post and to it is fastened a channel-bent wire, one end of which is equipped with an insulated grip. The tester is normally in the position shown in Fig. 7, but when the engine begins to miss fire the tester wires of three cylinders are turned down so that the free end of each contacts with the shell of the plug, thereby shorting the current. This procedure is carried out with each three plugs short-circuited, and when the motor stops the cylinder whose plug is not short-circuited is proved to be the missing one. If the switch is then so regulated that the end of the wire is within .03125 inch of the shell and the other cylinders are put in operation, the following observations may be made with the missing cylinder: If a spark jumps between tester wire and shell, the plug is fouled; if no spark occurs the trouble lies in the wiring of the plug, and may be easily detected by following up the conduit leading from the distributer binding post to the plug.



Figs. 1 and 2—Side and end view of Universal tire repair boot, designed to prevent blowouts of weakened casings. Fig. 3—Terrible Swede self-vulcanizing blowout patch

The Automatic Valve Grinder

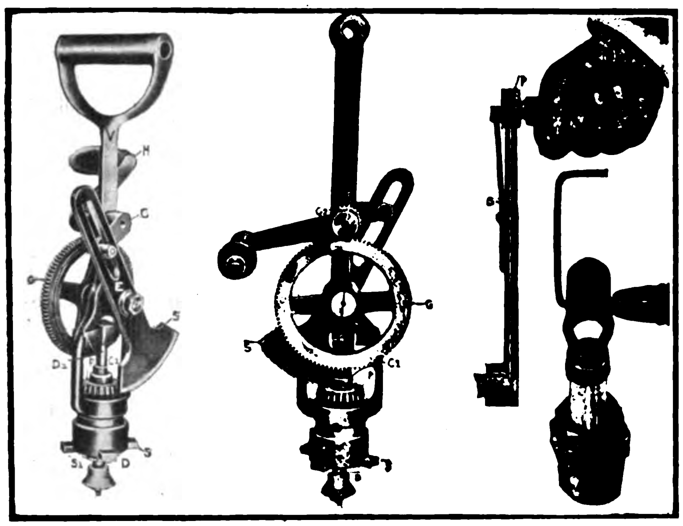
A novel type of valve grinder which has been designed on similar principles as the breast drill is being sold under the name of the Automatic valve grinder by the Specialty Machine Company, 95 Liberty street, New York. In this valve grinder the valve is kept rotating alternately in two directions, being lifted periodically and dropped back on its seat in a different angular position. The principle of operation is easily understood upon reference to Figs. 4 and 5. The device is actuated by turning the handle H of the crank C which is pivoted at P on the support V. The extension E of the segment S is slotted and the end pin of E rotated by the crank C simultaneously reciprocates in this slot and moves the extension from one side to the other. The effect of this motion turns the pinion P alternately in two directions. This pinion P is fixed to the shaft D, which is coupled to the shaft D1 by a clutch C1. The gear G1, mounted on the crank C, also actuates gear G, the inner side of which carries a cam which periodically lifts the roller R. When this occurs the clutch C1 is lifted and the same refers to the shaft H carrying the valve. As soon as the cam has passed under the latter drops and the valve again contacts with the seat, but in a different angular position as before. It is now rotated until the roller is lifted again. In order to permit the use of this valve grinder with the valve of motors of different sizes, the spring S1 is provided which is so adjustable that a greater spring pressure may be used in grinding in a large valve than a small one.

Flat Spring Wink Safety Crank

The legion of safety cranks which forms the missing link between the ordinary crank and the self-starter has been increased by another design. This latest addition is the Wink Crank, Fig. 6, which operates on an extremely simple principle. The handle of this crank is pivoted on the pin P and when the crank is used is in the position shown in Fig. 6. As soon, however, as backfiring occurs in the motor, the reversed rotation of the crank pulls the handle out of the operator's hand, due to the tension of the spring S which holds the handle in the cranking position. In all other ways this crank is constructed like the ordinary type, the inner end being shaped to fit over the keyed end of the crankshaft and acting without the agency of a ratchet joint. This crank is a product of the Wink Crank Company, 2106 Superior Viaduct, Cleveland, Ohio.

Terrible Swede Blowout Patch

A three-ply, 16-ounce fabric blowout patch vulcanized with high-grade Para rubber is being manufactured by the Hagstrom Brothers, Lindsborg, Kans. This patch is shaped to fit the inside of a vulcanized casing and has two flaps F at-



Figs. 4 and 5—Automatic valve grinder. Fig. 6—Wink safety crank, using a flat spring to counteract back-kicks. Fig. 7—Star spark-plug switch for easy locating of misfires

tached to it which fold around the bead of the casing between the same and the rim. It is not necessary in the use of this patch, which is named the Terrible Swede, to vulcanize the same in place in the tire. It merely needs to be inserted in the casing and is there vulcanized by the heat produced in the tire while running. It is made in three sizes.

Detectorphone to Locate Knocks

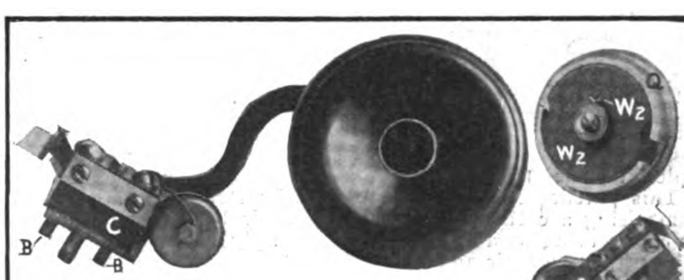
Locating knocks is no easy work, and to facilitate it the Boston Talking Machine Company, 41 West street, Boston, Mass., has designed the Detectorphone, by means of which sounds may be greatly intensified and their difference easily noted. The device, Figs. 8 and 9, consists of a sound receiver through which sound enters the apparatus, the electric conductor and intensifier, the transmitter and the operator's receiver in which the electric undulations are again transformed into sound. The exterior of the device is seen in Fig. 8, and attention is called to the push-buton P which when depressed closes a circuit and puts the instrument in operating condition. Fig. 9 illustrates the interior construction. The part C contains a coil, the armature of which is contained inside A and is subject to sound vibrations entering by way of the steel rod R when the latter is in place as in Fig. 8. The current is supplied by a dry cell inside the Detectorphone casing, which takes up the space marked on its outside (in the illustration) C1. The undulating current flows from one end of the battery through the coil and the casing of the device, while the other end contacts with a metal screw on the insulated face of the part Q. The end of an insulated wire surrounding this insulated face contacts with the wall of the casing and both wires, which are silk wound, are connected to the operator's receiver, which is held to the ear while the push-button P is pressed.

In the use of this device it is necessary to first become accustomed to the normal sound or sounds of the motor by listening to it at various portions of the power plant. Being once familiar with the characteristic sounds produced by the various parts, automobilists will by a quick inspection of their motor with this device be able to locate a knock positively and with ease.

Rexo Electric Vibrator Horn

The low-priced electric horn has been given another impetus by the action of the Dean Electric Company, Elyria, Ohio who, have brought out the Rexo, Figs. 10 and 11. The principles on which this device is constructed are the same as those that serve in the Tuto horn made by the same company. A steel diaphragm is fixed inside the flanged portion P of the horn casing by six screws S, tightness between the casing and the diaphragm being insured by the use of a circular brass washer consisting of three sections. To the center of the diaphragm a bolt is fixed and when the latter is struck by the vibrating armature of the electric magnet, which constitutes the actuating member of the appartus, the vibrations are imparted to the diaphragm, producing the warning sound which resembles that of the Tuto. The Rexo horn is 11 inches long and the megaphone has a diameter of 6 inches. The horn is finished in brilliant black, with the fittings either nickel or brass colored. The equipment of the horn includes silk-covered cable and a push-button switch.

The mechanism actuating the diaphragm is contained in the horn casing which has two portions P1 and P2, the latter serving as a cap. When P2 is removed, the contact mechanism, Fig. 11, becomes visible. A is the armature of the electric magnet and A1 an adjusting screw for the contact breaker B. The contacts T1 and T2 are insulated from one another, and while from T1 an insulated cable leads directly to one end of the magneto winding, the contact from T2 is through the screw A1, the contact breaker B and the screw S1. When by pressing a button in the circuit the contact is closed the magnetized vibrator coil attracts the armature which has the part B attached to it, thereby interrupting the circuit between B and A1. B, which is a flat steel spring, returns to its original position, and as it closes the circuit the cycle begins over again. The horn comes fully equipped with cable and push-button.



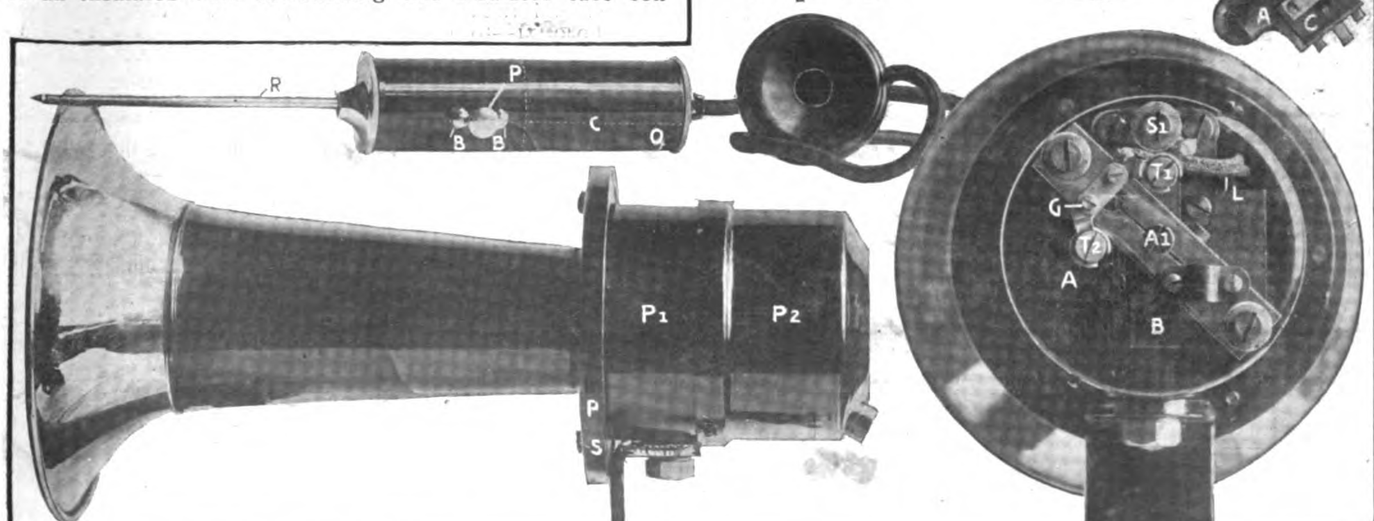


Fig. 8—View of Detectorphone which may be used as a stethoscope in diagnosing the ills of the motor. Fig. 9—Interior construction of the Detectorphone, comprising a coil-and-diaphragm mechanism, similar to a telephone construction. Fig. 10—Side view of the Rexo electric vibrator horn. Fig. 11—Rear end view of Rexo horn, showing the vibrator mechanism and terminals

INTERNAL Combustion Motor Valve—Being a sleeve which regulates the passage of gases between the interior of the cylinder and gas passages in the head.

The subject-matter of this patent, a valve mechanism, is illustrated in Fig. 1. An open-ended cylinder C is fitted with a removable head H which incloses its open end and which has admission ports A and exhaust ports E communicating with the interior of the cylinder. A partition P divides the head H in two sections, which are referred to in the patent as admission and exhaust belt. In the cylinder head a sleeve valve V is inclosd, which controls the ports.

No. 1,040,613—to Ernest Windsor Bowen, London, Eng. Granted October 8, 1912; filed November 25, 1911.

Brake Lever Lock—In which the brake lever carries a lock holding a dog in place on a toothed bar.

This patent refers to the combination of a brake lever L which carries a movable dog D adapted to engage a toothed bar B with a fixed abutment in the plane of a portion of the dog D. To enable the brake lever to be locked relatively to the toothed bar, a lock L1 is secured to L, which is fitted with a bolt; the latter may be projected by the working of a key so as to take a position between the dog and the fixed abutment and to engage both.

No. 1,040,844—to Peter F. Augenbraun, Stamford, Conn. Granted October 8, 1912; filed September 9, 1909.

Non-Collapsible Tire—Being a pneumatic design of substantial construction.

In Fig. 3 is shown the pneumatic, non-collapsible tire described in this patent comprising a substantially flat tread portion T and a seat portion. Fabric layers F are permanently embodied in the tire; of these an outer layer O extends down from the tread portion along the sides, while a layer P is arranged parallel with the tread and a third layer C is circular in shape, its office being to give rigidity to the fabric structure. Adjacent to the seat portion of the tire a riding cushion R is located, whose central portion is raised toward the tread portion of the tire. An oppositely disposed interior surface S co-operates with the cushion R.

No. 1,040,920—to Henry G. Fiske, New York City. Granted October 8, 1912; filed July 1, 1899.

Carbureter for Automobile Motors—Working on a multiple-jet principle.

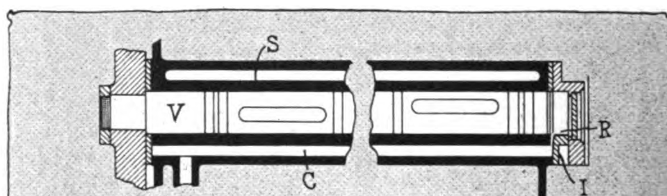
This patent has reference to a carbureter design, Fig. 4, comprising a casing including a reservoir R, with an extension C serving as a carbureter fuel supply chamber concentric to the reservoir and being shaped as an arc. This chamber is connectible to the intake manifold of an engine; it is divided into a number of circular chambers which are connected by leads C1 to the reservoir R and have independent air inlets. In each circular chamber is an independent nozzle and a controller C2 which consists of an inverted cylindrical sleeve valve movable by engine suction.

No. 1,040,414—to George P. Rettig, Richmond, Ind. Granted October 8, 1912; filed September 7, 1910.

Rotary Valve for Combustion Motors—Constructional detail for lubricating a rotating cylinder valve.

The rotating cylinder valve feature described in this patent consists in the use of a channel C, Fig. 5, formed transversely in the seat S of the valve V. In the mouth of that channel a segmental insert I forms a restricted passage R.

No. 1,040,738—to Emil A. Nelson, assignor to Rotary Valve Motor Company, Detroit, Mich. Granted October 8, 1912; filed February 5, 1910.



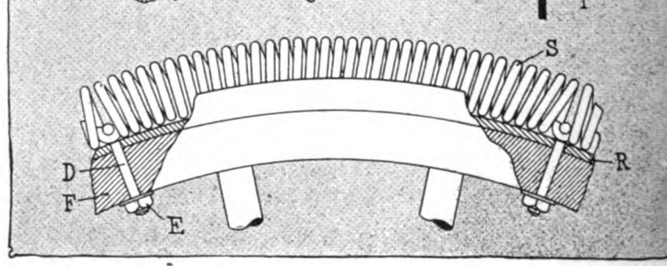


Fig. 5—Nelson rotary valve. Fig. 6—Van Smith spring tire

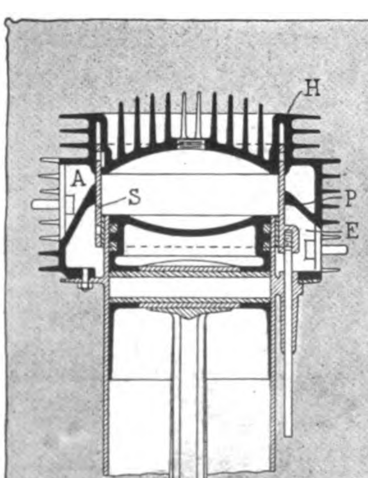
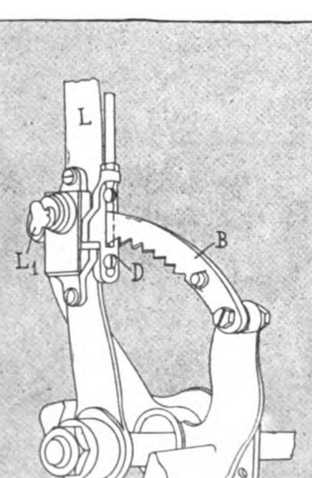
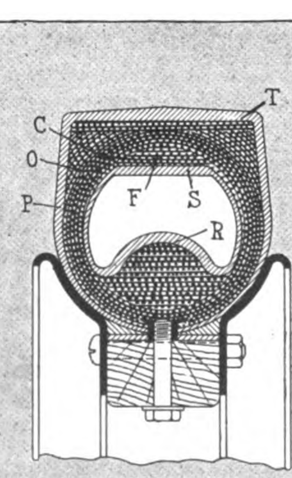
Automobile Spring Tire—In which resiliency is obtained by the use of coiled springs encircling the rim.

This patent refers to a wheel having a rim R and felloe F, the rim being of the channeled type and containing in its inner portion a coiled spring tire S. The latter consists of a number of coiled springs arranged end to end and terminating in hooks. Between the hooks pass fastening devices D which extend radially through rim and felloe.

No. 1,040,471—to Charles Van Smith, Kansas City, Mo. Granted October 8, 1912; filed September 3, 1910.







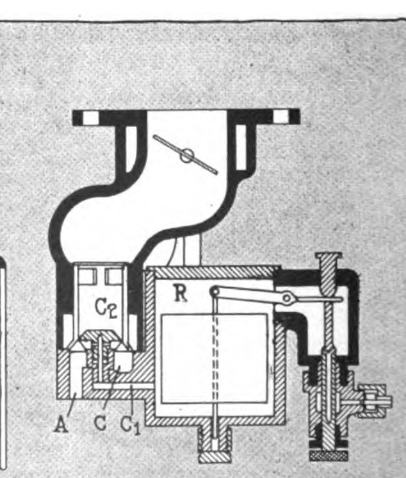


Fig. 1—Bowen sleeve valve. Fig. 2—Augenbraun brake-lever lock. Fig. 3—Fiske tire. Fig. 4—Rettig carbureter

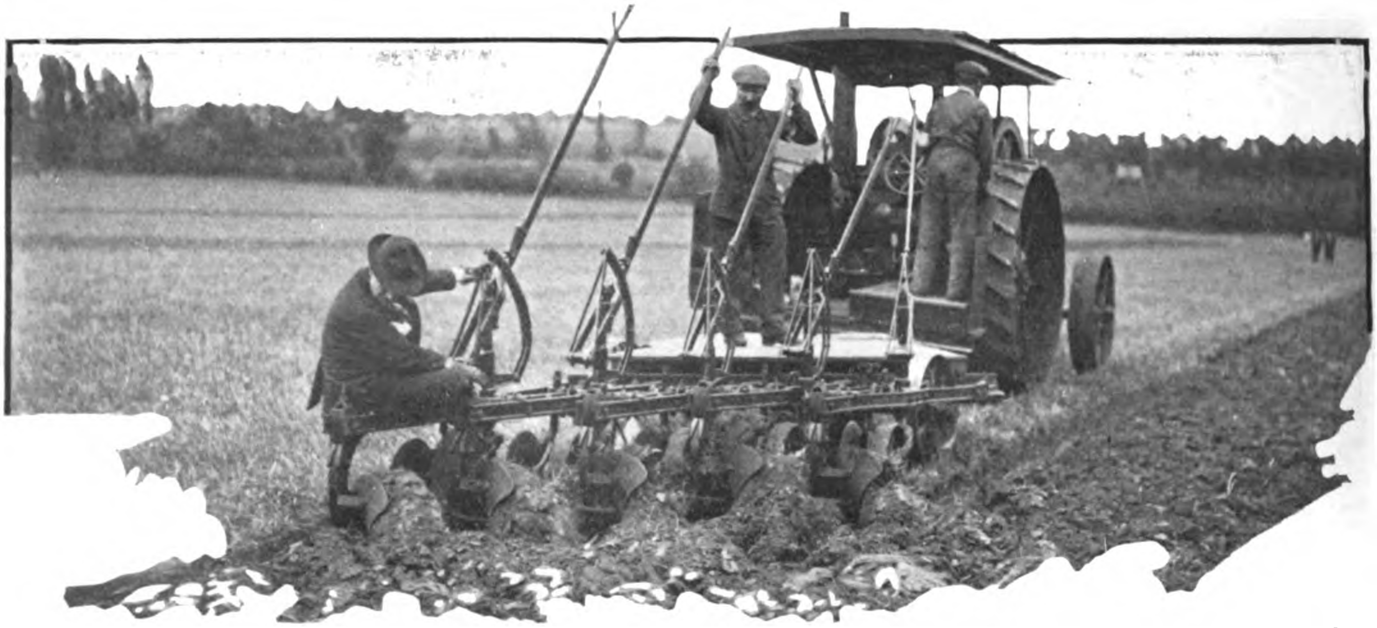
GILBERT
$5.20 per acre

BOURGES, France, Oct. 7—France and America have just competed in the most important plowing competition held in this country, in which honors were very evenly divided. The event, put on foot by the Central Automobile Club, with the assistance of the Agricultural Commission of the Automobile Club of France, united twelve machines of widely different types, nine machines taking part in the practical tests. The competition was decided on the amount of plowing done, the depth attained, ease of operation, fuel cost and freedom from breakdowns. Owing, however to the machines varying enormously in original cost, amount of work they were able to perform and number of men required to handle them, it was a difficult matter to class them in order of merit. The demonstration they gave was the most valuable yet seen in France.

On the first day the ground was bad, having a stony subsoil into which the plows stuck as soon as they attempted to reach a reasonable depth. On the second day the ground was heavy, but with a much greater depth of soil. The third day, which should have been devoted to deep plowing, was changed into a demonstration, for it was found that the ground, which had been offered by a local farmer, was so bad that no machines cared to tackle it on a competitive basis. It afterwards transpired that having very great difficulty in plowing this land to any depth by the use of horses or oxen, the farmer had conceived the idea of letting the motor machines work on it, but had neglected to state its particularly difficult nature to the committee. The ground was not uniform; thus the weak machines withdrew altogether, and the more competent appliances were held back on the ground that if they got a bad patch an unfavorable impression would be created among the public. The cost figures are considered the most authentic which have been obtained to date in such competitions.

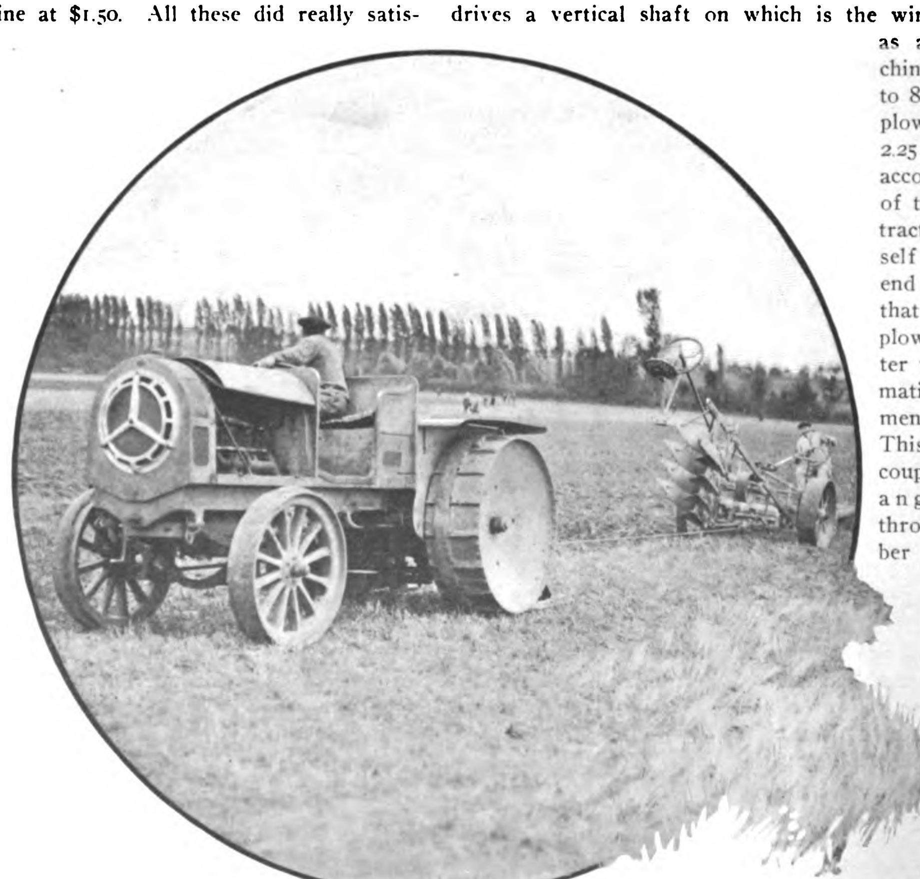
Considered from a fuel cost basis only, the most successful machine was the J. I. Case Company's steam tractor, which worked at the rate of 52 cents per acre, using compressed coal bricks of the type commonly employed on the French railroads.



Single-cylinder gasoline tractor of International Harvester Company plowing at $1.50 per acre

This was the only steamer in the competition, all the others being of the internal combustion type and all but one running on benzol. As an offset against the low price of the Case steamer must be set the fact that it employed three men, while practically all the other machines worked with either one or two operatives. The next in order of merit on a cost basis was the De Mesmay at 74 cents per acre. There was no comparison, however, between this machine and the American, for while the latter did deep plowing, and a large amount of it, the French appliance was really only a motor hoe which, with a two-blade plow attached, did a mere surface plowing. Very closely placed after these two were the Lefebvre caterpillar type plow at $1.16 per acre, the Bajac at $1.20, the Filtz at $1.22 and the International Harvester Company's machine at $1.50. All these did really satisfactory work, but with so many other factors to consider, it would not be equitable to judge of their value on a fuel cost only. The remainder cannot be considered very practical machines, for the fuel cost varied from $2.62 for the rotary Vermond & Quellennec to $5.20 for the small Gilbert.

The two American machines were the respective firm's standard models, the Case being the company's 30-horsepower steam tractor hauling a platform with eight plows, and the International Harvester machine being the 25-horsepower single-cylinder gasoline tractor working with five plows. Compared with the Americans the French machines were designed for work on small areas, they were more complicated and better finished.



Bajac drum type plowing at $1.20 per acre

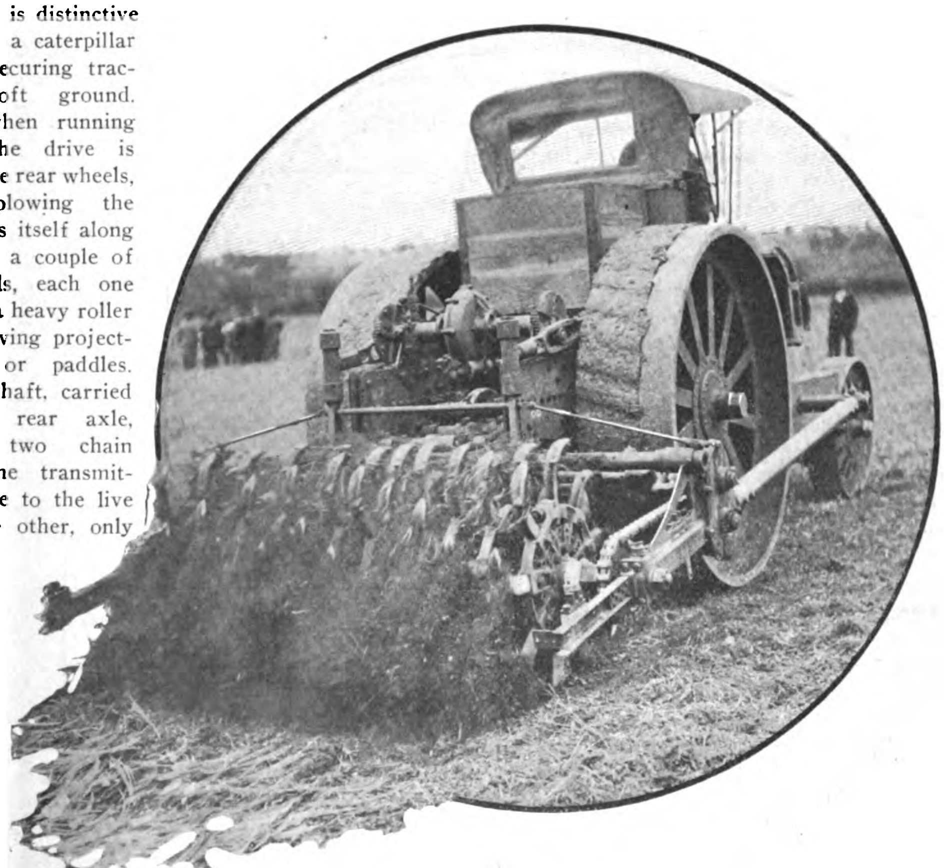
Bajac, Lefebvre and Filtz gave about equally good results, although representing three entirely different types of machines. The Bajac, which is built by the Bajac Company in conjunction with the De Dion Bouton Company, is a tractor with a winding drum having a sufficient length of cable to haul a plow across a field about 100 yards in length. The tractor carries its motor, a four-cylinder of 35 horsepower, identical with those used on the Paris omnibuses, forward under a bonnet, transmits through a clutch and a propeller shaft to a combined gearbox and differential housing, and takes final drive by transverse shafts having pinions meshing with internal gears on the large diameter road wheels. The propeller shaft is continued rearwards and drives a vertical shaft on which is the winding drum. Used as a tractor, the machine has a speed of 6 to 8 miles an hour; its plowing speed is from 2.25 to 3 miles an hour, according to the nature of the ground. As the tractor has to place itself on the opposite end of the ground to that occupied by the plow and haul this latter to it, a quick automatic locking arrangement is necessary. This is obtained by a couple of stout triangular frames through the base member of which projects a stout steel prod. Suspended at the rear, these two frames can be raised and lowered by means of a winding drum operated by the driver, and when lowered one of the sides of the

De Mesmay gasoline motor hoe worked at a cost of 74 cents per acre in the tests

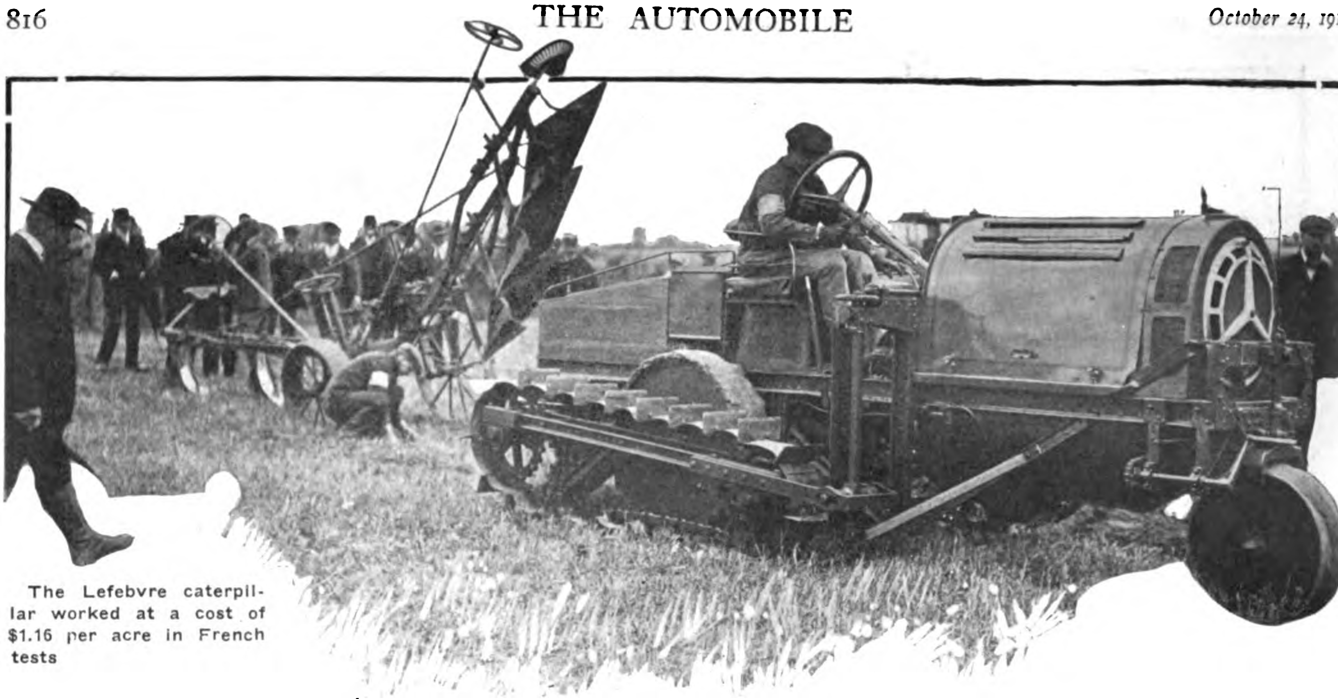
triangle is in contact with the road wheel and another is on the ground. By backing a short distance the prod is forced into the ground and the greater the strain on the cable the more tightly the rear wheels are wedged. A certain amount of time is naturally lost in running backwards and forwards on the field, but the losses are reduced to the minimum by the automatic locking device. The machine requires the services of two men, one operating the tractor and the other working the balanced plow.

The Lefebvre is a direct hauler, being a three-wheel tractor to which a balanced plow is attached. The motor is in front under a bonnet, and the single steering wheel is controlled by means of an inclined steering column with worm and sector. The machine is distinctive by reason of a caterpillar device for securing traction on soft ground. Normally, when running on roads the drive is through to the rear wheels, but when plowing the machine hauls itself along by means of a couple of endless bands, each one surrounding a heavy roller chain and having projecting blades or paddles. On the jackshaft, carried behind the rear axle, there are two chain sprockets, one transmitting the drive to the live axle and the other, only brought into use when plowing, carrying the power to a large chain sprocket on each side of the tractor. The tractor is provided with an external trussed frame, the fore end of which can be raised or lowered by a worm and screw belt driven off the motor; at the front end of this frame is a sprocket of the same diameter as the rear one, and a chain surrounding the two. Around the chain, and attached to it, is a broad leather band carrying the projecting blades already mentioned. The front end of the frame being lowered the blades enter the ground and by the rotation of the chains drive the machine ahead.

The Filtz machine is a four-wheel bogey carrying a 25-horsepower gasoline motor under a bonnet, having the driver's seat in the center and the radiator at the extreme rear. Through a cone clutch the power is transmitted to a propeller shaft, a pinion on the extremity of which engages with a crown bevel gear on a transverse shaft. There are two crown wheels on this shaft with an arrangement for bringing either one of the other into engagement with the driving pinion. On one end of the jackshaft is mounted a grooved pulley, outside the frame member, and there is a second and similar idler pulley also outside the frame member. A fixed cable rigidly attached to each extremity of the land to be plowed is given four or five turns round these two pulleys and according to which pinion is in engagement the machine will haul itself and its plow across the field in either direction. The tractor is light and simple, but it is not self-propelling. Three men are required, one being on the tractor and one at each end of the field to maintain the tension on the cable and haul the bogey to which the extremities of the cable are attached. This bogey has disk wheels and a couple of winding drums with ratchets, one being for the



Vermond & Quellennec rotary worked at $2.62 per acre



The Lefebvre caterpillar worked at a cost of $1.16 per acre in French tests

plowing cable and the other to haul the bogey along the field as the furrows are traced.

Three different types of rotary plows were presented, but not one of them went completely through the 2-days test. The Motoculture Française, the lightest and simplest of the three, carries a three-cylinder gasoline motor set across the frame, with single chain drive to the road wheel and a second chain drive from the rear axle to a second shaft having 100 flexible hooks mounted on it. Both chains are inclosed and a device is provided for raising or lowering the shaft carrying the plows. The distinctiveness of the apparatus lies in the fact that the ground is turned up by a set of flexible, spring-mounted hooks, rather than picks, of such a nature that they will bend if brought in contact with a hard object. The plowing rate of the machine is very slow, being less than half a mile an hour, working on a width of 78 inches. The machine might be suitable for soft ground, but was defective in heavy and stony earth. When it got on to the heavy clay soil of the second day it was unable to obtain traction. The motor, too, was underpowered, the engine continually overheating.

There were two Vermond & Quellennec machines, similar in principle but differing considerably in construction. Only one actually plowed, the other being held up first by mechanical troubles, then by reason of its inability to get over the soft ground to the field. The more successful of the two has a Schneider four-cylinder motor of about 4 by 5 inches, similar to the motors used on the Schneider buses in Paris. It drives the rear wheels through a clutch, gearset and jackshaft meshing with an internal gear on the rear wheels. In addition a second jackshaft is driven off the rear extension of the propeller shaft and carries a sprocket at each end from which the power is taken to the pick shaft by means of chains. The plowing in this case is done by very heavy, rigid picks, ninety-nine in number, mounted on the rear shaft. The speed is under a mile an hour for a width of 66 inches, and, although the depth attained is fairly satisfactory, with the 35 horsepower available, the machine cannot be considered a success, for the motor was constantly overdriven, was overheating and was frequently on the point of being stalled.

The De Mesmay and Gilbert machines are only of value for small work. They have very little power, the former having a single-cylinder motor, which is really only designed to work a motor hoe, and the latter having a twin-cylinder motor driving a single wheel and obtaining its traction by reason of a series of eccentrically mounted blades projecting through slots in the rim of the wheel. This mechanism gave trouble, and deprived of its blades the machine was unable to get sufficient traction.

The plowing was watched by a large number of farmers and also by an official delegation from the Paris municipality interested in motor plowing for the city's sewage farm. Conditions were arduous, but real work was done and orders were placed for motor plows. Both the Case and the International Harvester companies report that several of their plows are now working on French farms.

At the Winnipeg agricultural show organized by the Royal Agricultural Society of England a large number of agricultural tractors equipped with motors rated between 8 horsepower and 105 were recently exhibited and offer some figures for comparison.

The tractors haul from four to twenty plowshares when used

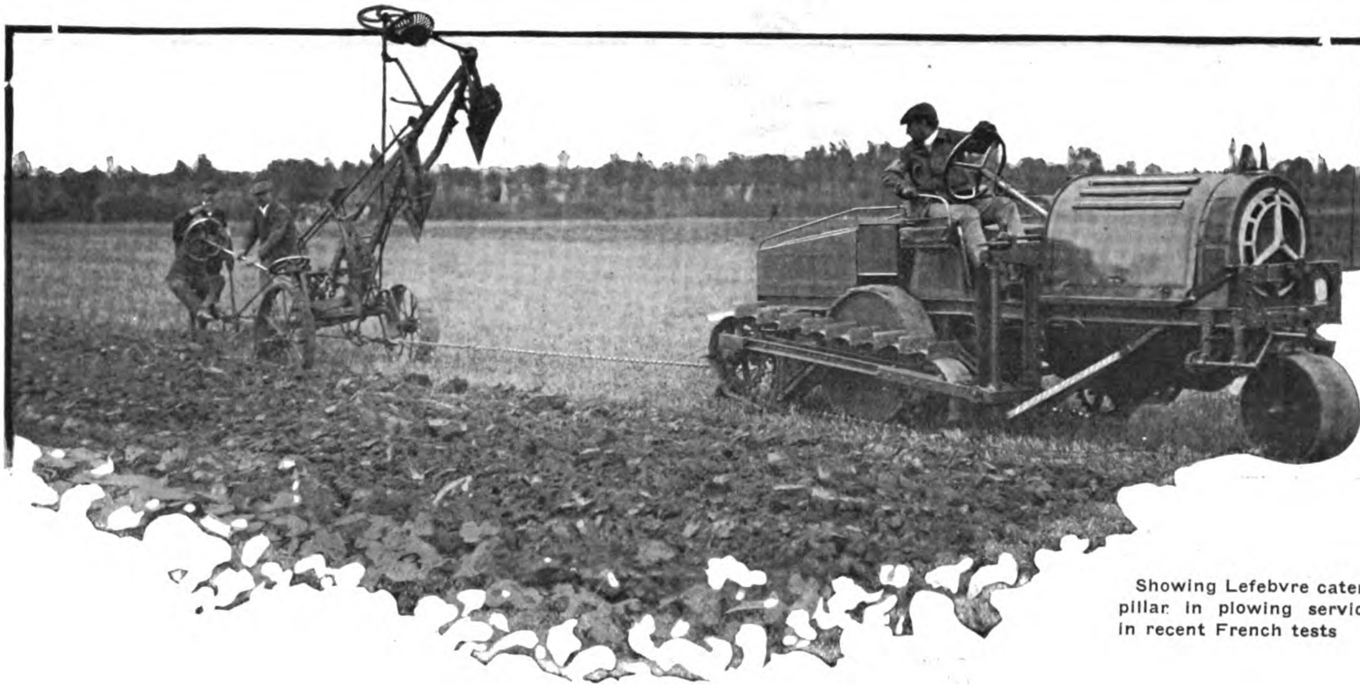
*Speed of tractor only 6 to 8 miles an hour. †Benzol at



Showing Lefebvre caterpillar in plowing service in recent French tests

for plowing and some of the representative machines demonstrated ability to plow ground at $1.38 per acre. Among the exhibits was a Daimler tractor rated at 36 horsepower for which figures of cost in this variety of work were submitted. The figures showed that using gasoline as fuel the daily cost of operation, including every possible expense and working 10 acres a day, was $10.72, which would make the per acre cost $1.07.

Using kerosene the cost was reduced to $8.94 per day, or 89 cents per acre.

Conditions of actual service differ so widely one from another that any absolute standard of efficiency is impossible to reach.

One of the smaller tractors shown at Winnipeg used a six-furrow plow and in one test covering 21.5 acres it averaged 74 cents an acre.

An Ivel three-wheel tractor attracted much attention at the show. In a recent English test it was reported that a tractor of the same model using kerosene for fuel and equipped with two plowshares worked 6 acres of land in 9 hours at a cost of $5.55, or 92.5 cents an acre.

The field trials of some of the tractors used for plowing, which were displayed at Winnipeg, were interesting.

Twenty-five tractors entered the competition. The furrows were all gauged at 14 inches apart and the machines pulled all the way from four to ten bottoms. They traveled 6 miles, and the amount of land plowed depended entirely upon the number of plowshares attached to the particular machine. A fair representation of the average work done by tractors of modern type may be seen in the experience of actual users of the machines. One concern using two tractors, one of which was 20 horsepower and the other 35 horsepower, has cultivated 2,000 acres of land by their use.

One test to which this concern put the tractors was breaking up a field of blue grass sod 30 years old. The field was 15 acres in extent and the two tractors drawing plows broke up the whole field in 10 hours to a depth of 6.5 inches. With disk plows it has been found that from 65 to 80 acres a day can be worked. The tractors have two or more speeds and the usual powing speed ranges from 2 to 3 miles an hour.

Fuel cost per acre as shown in a series of tests where five plows were attached to each tractor and the acreage covered ranged from 15 to 18 per day, was in the neighborhood of 42 cents and the total cost, including up-keep, interest and insurance, was 85 cents an acre.

The tractor that performed its task quickest was an Aultman-Taylor using gasoline as fuel. It required 144 minutes to do the 6 miles. The first place as far as acreage covered is concerned went to a big Case tractor, which worked 3.79 acres in the 6-mile trip, but required 20 minutes more time.

The machine making the lowest fuel cost per acre was a Rumely using kerosene. The cost was 33.7 cents per acre. The high cost was made by a big steam tractor, being 66.3 cents per acre plowed.

The average ran around 46 cents, but it should be considered that some of the plows carried as many as twelve bottoms. In the paragraph above where the cost was given as 42 cents per acre only five plows were used.

The kerosene tractor entered by the International Harvester Company required 14 minutes to make the turns, while an Avery gasoline tractor made them with a loss of only 5.7 minutes.

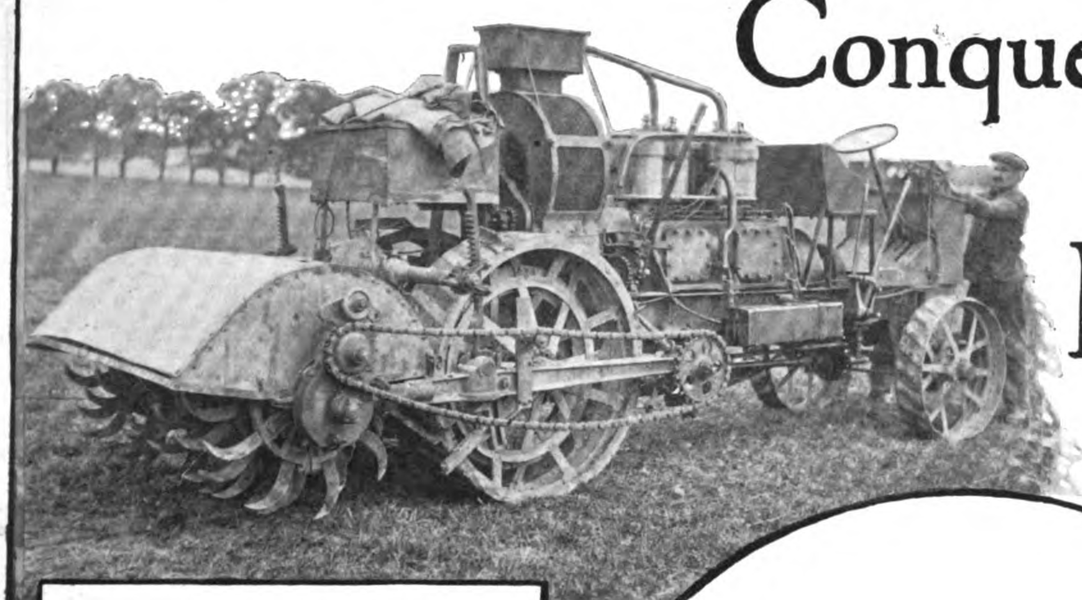
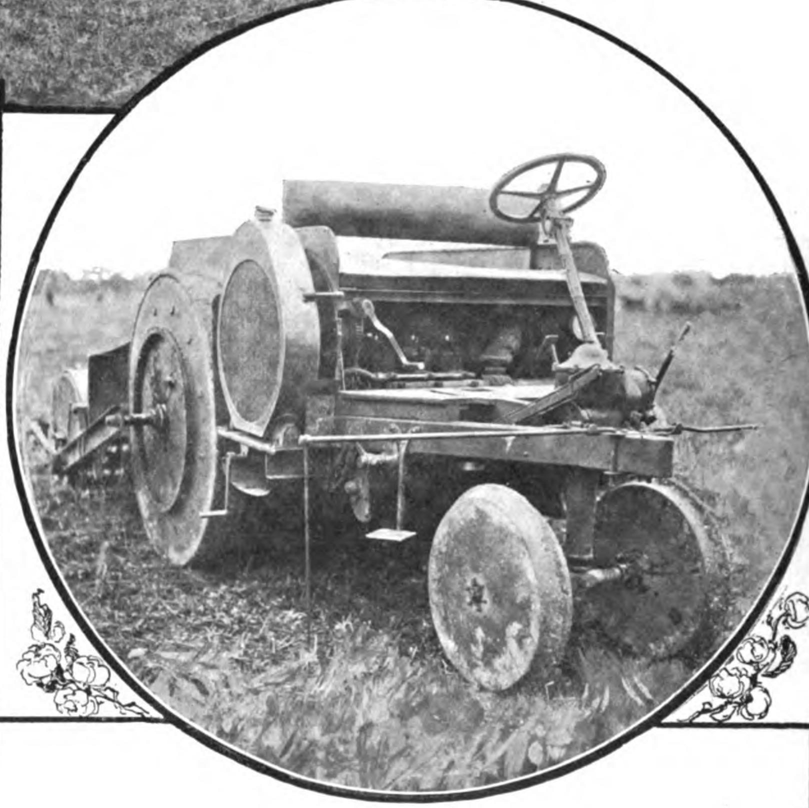
Conquering the Farm





Top Illustration

Vermond & Quellennec motor plow in operation during the recent agricultural competition, when this equipment plowed at the cost of $2.62 an acre. The V. & Q. plow is driven by a 4 by 5-inch, four-cylinder Schneider motor of the omnibus type, the drive being from the propeller shaft both to the rear wheels and the plowshares arranged on a rotating axle

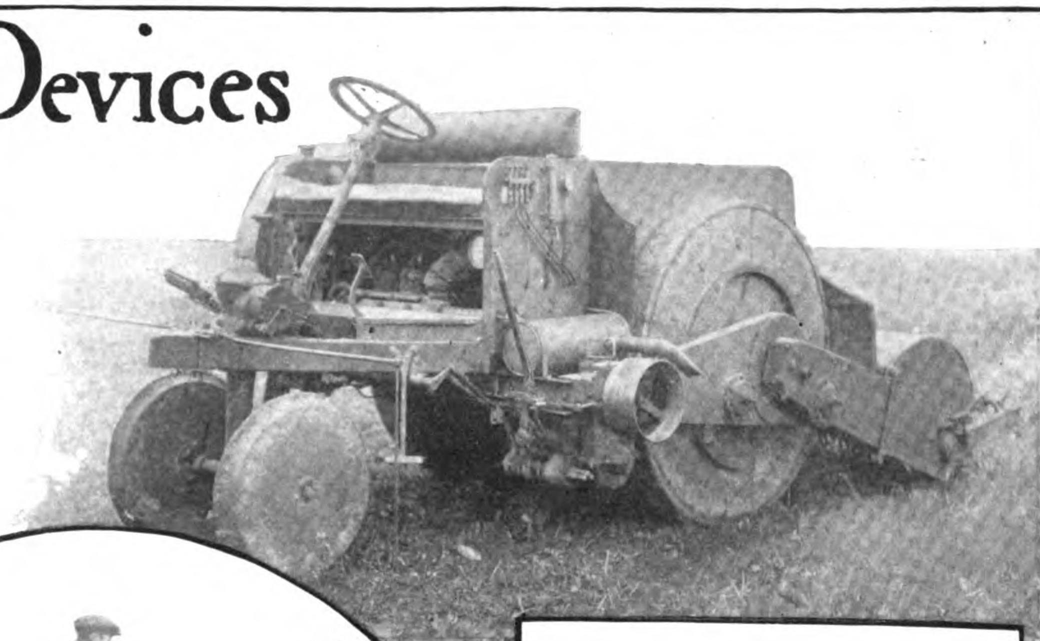
Center Illustration

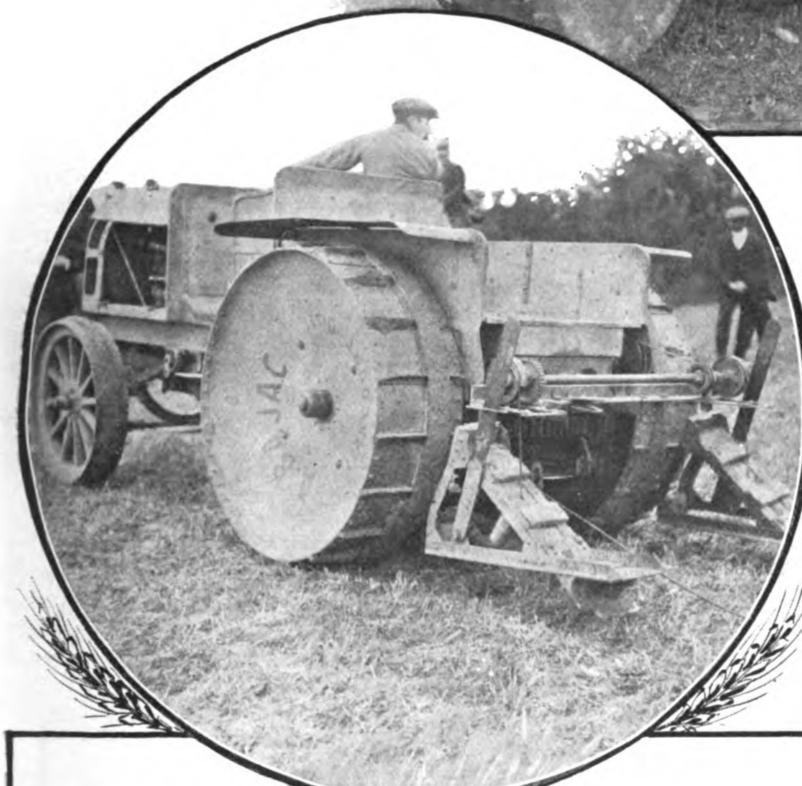
View of the Motorculture Française motor plow which was among the simplest and lightest designs demonstrated. A chain drives the road wheels and another chain the flexible spring mounted hooks which are mounted on a shaft. This type of plow is well suited for soft soil and, due to the use of an engine of low power, works slowly and at $3.60 an acre

Bottom Illustration

A typical scene during the agricultural contest, when crowds of peasants lined the paths of the motor-plows. The farming populace showed great interest in the demonstration of the novel appliances and manufacturers look forward to a lot of business with automobile farming equipment among the French peasantry during the next few years

Motor Devices Show Value





Top Illustration

Another view of the Motorculture Française tractor which, like the majority of equipments, uses benzol for fuel. This illustration shows the left side of the vehicle, illustrating the double chain drive, from the jackshaft to the axle and to the plowshare axle, both chains being incased to shield them from interference with objects on the field

Center Illustration

Tractor built by Bajac and De Dion companies, which is equipped with a 35-horsepower motor, permitting of a traveling speed of 8 miles and of a plowing speed of 3 miles an hour. The winding drum around which the propelling cable is laid is shaft-driven and vertical. The operating cost was $1.20.

Bottom Illustration

Filtz tractor driven by a 25-horsepower engine has a very automobile-like appearance. The drive to the plow mechanism is through a propeller shaft and a bogey, to the ends of which cables are attached which, in turn, are secured to the end of the furrow to be plowed, so that the machine may propel itself across the ground. This machine plowed an acre for $1.22

Peerless Increases Capital

Report Current That $1,500,000 Has Been Secured to Enlarge the Scope of the Company

Outlook Bright for Atlas Motor Car Company—Continental Motor Increases Capital to $2,400,000

ADDITIONAL finances, said to be $1,500,000, to enlarge the scope of the Peerless Motor Car Company, of Cleveland, have been secured, according to indireet reports received in New York this week. President S. J. Kittredge interested J. Robert Crouse, a multimillionaire, of Cleveland, in the project and the funds were obtained without going into the general market. Reports have been current that Kittredge was to retire from active direction of the Peerless affairs in the near future but official denials have followed the spreading of the reports.

The expansion of the truck end of the manufacturing business is given as the main cause for the new financing.

Planning to Renovate Atlas

SPRINGFIELD, MASS., Oct. 21—Attorney Edward W. Beattie, who is acting for the Atlas Motor Car Company, of Springfield, Mass., announces that despite the fact that three more attachments had been placed upon the company's property the outlook for resuming business is much brighter than ever and there is a good prospect that all the financial difficulties of the company will be settled in the near future and the concern reorganized.

At present the entire plant with the exception of the repair department is shut down, but Attorney Beattie states that if the plans under consideration go through it will mean the employment of a larger number of hands than before, when the regular list totaled 140 employees.

Continental Motor Increases Capital

DETROIT, MICH., Oct. 21—At a recent meeting of the directors of the Continental Motor Manufacturing Company the capital stock of the concern was increased from $500,000 to $2,400,000. Of this amount, $900,000 was made preferred stock and $1,500,000 common. The latter will remain in the treasury to take care of present improvements and additions to the plant, as well as to cover any dividends to stockholders. According to President Tobin, the concern is in an exceedingly prosperous condition, the entire output of the large plant being sold up through August, 1913.

Crude Rubber Easier; Price Unchanged

Crude rubber was easier in the world's markets during the past week. Quotations were practically unchanged, standing at $1.08 for up-river fine but there was an easier tone in all grades. Trade was equally balanced but some of the market sharps believe that the volume of inquiry is somewhat larger. Shipments of plantations from the East are growing steadily larger and consumers apparently are waiting for lower offerings before accepting commitments on a large scale.

Ohio Receiver to Petition Sale

CINCINNATI, O., Oct. 21—Edward G. Schultz, receiver of the Ohio Motor Car Company, having decided that it will be to the best interest of creditors and all parties in interest to sell the entire plant of the company, including the real estate, machinery, supplies, etc., at as early a date as is practicable, has made application to the court for an order to sell the property at such time, in such manner and upon such terms as the court may deem proper.

The application will be considered in open court by Wade Cushing, Judge of the Court of Common Pleas of Hamilton County, on Tuesday, October 22, at which time all creditors and others interested may appear and express their opinion with reference to said sale.

The appraisers appointed by the Court have filed their report, showing that, in their judgment, the plant as an entirety and going concern is worth $239,000 and if sold piecemeal and in separate lots, is worth $211,000. The liabilities are approximately $180,000, less the value of certain cars held by the banks.

The appraisers were A. A. Geis, connected with The Anchor Buggy Company, Wm. J. Peck, connected with The Hess Spring & Axle Company, and Cecil Evans, formerly superintendent of The Ohio Motor Car Company.

Old Knox Notes Cause Assignments

SPRINGFIELD, MASS., Oct. 21—Another result indirectly due to the recent assignment of the Knox Automobile Company and more directly due to the former difficulties of the company is that of the assignments made by William E. Wright, Albert E. Smith and Elihu H. Cutler of their real and personal property to Walter S. Robinson as trustee. The assignment was brought about because of notes held by several banks which were given by these men at the time the Knox company was reorganized in 1908. The demands of the commercial creditors of the company were satisfied at that time by giving them preferred stock in the reorganized company, but the banks holding notes of the old company endorsed by Messrs. Wright, Smith and Cutler refused to accept this stock as a settlement of their claims.

To make an arrangement satisfactory to the banks the three

Automobile Securities Quotations

The past week saw a continuation of the irregular market for automobile stocks. Goodyear gained 7 points, Goodrich 3, Firestone 3, General Motors 2 1-2, and Studebaker 2. On the weaker side were International, Lozier, Pope, which was down 3 points, and several of the other issues. The table:

men took the preferred stock and divided it among themselves and exchanged their personal notes for the notes of the company which they had endorsed. All three men held executive offices in the company, Mr. Cutler at one time being president back in 1907 before its first failure, Mr. Wright, vice-president and Mr. Smith assistant vice-president and secretary, of the reorganized company. The amount of the notes cannot be learned but it is believed to be somewhere between $80,000 and $100,000. One Springfield bank has some, the others being held by banks elsewhere.

The following officers have been chosen by the corporation: W. E. Wright, president; H. G. Fisk, vice-president; A. E. Smith, treasurer; Charles H. Beckwith, clerk. A committee has been named to investigate conditions.

Dean to Make Otho System

ELYRIA, O., Oct. 21—The Dean Electric Company, of this city, has secured the exclusive manufacturing rights for the Otho electric system for lighting and starting automobiles. The device is a single motor-generator, which serves to furnish current for both lighting and starting. When the motor is in motion the system acts as a generator and when it is necessary to start the engine the functions are reversed and the system bcomes a motor. The power unit takes the place of the flywheel, thus eliminating gearing. It has no brushes or wires in the rotary part of the wheel, the winding and brushes being stationary.

Wishart-Dayton Owes $33,899

Schedules in bankruptcy filed in the United States District Court by the Wishart Dayton Auto Truck Company show liabilities of $33,899 and nominal assets of $13,569. The latter consist of one truck, a few accounts and a claim of $10,000 for damages against the Dayton Auto Truck Company. The creditors are mostly banks.

Market Changes of the Week

Lead, rubber, and tin experienced small changes in the market during the past week. Lead closed at $5.07 1-2, a loss of $.02 1-2. Rubber's decline of $.03 was due to small sales, while tin, which had a gain of $.03, fluctuating throughout the week, closed at $5.02, due to lack of speculative interests. Linseed oil, which has been constant in the market, suddenly dropped $.04, closing at $.60. This is due to the decline in seed prices at Duluth.

Briscoe Resigns His Post

Organizer of U. S. Motors Makes Room for New Man Unhampered by Influences of the Past

Will Go Abroad—New Stock of $35,091,393 Company Introduced in New York Curb Market

BENJAMIN BRISCOE, president of the United States Motor Company, has announced his retirement from the leadership of the corporation to take effect about November 15. The resignation was presented to the directors 3 weeks ago, or as soon as it was apparent that the reorganization plan would go through substantially on the basis agreed to by the creditors.

Mr. Briscoe has been a prominent figure in the automobile world for many years, but has been a leader since 1910. He was one of the founders of the Maxwell-Briscoe Motor Company, Briscoe Manufacturing Company and other large and profitable concerns. He was instrumental in the formation of the United States Motor Company. He was organizer and president of the A. M. C. M. A., and at present holds the post of vice-president N. A. A. M. He is secretary and director of the Automobile Board of Trade.

Mr. Briscoe has announced that he contemplates a trip to Europe with his family, during which he will arrange several matters of importance to the extension of the export business of the company.

The new stock issues of the reorganized company have been introduced into the curb market and have been traded in conditionally since last week. All the transactions are made with the proviso that the deliveries shall be made when the stocks are issued. The new common sold as high as 11 1-2; first preferred up to 80 and second preferred at 40.

Under the proposed plan of reorganization the stock will remain in a voting trust for not to exceed 5 years, except such shares as are required for the qualification of directors. The capitalization will be:

First preferred, 7 per cent cumulative................	$11,000,000
Second preferred, 6 per cent. non-comulative..............	9,000,000
Common	11,000,000
Existing Real Estate mortgages........................	164,540
Total	$31,164,540
The total authorized capitalization will be...............	$35,091,393

In a tabulation of estimated earnings for the first full fiscal year under the reorganization, the net is placed at $1,500,000. This sum would be sufficient to pay dividends on both preferred issues and leave $190,000 for the common.

Charles H. Sabin, Henry Bronner and James C. Brady have been named as the voting trustees in whom the active rights of the shares shall be vested for a term of years.

The underwriting syndicate by which it is proposed to finance the new company has agreed to purchase for $5,720,996 all the voting trust certificates representing the stock allotted to assenting stockholders.

The Central Trust Company, of New York, has been designated as depositary for securities and claims.

The return day for the court action commenced by the Brown & Sharpe Manufacturing Company is October 28, when it is expected that the official status of the proposed reorganization will be determined.

Benjamin Briscoe, in referring to his forthcoming departure from the company, said: "I am going away for a rest and one of the main objects will be to regain the correct perspective of things. I believe that some other man, unhampered by any of the old influences and traditions of the company, can carry it through successfully. I have been asked to remain, but I feel that it would be better for me to go."

Willys Adds $10,000,000 Capital Stock

Willys-Overland Capital $25,000,000—Banker Buys $7,900,000—Willys Retains 75 Per Cent. of Stock

Conservative Expansion To Follow—No Changes in Management—Willys Retains the Presidency

John North Willys, president of the Willys-Overland Company, Toledo, O., has increased the capital stock of this company from $15,000,000 to $25,000,000 and in doing so has sold outright $7,900,000 common and preferred stock to Wm. Salomon & Co., bankers, 25 Broad street, New York City, and retains 75 per cent of the company stock himself. Under the new capitalization the division of common and preferred stock is as follows:

Total capitalization	$25,000,000
Common stock	20,000,000
Preferred stock	5,000,000

The ownership of this stock is divided between Mr. Willys and the Salomon company as follows:

J. N. Willys common stock	$15,000,000
J. N. Willys preferred stock	2,100,000
W. Salomon & Co. common stock	5,000,000
W. Salomon & Co. preferred stock	2,900,000

The purchase of $7,900,000 by Salomon & Co., in common and preferred, means that this will be for general sale and application will be made to have this stock listed on the New York Stock Exchange.

Up to the present time Mr. Willys has been sole owner of Willys-Overland stock, both common and preferred, and this issue of additional capital and its sale means that Mrs. Willys will practically take this amount of money in cash to himself.

No changes will be made in the direction or control of the Willys-Overland Company because of this expansion. Mr. Willys, who is now president, will continue in this capacity and direct the affairs of the organization as he has done in the past, and his able corps of lieutenants will be continued. There will be a gradual and conservative expansion of the company as well as of the five subsidiary companies, namely:

Kinsey Mfg. Company	Toledo, O.
Federal Motor Works	Indianapolis, Ind.
Garford Mfg. Company	Elyria, O.
Morrow Mfg. Company	Elmira, N. Y.
Gramm Motor Truck Company	Lima, O.

No changes will be made in the management of these organizations, of which the Willys-Overland Company is a holding organization, the $25,000,000 stock of the Willys-Overland Company representing the stock of these companies, which are as follows:

Kinsey Mfg. Co., capital	$3,000,000
Morrow Mfg. Co., capital	1,000,000
Federal Motor Works, capital	300,000
Gramm Motor Truck Co., capital	1,500,000
Garford Mfg. Co., capital	2,000,000

While purchasing practically 25 per cent. of the Willys-Overland stock Wm. Salomon & Co. will not be represented on the executive committee, but it is understood that the board of directors will be increased from five to seven and that the two added members will represent the Salomon capital, giving Willys a representation of five.

With the ending of the Willys-Overland fiscal year on June 30, 1912, the statement showed a profit of $3,300,000 for the previous 11 months. Prospects are that for the coming year this will be greatly increased. The company is at present shipping 150 cars per day. The output for 1913 is 40,000 cars, and for the year following 60,000 is the mark. The company will ship 15,000 cars from July 1 to December 31 of this year.

All of Mr. Willys' capital is not tied up in the Willys-Overland and subsidiary companies, but he has additional investments of $3,000,000 in other companies in the automobile business, so that his present holdings in the industry total $20,100,000.

At present the working force in the various Willys interests are as follows:

Willys-Overland, 5300; Kinsey, 1200; Morrow, 1000; Garford, 900; Gramm, 400, and Federal, 300. Total, 9,100.

These companies are engaged in the following manufacture: Kinsey makes frames and radiators for the Overland and the trade in general; the Morrow company manufactures gearset, universal joints and screw machine parts for Overland and the trade; the Federal manufactures motor and repair parts for the trade; the Garford company builds pleasure cars and trucks, and the Gramm company builds trucks.

Mr. Willys has announced some future plans for the Gramm and Garford concerns. Attention will be focused in the Gramm on bringing out a new 150-pound delivery truck, and at the Garford a new six-cylinder car to list around $2,500 will be brought out soon.

During the last 10 days rumors have been frequent to the effect that a merger of the Willys and other factories were on foot, but Mr. Willys positively denies such and officially states that the increased capitalization and sale of stock to Salomon are the only negotiations that have been on foot.

Bayerline in Charge of King Plant

Detroit, Mich., Oct. 21—The King Motor Car Company, the entire assets of which were purchased outright by Artemus Ward, of the firm of Ward & Gow, of New York City, has been placed on a sound financial basis by its new owner. Already operations have been commenced in the plant for the turning out of the new models for the 1913 season, which consist of a roadster, tuoring car and coupé. The personnel of the new company has been changed and it is in the hands of men who have had long experience in the automobile industry. J. G. Bayerline, formerly connected with the Pope-Toledo, Pope-Hartford, Oldsmobile and Hudson companies and up to a short time ago vice-president and general manager of the Warren Motor Car Company, has assumed the management, while T. A. Bollinger has been made factory manager.

It is the intention of the new King company to protect owners and all guarantees issued by the old concern will be assumed. It is also announced that a cômplete supply of repair parts will be carried in stock, and that deliveries on the new models are now being made. The cars will continue to be sold under the trade name of King.

Tractors Busy in Canadian Fields

Winnipeg, Man., Oct. 21—During the past summer 6,500 motor tractors have been breaking new land for crop next year in the Canadian west. Putting their daily average at the extremely low figure of 10 acres a day, and allowing them 60 days' work during the season, this would represent 3,900,000 acres of new land for 1913, and to this must be added the many thousand acres that have been broken by horses and oxen.

Daimler Import in Bankruptcy

Bankruptcy proceedings have been instituted in the United States District Court against the Daimler Import Company, which up to a short time ago represented the importation of Mercedes cars and trucks into the United States. The crisis resulted from alleged non-payment of rent to Harry Content & Company, owners of the premises at 751 Fifth avenue. The claim is for $1,826. The Daimler Import Company was incorporated under the laws of New York in June, 1910, and the capitalization was placed at $300,000. The recent agreement or compact with the Paul La Croix Automobile Company to handle the pleasure cars of the line and the achievement of the rights to import and manufacture the truck line by the General Vehicle Company foreshadowed some developments with regard to the importing company.

Judgments in favor of banking creditors have been rendered against the company within the past week amounting to $23,278. Nobody with any substantial interest in the company would predict its future course and Paul La Croix stated that he understood that the concern had been practically abandoned.

La Croix Threatens Mercedes Infringers

Aggressive action on the part of the American representatives of the Mercedes pleasure cars has been indicated by the announcement made by Paul La Croix, of New York, licensee of the Daimler Manufacturing Company, that infringement of the Mercedes patents and the license rights of the La Croix company will result in prosecution.

The chief element of the difficulty is that a number of Americans have purchased Mercedes cars abroad and imported them without paying license to La Croix. The broader question of patent infringement is included in the problem but is not foremost as a factor in immediate action.

Solid Tire Company for Cincinnati

CINCINNATI, O., Oct. 21—The Ideal Steel Wheel Company, a new Cincinnati corporation, has bought the former plant of the Seufferle Cooperage Company. The transaction is said to have involved $41,000. The new corporation, formed under the direction of the Kirgen-Parker Company, expects to produce a solid tire. The general dimensions of the building just acquired are 200 by 226 feet, together with several minor structures. According to the president of the company, this will be greatly enlarged. J. B. Fitch is president; J. E. Strielmeiler, the inventor of the tire, vice-president; E. H. Massey, treasurer, and Harrie Walker, secretary and manager.

Mexican Row Cuts Rubber Profits

Owing to the Mexican revolution the profits of the Intercontinental Rubber Company for the fiscal year ending July 31 showed a large decrease as compared with the previous year. The net profits from operation, available for dividends and surplus were $1,108,959, a loss on that item of $1,531,559, in comparison with the showing of 1911. Regular dividens were paid on the preferred stock, amounting to $87,500, but the distribution on the common was passed. The company earned an amount equal to 3.52 per cent. on its common capitalization of over $29,000,000. The insurrection caused a halt in commercial shipments as well as cultivation of guayule. The situation is rapidly improving in the vicinity of the company's properties and a resumption of business on a broad scale is probable in the near future.

Souther to Study Wire Wheel Rims

Henry Souther, metallurgical expert and former president of the Society of Automobile Engineers, has sailed for Europe in company with two representatives of the Standard Roller Bearing Company to inspect the plant of the Rudge-Whitworth Company in England and to visit other manufacturing plants on the continent.

It has been announced that Mr. Souther and his party will make a special study of the combination of the Sangster-Houk demountable rim with wire wheels of the type made by the Rudge-Whitworth company.

British Gale Is Thin Air

English Expert Says That There Is No Foundation for Report of Giant Company to Fight America

Government Asks Bids for Automobiles to Be Used in the Service of Various Departments

COVENTRY, England, Oct. 14—I do not know where your New York correspondent gets his information from, but he is considerably at sea when, in your issue of September 26, he writes and talks of the formation of a $25,000,000 capitalization here to compete with the American cheap cars which are coming over here in quantities. You can take it from me that there is not $25,000,000 in this country available for any sort of wildcat scheme which financiers choose to put forward, but the real trouble with the British industry is that adequate capital is lacking for dealing with it as it should be dealt with and the failure of your big combination to make good does not help things any..

The truth about this story of the $25,000,000 company to meet American competition is that one of our halfpenny papers—what you would term the yellow press—got its hair off over the success of the Ford and beat the big drum on the decline of British industry and the Americans sweeping the board. One or two of our impressionables here in trade, who were out for a bit of self-advertisement as much as anything else, played up to them, with the result that the paper gave a swagger invitation dinner to the trade to discuss things. None of the representative British houses took the trouble to go, but a few others attended at the dinner and talked, and the talk was around a wholly impracticable proposal—of Mr. William Letts—for a combination of British firms to make a cheap car and another suggestion was that a $2,500,000—not $25,000,000—independent company might be formed for the purpose. The general result of the discussion was a beating of thin air. Both suggestions were turned down as unworkable and, having digested the newspaper's good dinner, the crowd went home. And I think you can leave it at that. Our manufacturers of class cars are not tumbling over themselves to get into the cheap trade any more than are the Peerless, Packard, Pierce-Arrow and other makers on your side who are making similar class machines.—HENRY STURMEY.

Government Seeks Bid on Automobiles

WASHINGTON, D. C., Oct. 21—More than ordinary interest attaches to a call for bids issued by the general supply committee of the government departments for furnishing various branches of the government service with both gasoline and electric vehicles. The bids will be opened in this city October 29. Complete specifications are given in the blanks to be furnished manufacturers who have been asked to submit proposals. The specifications have been standardized by the Bureau of Standards, the purpose being to have trucks of a distinct type in the government service in the future. The specifications call for bids on trucks ranging from 1,000 pounds to 3,000 pounds capacity. The small trucks are intended for mail wagons, but the government does not yet know whether it will buy small or large machines or how many of each type after the sizes have been determined by actual test.

The object of asking for bids on different types of cars, both electric and gasoline, is to obtain comparative information as to prices, etc. Manufacturers are told that for the present probably not over six machines will be bought, but that this number will be increased in the future.

G. M. Profits $4,746,756

Company's Net Earnings for Fiscal Year Come to That Amount—Surplus of $2,856,082

Gross Business Totaled $64,744,496—A Gain of 50 Per Cent. Over 1911

DETROIT, Oct. 21—The annual report of the General Motors Company for the fiscal year ending July 31, 1912, has been issued. The gross business done during the year reached the enormous figures of $64,744,496, as against $42,733,303 in 1911, or slightly over 50 per cent. increase. The net profits of the year were $4,746,756. Fixed charges of $850,463 for interest on the 6 per cent. loan and dividends on the preferred stock of the company of $1,040,210 are deducted from the net manufacturing profits, leaving a surplus of $2,856,082.

At the end of the 1911 season there was a surplus in the treasury of $1,240,175 and by adding the surplus for the year ending last July the total surplus was brought up to $4,096,258.

Prior to October 1, 1910, certain inventories were made covering material and assets that are now considered obsolete. Last year a part of this obsolete material was written off and this year, following the usual rule, the directors have wiped out $2,833,594, which is practically the amount of additional surplus accumulated during the past year. After making this deduction the surplus account stands at $1,262,663.

The subsidiary companies operated at a profit of $5,770,177, but from that sum losses of $1,023,421 are deducted, covering the operations of unsuccessful concerns affiliated with the big company. The report states that all the subsidiaries completed their manufacturing schedules on time and disposed of all their product before the close of the fiscal year.

The inventories have been given a rigid examination with the result referred to above, and President Neal states that the action of the directors in writing off and abandoning the eliminated items will afford material relief to the manufacturing and sales organizations and make for further efficiency as the organizations will not have to try to salvage obsolete and undesirable models, materials and products.

With regard to the distinct plan of centralization that has been introduced since the new management took control of General Motors, President Neal says:

"Accordingly, your directors have been gradually concentrating the operations of the smaller companies with the larger and more profitable companies, or else, in some cases, eliminating the greater part of their machinery operations and so turning the operations of the smaller companies into plants merely for the assembly and distribution of automobiles. This policy was inaugurated cautiously, and necessarily has proceeded slowly. The transfer of the manufacturing operations has in most cases involved the completion of the entire operations in hand at the smaller factories and also generally the design of new models for the necessarily standardized output of the larger factories could be utilized. This process has gathered momentum during the year just closed, and will be continued in the case of several of the companies during the coming year, the machinery of the smaller plants being gradually concentrated at the larger manufacturing plants."

This explains the course of the company with regard to the Marquette and Elmore factories.

Motors for the automobiles of some of the smaller companies are made by the Northway Motor & Manufacturing Company, which produced 10,430 last year and is scheduled to make 20,000 during the current fiscal season. All the product of the motor company is not used by the General Motors subsidiaries and the surplus is sold to outside manufacturers of automobiles. According to the report, the advantage of centering engine manufacture in a special plant lies in the fact that the smaller users get a better motor for less expenditure of money, time and trouble.

The foreign business of the company, exclusive of Canada, has about doubled and was approximately $1,700,000 during the past year.

The Weston-Mott Company, which makes axles for several of the subsidiaries and the stock of which was about half owned by General Motors, has been fully purchased. The outstanding capital stock, amounting to 50.2 per cent., was purchased by exchange of securities, of which $520,000 of common and the same amount of preferred was a part.

The number of employees at the time the report was made, which was some time after the close of the fiscal year, was 17,173. This compares with the high number in 1911 of 11,474 and 1912 of 16,584. President Neal in conclusion states that during the first 2 months of the present fiscal year the receipts of the company have been over $1,000,000 more than they were in the corresponding period covered by the tabular report.

The capitalization of the company outstanding is as follows:

Preferred cumulative 7 per cent.	$14,936,800
Common	16,371,183
Total	$31,307,983

This represents an increase of $543,300 preferred and $548,853 common during the year.

The funded debt of the company October 1, 1910, consisted of $15,000,000 of 6 per cent. gold notes. Since that date the amount has been reduced by sinking fund operations to $11,922,000, the proportion taken care of and retired this year being $1,530,000. The total amount of the reduction to date is $3,078,0000, which represents a reduction of the item in the fixed charges of $184,680 per annum. The notes are due October 1, 1915, and under the original schedule the outstanding indebtedness will be reduced at least $5,500,000 by that date.

This would leave the bonded debt at $6,422,000, even if a larger proportion of the notes is not retired in the meantime.

In acquiring the Weston-Mott Company General Motors assumed $600,000 of notes issued by the company. Half of this issue has been retired and the other half is due next September.

The condensed balance sheet for the year is as follows:

ASSETS	
Fixed assets: real estate, plants and equipment	$19,280,888
Patents, agreements	1,871,436
Investments	560,499
Cash	3,080,920
Notes and accounts receivable	4,229,112
Inventories	17,578,366
Prepaid expenses	422,736
Total	$54,958,158

LIABILITIES	
Capital stock	$31,307,983
Bonds, as of July 31, 1912	12,452,000
Stocks of subsidiaries not owned by General Motors	991,838
Current liabilities	4,382,876
Reserves for dividend	261,394
Reserves for special purposes	4,299,471
Surplus	1,262,594
Total	$54,958,158

The constituent companies of General Motors are as follows: Buick, Cadillac, Oldsmobile, Oakland, Elmore, Cartercar, Northway Motor, Peninsular (formerly Marquette), Randolph, Rapid, Reliance, Welch-Detroit, Welch, Champion Ignition, Jackson-Church-Wilcox, Michigan Auto Parts, Michigan Motor Castings, Oak Park Power, McLaughlin, Weston-Mott, General Motors Export, General Motors Truck, General Motors, Ltd., General Motors Company of Michigan.

The official roster of the company is as follows: Thomas Neal, president; W. C. Durant, C. W. Nash, Emory W. Clark, vice-presidents; Standish Backus, secretary; James T. Shaw, treasurer, and W. H. Alford, comptroller.

Applying Chassis Finish

Running Gear Should Be Thoroughly Painted and Surfaced Before the Car Is Taken from the Shop

Car Owner Should Study Qualities of Various Varnishes and Should Aim at Uniformity of Color

IT is not an easy matter to obtain a varnish that will stand up and shine with a strong luster through the hard and varied service to which the average car is exposed. Such a varnish, for one thing, must have great elasticity and at the same time it must dry hard as nails. No vehicle has so much harsh cleaning and such varied methods of cleaning applied to it as the automobile. Road conditions are often bad beyond description. Some one lately returned from a tour of the West in an automobile has said that **"the highways of the United States furnish a greater variety of mud and dust, a large part of it being of the worst imaginable sort, than any country under the sun."** This explains in part, at least, why it is so difficult to keep the car in proper condition even though frequent varnishing be resorted to.

Usually the chassis presents the most neglected and unkempt appearance. It has been customary heretofore, we believe, to apply an ordinary finish to the chassis and let it go at that, which practice, it goes without saying, is entirely at odds with the actual needs of the situation.

The chassis should have thorough-going methods of painting and surfacing applied to it, and no car owner should take the car from the shop unless the evidence is unmistakable that such methods of work have been applied to the running parts. Over these parts a couple of good varnish color coats should be applied, both to be rubbed lightly with pulverized pumice stone and water. Then have the striping applied, after which arrange for a coat of clear rubbing varnish, this to be in due season topped off with a stout coat of a quick-drying elastic varnish.

Especially should the chassis varnish be capable of resisting the action of soap, much of which is used in cleaning these parts of the car. The more nearly the varnish will resist and prove immune to the action of soap and water the more valuable it becomes to both the painter and to the car owner. In trying out a varnish for its capacity to do the things here referred to **the car owner should go into something like definite details so that eventually he can choose for himself, if he so wills, the varnish best adapted for his particular needs.**

Logically the finish on the automobile hood should be baked on and it should consist of as few coats as possible consistent with a finish to correspond with other parts of the car. For a new hood, clean off dirt and grease and apply a metal primer and bake in an oven for three hours at a temperature of 175 degrees. Over this put on a knifing surface, working it down smooth and fine, and bake at 200 degrees for three hours. Then sandpaper this coat thoroughly, after which apply two coats of some reliable baking enamel. If this enamel is black bake for five hours at 200 degrees. Then two coats of a hard-drying but elastic finishing varnish, each coat baked for five hours at 125 degrees, should be put on. **Generally speaking the fewer coats comprising the finish for the hoods the more likely is it to escape cracking and fracturing from the heat of the motor.** Engine oil, dirt, rain, etc., on the heated surface of the hood is particularly destructive to any but a finish each coat of which is baked to a nicety.

The fenders of the car are parts upon which an exceptionally good finish is needed; a finish that will stand extraordinary vibration, harsh and constant exposure and severe usage. In washing the chassis with soapy water a process that has reached widespread practice, the fenders apparently come in for a full measure of this treatment, and a finish, therefore, anything short of first class is practically certain to suffer an early decline. **Such a finish should be built up over a foundation consisting of primary coats sufficiently elastic to stand the strain of the rigorous vibration.** This elasticity can be provided by the use of raw linseed oil gradually lessening the quantity in one, two, three order as the coats go on until the color is reached. In the use of japan ground color coats thin down with pure turpentine, adding one part oil to every eight or nine parts turpentine. This will furnish a graduated elasticity over which a couple of coats of varnish-color may be applied, these to be followed by a coat or two, according to the quality of finish desired, of a hard drying finishing varnish which possesses the property of being elastic. The varnish color to be used upon the fenders should be made of finishing varnish, rubbing varnish being too brittle to stand the vibration strain. **No rubbing varnish should be used upon the fender for this reason and for the additional one that it will not properly respond to the contraction and expansion under the variations of temperature to which these parts are exposed.**

Another point which the car owner seeking to develop and maintain the best possible appearance of his car should insist upon is in the treatment of the color coats. In the hurry to get the color under varnish, it is often the case that the color is not adequately dry when the varnish is put on, the result being that the color shows a shade which under normal conditions of treatment it does not possess and which, in fact, it should not possess. The color on the car, when it is given time to dry properly before varnishing, will look, and should look, precisely as the same color looks in liquid form in the mixing cup. Then you have color purity in its original and perfect shade. There are, for example, some of the greens, very beautiful when properly placed on the surface and permitted to dry solid and firm, which if smothered under a coat of varnish before being thoroughly dry will show not only two or three different shades of color, but all of these shades will vary from the true shade.

Another matter of color for the car owner to recognize as important is that of having the same shade of color, when but one color for the body is desired, established over all the surface. In a New York showroom recently the writer inspected a car painted a dark blue, closely approaching Royal blue, which ran through two or three shades. This was due, apparently, to the neglect of the painter to mix up enough color at one time to coat the entire surface. In mixing up a second batch of the color he failed to perfectly match it to the first lot and the subsequent coats of varnish had served to exaggerate the varying color shades.

The prospective car buyer may very properly subject the color on the car to close inspection for uniformity of color. A lack of this quality does much to put the appearance and finish into disrepute.

The car owner should understand and familiarize himself with the fact that virtually all colors used in automobile painting to-day are delicate and sensitive colors in that they require thorough varnish protection. Because of this need the car requires to be varnished at least a couple of times a year—say in spring and autumn. In this manner the colors are made to wear longer and appear to better advantage, while they are wearing, than would be the case in the event of deferring the revarnishing until the old varnish has quite lost its protective capacity.

Especially is the varnish protection here advised of value in getting permanent or durable wear out of the rare and lovely lake pigments now so largely used upon automobile work.

Compact Dynamometer Adaptable to Outdoor Efficiency Testing—Sprags Denounced in Germany as Antiquated—New Removable Rim—The "Bumpograph" to Save Lives and Money for Railways—World Trust in Aluminum—Sundry Topics

TRANSMISSION Dynamometer—A device has been developed by A. Wallon by means of which it should be practicable to determine the amount of power utilized for propelling an automobile at any given speed and for any actual condition of the road, by applying it to the clutch shaft, and either simultaneously or subsequently to decide the power absorbed in the gearbox and the front universal joint of the driving shaft, by applying it to the latter. Perhaps it could also be used to decide the frictions in the bevel gear and the differential when applied to the wheel-driving shafts. It is a dynamometer which, when equipped with a registering dial or roll, may be used to measure and record, in the form of diagrams, torque and torque reactions under practical working conditions. By using it first under one road condition and then under another with the same vehicle it should lend itself to determinations of the properties of various road surfaces, and similarly it might be used for establishing reliable data with regard to the traction resistance encountered with different tire treads and tire constructions. Its range of utility seems comparable with that of the Wymperic accelerometer, mentioned at length in THE AUTOMOBILE of October 10. A special field for the Wallon device lies in its suitability for measuring at the same time the power applied to a propeller shaft and the thrust of the propeller, whether in the case of boats or aeroplanes. In this application the device promises to remove many doubts with regard to the varying efficiency of propellers throughout the ranges of motor and vehicle speed, while at the same time throwing new light on the different values of different shapes for penetrating water or air.

Unfortunately the exact mechanical construction of the Wallon device is not disclosed, but the principle upon which it operates may be understood in the main features by the following description and the accompanying drawings, Figs. 1 to 6.

The leading principle is that the torque is made to cause a hydraulic pressure, and this pressure is measured. To this end the motor shaft is coupled to the driven shaft by means of a sleeve secured to the latter. In the sleeve is secured a jaw clutch to which corresponds a clutch member on the shaft. Both are cut helically with a pitch exceeding 45 degrees, so that the turning of either the shaft or the sleeve will tend to force the two clutch members apart. To minimize and regulate friction between them, ball-bearings in a suitable casing are interposed between the helicoid working surfaces. Figs. 1 and 2 show the shaft and the sleeve separately but not the ball bearings. The sleeve is closed and packed around the entering shaft so as to form a sort of dashpot in which, however, the relative movement of the parts is exceedingly small, as the space is completely filled with fluid, preventing displacement of the clutch surfaces. The only movement possible is that necessary for transmitting pressure through the inclosed fluid to the attached manometer. The movement required of the ball-bearing is therefore also very strictly limited, as it must be to make the construction practicable. The manometer may be of ordinary construction, registering or merely indicating, and is connected with the interior of the sleeve by means of such a swiveled valve as shown in Fig. 4 inserted in that end of the sleeve in which the piston and clutch formation of the motor shaft is located. [This arrangement apparently makes it necessary to connect the sleeve with the driven shaft by means of two semi-circular arms or other equivalent elements allowing space for the manometer and the registering apparatus. At this point the fragmentary description suggests that the device may still be in its experimental stage with regard to its mechanical execution for use in automobiles.—ED.]

In order that this device may be used for measuring with accuracy the force applied to establish a certain pressure in the fluid, it is evidently necessary that the reaction between the helicoid surfaces of the clutch, with the intermediation of the ball-bearings, shall be proportionate to the forces by which they are produced. This reaction is represented in the diagram Fig. 3, being the resultant R of the tangential force due to the torque C and of the force P_s which the fluid pressure P exerts upon the cross-sectional area s of the shaft. The tangential force takes the form $C \div r$ if r is the radius of the shaft, and as r, s and a, the latter being the pitch angle of the clutch surfaces, are constants in any one apparatus, the resultant R is bound to be proportional to the torque and capable of furnishing a measure for it. The factor of proportionality may be calculated more simply by applying the theorem of virtual displacements, so-called. If it is assumed that the torque C causes a rotation w of the shaft with relation to the sleeve, then the work of the torque is Cw. The stroke of the piston—the longitudinal movement of the shaft—corresponding to w is $hw \div 2\pi$, in which h is the pitch of the helical surfaces. The work of the pressure is then equal to $Ps \times hw \div 2\pi$. When there is equilibrium between the work done by the torque in displacing the clutch and the work done by the clutch in effecting a pressure upon the fluid—or, in other words, when the power is transmitted integrally from the driving to the driven shaft—the two values become equal, or

$$Cw = Ps \times hw \div 2\pi$$

from which

$$C = P \times sh \div 2\pi = PK$$

if K is the constant factor corresponding to $sh \div 2\pi$ in any given apparatus.

Applying the usual formula for converting the force into horsepower [under the French notation in which 60×75 kilogram-meters corresponds to 33,000 foot-pounds in the English notation], the above value for the torque is equivalent to the following for horsepower:

$$\text{Horsepower} = PK \times 2\pi n \div (60 \times 75)$$

and this takes the simpler form of PnK' by summarizing the constant factors as K'. In order to simplify calculations with any given apparatus its dimensions are so co-ordinated that K' becomes a simple factor, preferably a power of 10.

A dynamometer constructed on this principle is very robust and gives readings whose accuracy depends upon the sensitive-ness of the manometer used with it. As the quantity of liquid moved in it is very small, the variations in torque are not masked by any effect arising from the inertia of parts, even if the variations are rapid, and the diagrams taken from it should be reliable. It is also not affected by centrifugality owing to its great compactness, and it may be operated at a speed up to 1,500 revolutions per minute or more.

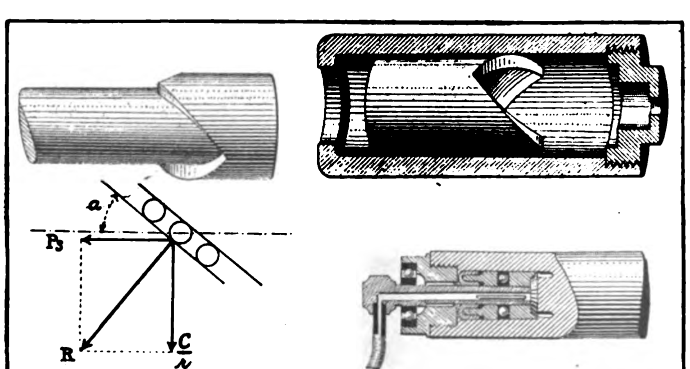
[On the other hand, since PnK' means that the manometer pressure should be multiplied by the number of revolutions and the product by a certain constant factor, a revolution-counter with registering device must be synchronized with the manometer register if it shall be possible to compare two or more performances which are not conducted with exactly the same motor speed, and this a constant one pending the duration of the test. It also seems that the friction of the piston-shaped end of the driving shaft would influence pressure-readings relating to rapid variations of power, though not those relating to a constant power development, since this friction must be considerable in order to make the piston so tight that no leakage can take place. These discrepancies may be only apparent, however. A complete description of the apparatus might show them to be obviated in some manner.—ED.]

Figs. 5 and 6 indicate how the device is used to measure both the power applied in driving an aeroplane propeller and the thrust against the atmosphere into which this power is transformed. In the position represented in Fig. 5 the thrust is received by the collar A (the thrust being toward the propeller), and the reading of the manometer will then indicate only the torque transmitted to the sleeve. But by releasing the collar A from rigid relations to the frame, as indicated in Fig. 6, and fixing collar B in the frame so as to absorb end-thrust from the sleeve, the manometer will show a pressure smaller than before, as the propeller thrust, now released, works oppositely to the pressure caused by the spreading of the clutch. By determining the factor of loss in transmitting the propeller thrust, or pull, to the clutch elements, the equation by which the propeller efficiency may be determined takes the form

$$P_1 = C \div K = P_2 + (T \div S)$$

in which P_1 is the previous manometer pressure, equaling the torque C divided by a constant K, and P_2 the new manometer pressure, T the propeller thrust and S a constant expressing the loss in the transmission of the thrust.—From *La Technique Moderne*, October 1.

LOCATION of Sprags—An exhaustive analysis of sprags, with special reference to the compulsory equipment of German army motor trucks with these devices, has been prepared by engineer Schwerdtfeger of Frankfurt-am-Main. He is of the opinion that it would be better to rely on good brakes and supports this opinion with a number of diagrams taken from truck and touring car practice and with many accompanying calculations. The most important viewpoints with regard to the reliability of the sprag deal with the uncertainty



Features of the Wallon transmission dynamometer

of making the sprag take hold in the ground if the latter is hard and uneven and the sprag is held at a small angle, which otherwise would give the best support once a resting point were found, and with the danger of having the vehicle climb over the sprag if its angle is large. If the last-mentioned trouble is obviated by tying the sprag up to a maximum angle, it may not take hold in soft ground. If a double sprag is used, the likelihood is that only one of the points will take hold at first, and in that case a turning of the vehicle around the point which has become fixed is to be feared. The most important conclusion is that a sprag, if it must be fitted, should be hung from the front portion of the vehicle and not so as to take effect under or behind the rear axle. The argument in this respect is taken from calculations showing to what extent the application of a sprag takes the load off the driving wheels at different angles of the sprag and at different inclinations of the road surface. It is especially accentuated that the greater the gradient of the road the more of the load will be taken off the rear axle, and that consequently, when the vehicle is to be started to go forward again, the difficulty in obtaining traction for the driving wheels will be in direct proportion to the need of it. As another reason for the abolition of sprags in favor of strong brakes, it is mentioned that there may be need of stopping a vehicle when it is going down a steep hill as well as when it is going up and that therefore if one sprag is necessary or desirable, two of them should in reality be fitted, capable of acting in opposite directions. Any other view would seem to stigmatize the sprag as a survival from the time when brakes would hold only in one direction.—From *Der Motorwagen*, September 10 and 20.

HARMONIC Noises—Most modern automobiles produce a humming noise at certain vehicle speeds while quite silent at other speeds, both higher and lower. The phenomenon is noticed in new cars as well as in old ones but perhaps mostly in those of light construction. As silence in operation is one of the properties most sought by constructors and most remunerative to manufacturers as well as pleasing to users, it is worth the while to seek the cause. It is perhaps to be found in the law of harmonics. It is well known that when a sharp note is sounded in a room its volume is much increased if there are objects in the room capable of emitting the same sound by vibration. One piece of cut-glass responds to one sound, another to a sound of different pitch. A note produced on a violin or by the voice is strengthened by resting one foot on the pedal of a piano, thereby leaving those chords free to vibrate which correspond to the tone produced. Frequently piano keys are seen moving as of their own accord when a person sings or a dog barks sharply. In the electric field similar things take place. Induction coils and transformers have been ruined by the great tension produced when the vibrations of one high tension current got into harmonic relations with those of another.

It seems probable that the different parts of an automobile, being made of steel and all vibrating more or less when the motor is working and the vehicle is shooting over the inequalities of a road surface, may get into similar harmonic relations under certain combinations of circumstances varying for different vehicles. A certain motor speed and a certain vehicle speed, combined, may set up vibrations in different parts of the chassis which strengthen each other and swell to the volume of a noise, the musical note which is primarily produced being spoiled by the accompanying discordant vibrations of other parts. It is noticed that a vehicle will emit such noises when going at a certain vehicle speed on third gear-speed but not when going at the same gait on the high gear, the inference being that in the latter combination the motor vibrations and those of the frame do not concord. In the American Ford cars which always travel on high gear the sound is produced always at between 40 and 45 kilometers per hour, but it does not come from either the motor alone or the chassis alone; for, when going down hill at the same speed but with the motor out of action the sound is not observed. Also, with any car, when the stage is reached at which the noise is heard and one then advances the spark and thereby interferes with the mathematics of the motor's vibrations, the sound disappears suddenly—only to reappear at another combination of motor and vehicle speed, however.

While probably no mathematical stringency is applicable in the case of automobiles to avoid the noises referred to, the observed facts seem to point a way to their suppression by experimental methods, perhaps especially by tying up those parts which are capable of regular periodic vibrations with others which are not so constituted.—After Antonin Marechal, engineer, in *Pratique Automobile,* August 10.

—

REMOVABLE and Demountable Rim—An engineer by name Laisne of Douai, France, has had made for himself a removable rim in which it is the main feature that the pneumatic tire is held by its two beads in a thin and elastic steel ring which at one point is split transversely and that this steel ring is held between the hooked flanges of a much stouter two-piece rim, one side of which is demountable. The other and larger part is, in the case of a wood wheel, secured directly upon the felloe and is recessed circumferentially at the edge which lies upon the felloe to receive an annular flange of the demountable side of the rim. At three or four points of the thinned edge of the permanently fixed rim portion there are shallow recesses formed to accommodate wedge-shaped lugs on the interior side of the overlapping annular flange of the other portion. These lugs are split, the slit going through the overlapping flanges as well, and in line with each of them a lug with a bolt hole is secured to the same rim portion, probably by autogenous welding, and by passing a bolt through this hole from the opposite side of the wheel felloe and under the permanent rim portion and drawing it tight with a nut, the shallow split lugs are drawn into the recesses under considerable tension, and in the same operation the thin elastic steel ring with the inflated tire, having been first placed in its proper position with relation to the permanent portion of the rim, is securely locked. The split lugs and the recesses may be formed by stamping with a die.

As applied to wire wheels the permanent rim portion is formed so as to replace the wheel felloe and the spokes are secured to it in the customary manner.

The valve hole in the elastic steel ring is slightly flanged so as to fit into the valve hole of the permanent rim portion, thereby protecting the valve stem and obviating rotation of the steel rim. To fit the latter to the tire it is only necessary to compress it, making the edges at the transverse split overlap and reducing the ring's diameter, and then to place it inside of the tire and allow it to expand, by which action it engages the retaining beads of the tire, and the latter may then be inflated the split in the steel ring being closed because the circumference of the ring corresponds accurately to the interior circumference of the tire.

The advantage of the construction lies largely in the fact that only the thin steel ring, with the reserve tire mounted on it, is to be carried as a spare part.—From *Omnia*, September 28.

FROM Automobile to Railway—Taking his inspiration from the registering devices which have been used for demonstrating the properties of shock absorbers on automobiles, for example, at the Massachuetts Institute of Technology, Mr. L. Schlüssel, an engineer, proposes in the August number of *Bulletin du Congrès des Chemins de Fer* to use similar devices for the important work of locating weak spots in the rails and roadbeds of railways, thereby obviating accidents. The principle of the mechanism in question is usually that a weight is secured to the free end of a horizontal leaf spring of which the other end is fixed in the floor or other rigid part of a vehicle, and that a registering stylus records on a roll of paper the movements of the weight, which correspond in an exaggerated manner to the jouncings to which the vehicle is subject. Mr. Schlüssel has developed the theory of the movements of such a weight with great detail and many diagrams and maintains that the installations of such suitable recording devices on railway trains, if supplemented by daily inspection of the diagrams taken from them, would not only serve the purpose of locating dangerous spots, but would also save the railway companies much money by locating the stretches where inspection and repairs are unnecessary.—From *Le Génie Civil,* September 28.

MANGANESE in Castings—At the fall meeting of the Iron and Steel Institute Mr. Coe, of Birmingham, who first called attention to the special behavior of cast iron under the influence of manganese, submitted the results of new investigations of the changes of volumes and temperatures which take place at the moment of freezing in white and gray iron containing this alloy. It appears from this work, which supplements the broader work of Professor Turner on the same subject, that in white iron the manganese causes an expansion at the moment of solidification of the molten mass which is independent of the carbon content and that this expansion reaches maximum at an alloy of 2 per cent. Thereafter the expansion dwindles again, reaching zero at 5 per cent. A new maximum comes at 7 per cent., a new zero at 10. Increasing the alloy still further, a maximum comes at 12 per cent. with a zero following at 15.3 per cent. The expansion remains constant between 21 and 39 per cent. of alloy.

In the case of gray iron there is a minimum expansion at 1.6 per cent. of manganese and thereafter a gradual increase up to 10 per cent. Another maximum was observed at 17.5 per cent.

Hardness is increased up to 2 per cent., then drops between 2 and 2.65 per cent. and thereafter rises steadily, according to Coe's observations.—From *Giesserei Zeitung,* October 1.

—

ALUMINUM Makers Combine—The expected coalition of French and American producers of aluminum has come in the form of a new enterprise incorporated with a capital stock of $6,400,000 at Whitney, N. C., under the name of the Southern Aluminum Company. It was founded by the combination of the *Société Aluminium Francaise* and the American Metal Company, the latter previously known as a group in the *Metallgesellschaft* of Frankfurt-am-Main. The combination was presaged through discoveries of new economical processes for extracting aluminum from bauxite and the relations of these processes to the chemical composition of the bauxite beds in France on one side and in America on the other.—From *Giesserei Zeitung,* October 1.

—

New Life for Old Rubber—It is claimed that frequent washing with a solution of 1 part of ammonia and 3 parts of water will keep rubber articles from getting hard and brittle with age. Immersion in the same fluid will to some extent restore the softness to old rubber if it is not too thick.—*Exchange.*

—

To Remove Rust—It is recommended to rub the rusted part with a woolen rag saturated with a mixture of lactic acid, one part, and oil of lavender, two parts.—*Exchange.*

Diesel Motor Explained

Developed from Experimental Coal Dust Motor—Present Oil Engines Aggregate 1,000,000 Horsepower

THE name oil engines today covers a number of types which utilize fuel oils varying in specific gravity from .68 to 1.0. After the nature of the fuel they use they are sometimes called gasoline, paraffin or kerosene engines, and they may be advantageously divided into two classes, light and heavy oil engines, depending on the density of the fuel used in them. Light oil engines comprise principally gasoline engines of various design, developed after the original Daimler motor, in which fuel averaging .72 in specific gravity is used. The second class includes motors utilizing heavy oils which, unlike the light fuels, cannot be simply carbureted, but must be preheated or prepared for combustion by atomization, as in the Diesel engine.

Priestman and Hornsby-Ackroyd engines comprise the so-called explosion engines. In these engines liquid oil is supplied to a heated bulb or baffle-plate and there vaporized, being then mixed with the carbureting air and ignited.

Diesel engines may be divided into two classes, Diesel type proper and semi-Diesel type. In the former, pure air is compressed to about 500 pounds, when oil is squirted into the cylinder at still higher pressure, causing its spontaneous combustion. In the semi-Diesel type only half the air compression need be used, the ignition temperature being reached by contact with a hot bulb.

Long and expensive research only made possible the Diesel engine of today, which, though now acknowledged as the most important type of oil engine, was not long ago but in its making. In 1892 Dr. Rudolf Diesel applied for his D. P. R. (German patent) and arranged with the Augsburg-Nuernberg Maschinenfabrik and Alfred Krupp of Essen to make all the necessary experiments and tests, a special laboratory being equipped in Augsburg.

It soon developed that Dr. Diesel could not realize his first ideal, the production of maximum temperature just before the combustion which should be isothermic. Water-jacketing proved necessary and a disappointment in view of the original expectations. Nevertheless, Diesel and his backers continued their work and in 1897 produced a 20-horsepower motor surpassing in thermal efficiency all previous internal-combustion types. Licenses were then sold, but until 1903 the Augsburg-Nuernberg stood practically alone as its manufacturer, due to difficulties first met by the licensees. In 1898 the Allgemeine Gesellschaft fuer Dieselmotoren, A. G., Augsburg, was formed, which acquired all rights to the Diesel designs. Vertical single-acting, horizontal single and double-acting and reversing marine types have since been developed and the total horsepower of Diesel engines in use today approximates 1,000,000.

In external and internal-combustion engines where useful work is produced from heat a heat fall is utilized, which may be measured by the number of thermal units made mechanically available by the transformation of the heating fluid which passes through the engine and whose temperature is simultaneously reduced. The fall of temperature, however, is in itself no measure of the heat fall, depending as it does on the manner of introducing and abstracting the heat-carrying fluid from the engine. As only a fraction of the heat introduced may be utilized mechanically there is a ratio between the heat theoretically abstractable from the fluid and between what is actually obtained in the form of power; this ratio which is always a true fraction is called actual thermal efficiency. But as the amount of heat which theoretically may be utilized is also but part of the heat introduced, the ratio between these two values is also a true fraction, the theoretical thermal efficiency. The latter is in turn greater than the actual thermal efficiency, and their ratio is referred to as efficiency ratio. The latter is for condensing steam engines using saturated steam, 60 to 80 per cent.; for condensing steam engines using super-heated steam, 50 to 70 per cent.; gas engines, 80 to 88 per cent., and oil, including Diesel engines, about 75 per cent.

Dr. Diesel first attempted to obtain maximum thermal efficiency through the use of a constant temperature of combustion in his engine cylinders, but as the abstraction of heat from the gases could not be effected at constant temperature, it was not possible to obtain the thermal efficiency of .855 which he expected and which would correspond to .25 pound of coal per horsepower-hour. In this connection it should be noted that the first trials were made with coal dust.

In the gas engine the heat is introduced theoretically at constant volume, the mixture being completely burned or rather exploded before the piston begins its power stroke. In practice this is not the case, and part of the mixture is added at increasing volume; this results in a loss. **In the Diesel engine the fuel is introduced comparatively gradually and the pressure remains almost constant, giving a flat top to the indicator diagram; but this is theoretical, and in practice the top of the curve is only approximately flat.**

One difference, then, between engines working on the Otto and Diesel cycle lies in the compression pressures used, the maximum pressure in Otto-cycle engines being 130 pounds per square inch, higher pressures giving rise to preignition; while in oil-engines of the Diesel type the pure air charge is compressed at a pressure of about 32 atmospheres, or almost 500 pounds per square inch, this being possibly due to the pressure of pure air only. The high pressure raises the temperature to about 700 degrees Centigrade, when, at the top of the piston stroke, the oil being injected meets with a high enough temperature to cause its ignition without a spark or hot tube. In the semi-Diesel engines the compression pressure is only one-half of that just cited, and ignition is by a hot bulb. Both types of Diesel designs are immune from preignition, a great advantage.

Up to the present most Diesel engines have been designed to operate on the four-stroke cycle, corresponding to the strokes in four-cycle gas engines. **But Diesel motors may also be constructed to work on the two-stroke cycle, by having a blast of air enter the cylinder at the instant the exhaust valve opens, whereby not only perfect scavenging is obtained, but also a full charge of pure air, which is then compressed.** Each down stroke is a combustion stroke. This type of Diesel motor is now making great strides.

The essential parts of a Diesel motor, whether working on the two or four-stroke cycle, are: A working cylinder containing a piston, the latter's connecting rod and crankshaft, water cooling for the cylinder, and an air valve, a fuel valve and an exhaust valve; furthermore, a fuel pump regulated by a governor and a high-pressure air compressor for atomizing and injecting the fuel. In addition to these members the two-cycle motor requires a low-pressure air-compressor or blower for supplying the scavenging air. The valve driving shaft in the four-cycle motor runs at half engine speed, in the two-cycle type at full crankshaft speed.

It may be added, in conclusion, that in the four-cycle motor the exhaust pressure is slightly in excess of and the intake suction slightly below atmospheric pressure, while in the two-cycle type very little time is left for exhaust and scavenge, and a much better torque than in the four-cycle design is obtained.—From a lecture of Capt. H. Riall Sankey, R. E., reproduced in the *Journal of the Royal Society of Arts.*

Foreign Constructions Designs and Practices

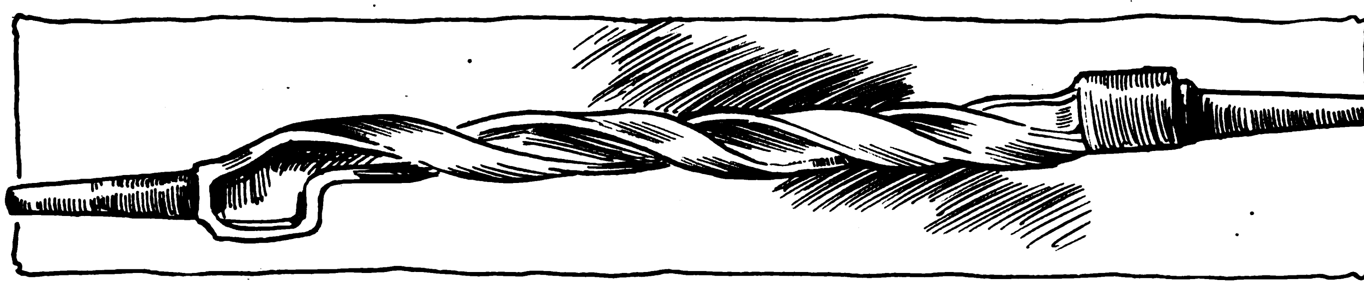

Fig. 1—Rear axle forging of chrome nickel steel after receiving nearly four complete twists in its length without showing distress of the fiber at any point

Steel Parts Must Be Thoroughly Tested Before Use—Samples Selected Are Tested to Destruction

STEEL as it comes from the mill is in the normal state so far as the purchaser is concerned. The steel, after it is rolled, is allowed to cool naturally. Annealed steel is the result of this process.

Normal steel then is an annealed product so far as actual practice is concerned, but when bars of normal steel are taken and used to make drop forgings, the steel must be subjected to a high heat and the forging process thereafter introduced may be looked upon as anything but gentle treatment. If the steel is required to assume an intricate shape demanding several forging operations, unless an annealing operation is introduced between successive forging operations the steel will be bruised and torn. Such forgings may look quite as good as they would were they properly processed.

Since it takes more time and adds more to the cost of production to anneal forgings during the forming process it is imprudent on the part of purchasers of forgings to take too much for granted. When the government contracts for forgings, a government inspector is always present at the forge and little by way of slighting the work is permitted by him. In the process of making automobile forgings instead of having an inspector on the ground reliance is placed on the integrity of the forger. In most instances the results are not such as will reflect adversely upon the forger's honesty and skill, but instances of poor results are too frequent to warrant disregarding the precautions of which the government takes the fullest advantage, even to the extent of sending several inspectors, rather than to depend upon the vigilance, skill and honesty of a single inspector. **In a word, the government does not expect too many accomplishments in a single man.**

The inspection of drop forgings for the purpose of locating faults such as seams and fissures is a difficult undertaking. If the plant wherein the forgings are made is operated for the avowed purpose of turning out none but good sound forgings the operation and annealing process will get good attention and inspection will be frequent.

The final inspection may take place after the forgings are sand-blasted, the idea being to uncover any faults that may be hiding under the scale which forms all over the surface during the forging process. But if the policy of the forger is to make forgings on a commercial basis, if an electric or autogenous welding equipment is a conspicuous part of the plant equipment, then every fissure or other faults will be plastered with soft iron; and, too, in a plant of this character, since the management exhibits a rare type of honesty, the workmen sit back on their haunches, slighting the processes to save their backs.

If common prudence demands that forgings be critically inspected before any work is done upon them in the machinery process, the question is, how is this inspection process to be conducted? If a laboratory is at hand, test proofs may be taken from the parts and the physical properties of these test proofs may be determined. But this somewhat long and rather expensive process will scarcely serve the end. The test bar may not be cut from the weakest part of the forging.

Test Part to Destruction

The way to find the defect in a part is to test the part to destruction.

Every automobile after it goes into the hands of the purchaser is tested to destruction.

The reason why the purchasing public consents to be the laboratory of the destruction test is due to the promise advanced by the maker that the test will take 10 years to complete it. The purchaser desire to work, and diligently, too, for a period of years at the destruction test before reporting results to the maker of the automobile. But the average user is led to believe that all the incidental tests are conducted to completion in the maker's plant. In order, however, for the maker to approach the user's test to destruction of the finished product, it is believed that it is imperative for the manufacturer to make destruction tests of the parts—enough of them to inspire confidence—before the automobiles are assembled and sold.

Consider axle forgings: Not a few of them are welded at the middle. Were one of these welded axles subjected to the torsion test, as shown in Fig. 1, it would fail at the weld.

A test to destruction by the torsion process is simple to make. All that is necessary is to set the part up in a stout tool, as a back-geared lathe, and by turning over the tool slowly, usually by hand, twist the part.

A first-class axle forging will perform as shown in Fig. 1. Welded axle forgings will fail at the weld. Forgings of other parts will show equivalent characteristics. The torsion test, if it is applied to one in ten of the forgings offered, will tell the tale of success or failure so thoroughly that success will attend the effort and the cost of the tenth forging will be negligible. If one in twenty of the forgings is twisted the information thus afforded will be of great value. A test of even one in each 100 forgings will be of great value. But the test to destruction by torsion should be made by the purchaser of the forgings. It is not enough to permit the forger to respond to the occasion.

In one instance of testing to destruction, front axle forgings being tried, the first seventeen axles failed at the weld. On the other hand, an extra price of $12 per axle was paid to the forger to get one-piece axles in this case. It would have been far better to pay the lower price for welded axles, for then the metals selected for use would have been more suitable to welding. In this case of failure the steel was specified knowing that it would not respond to a welding process, but the selection was justified because the specifications required and stipulated that the axles were to be forged in one piece.

Referring to welds, they belong to a bygone day—the period of iron. Steel is not pure enough to serve in a welding process if good strength of the weld is required. **Even weldable iron when the weld is made at a temperature so high that good steel would be destroyed, offers nothing better than 82 per cent. of the strength of the unwelded section, and the range of weld strength for good weldable iron is from the maximum of 82 per cent. down to a minimum of 34 per cent. of the strength of the unwelded section for steel, and the better it is the worse it behaves in the welding process, the strength of the weld is too indifferent to be given a moment's consideration, referring of course to the blacksmith's weld.**

Referring to the autogenous weld, if soft iron is run in between the members to be welded it is self-evident that the strength of the weld cannot be greater than the strength of the soft iron. But even the soft iron will fall below its normal strength, due to the abuse to which it is necessarily subjected in the welding process.

A very simple torsion testing equipment is selected in Fig. 2. An old stout lathe with a hollow spindle was fitted with a second head in place of the tailstock. The hollow spindle at both ends came handy in crankshaft testing. The flange F of the crankshaft is butted on to the face plate and clamped there too by dogs, D. The last throw at the other end is shown dog fastened to the tail end face plate. The lathe was worm-geared to a slow speed electric motor.

This tool was used from time to time to twist all sorts of forgings. A standard for each type of forging was first established. **All forgings which fell below the standard were delivered at the laboratory for further and detailed investigation.**

Method for Coloring Metals

The separation of the oxides of iron, manganese and nickel on the anode from ammoniacal solutions of their salts was recently dealt with in an article in the *Elektrochem, Zeitschrift.* The object was to produce colored films on the surface of a metallic article.

For a good adherence of the film, it was found necessary that the surface of the metal used as the anode should be free from grease, polished and free from foreign matter. The removal of the grease is best effected in an electric cleaner containing an alkali carbonate or a cyanide. By this process saponifiable as well as unsaponifiable matter is removed, this holding true especially if the article which is to be covered is alternately applied to the two ends of the conduit immersed in the electrolyte.

The investigations were carried out with iron or steel anodes in all cases. Ferric axide and manganese dioxide can easily be deposited as adherent layers of varying color, and under suitable conditions the process may be of commercial value. This is particularly the case with the deposit of manganese dioxide which is produced with a voltage of from 1.75 to 2.5.

From ammoniacal nickel solutions the deposits produced are not as satisfactory. The conditions under which the precipitation takes place are very limited and difficult to control. The color is unattractive and the deposit adheres badly. The potential required for the deposition of the oxides varies considerably with the metal. In the case of iron, a deposit which consists of partly ferrous iron is apparently obtained with very small potentials. As the potential rises, the amount of ferric iron in the deposit increases. In the case of manganese, no oxide at all is deposited below 0.4 volt, and in the case of nickel, the formation of the peroxide seems to be closely connected with the production of molecular oxygen; and consequently it only appears at potentials which allow the evolution of gaseous oxygen.

Fig. 1—Alco service building for metropolitan territory, located conveniently in Long Island City, L. I.

Alco's Metropolitan Service Building

Facilities to Serve Territory of 15,000,000—Three-Fold Nature of Plant Provides For Supplying of Parts, Repair of Cars and Trucks in District

GIVING complete and efficient service at lowest possible cost to the user of an automobile is the problem confronting the manufacturer-dealer today. Buyers are more and more demanding facilities for prompt supply and mounting of spare parts and adjusting whatever parts of their cars require to be adjusted, and they demand these facilities to be furnished at little or no expense to them.

Companies planning service departments for the territory of New York City and its surroundings are following up either of two possibilities in deciding the location of their service plants. One is to middle West Side of Manhattan, between Thirty-fourth and Seventy-second streets, which neighborhood is at present largely filled with tenements and flats; the other location is Long Island City and its suburbs, especially Astoria. While a number of large service departments have been placed in the section of Manhattan just mentioned, there is no doubt that the available space on the island which forms the heart of New York City is limited, it may even be said that if 10,000 commercial cars were to be used in Manhattan today instead of 4,000 now operating, it would not be possible at this moment to house them. Foreseeing future developments, many concerns are placing their service departments in the boroughs across the East River, thereby reserving ample opportunity for expansion in time to come. Nor should it be forgotten that real estate in Manhattan costs far in excess of what its price is in Long Island City.

To the group of service departments which has crystallized in the latter place during the past two years, another building of a representative company has been added early during this year. The newcomer is the department of the manufacturer of Alco cars, which is conducted jointly with the New York City branch of the Providence company.

The new service building, opened several months ago at Long Island City by the American Locomotive Company, covers a floor space of 315.33 by 98.66 feet and has a useful height of 15 feet, giving a total floor space of almost 31,200 square feet and a total volume of 468,000 cubic feet. For 9 hours every day ninety men work on the premises to repair pleasure and commercial Alco cars, to ship parts to machines in need of them and to carry on the office work necessary in this connection. The Metropolitan district, which embraces Greater New York, including Staten Island and Long Island, Southern Connecticut, and portions of New York State and New Jersey, with an approximate population of 15,000,000 souls, is served from this center of activity.

In constructing this department, the Alco company took every care in creating an establishment with all the manufacturing facilities required to keep cars going through years of service. Pursuing this plan, the construction of the building is as up-to-date as its equipment, and the method of operating it is part of the efficient line-and-staff organization for which the locomotive manufacturing company is famed.

Built for the Future

Facing Jackson avenue with a front of 282 feet and extending almost 100 feet toward the tracks of the Long Island Railroad, which passes hardly 60 feet behind the building, the service structure is bounded by an uncovered yard at its right side—looking from Jackson avenue—and by a similar free spot on the left, where the boiler room is stationed adjacent to and below the level of the building. The front wall, which, like the other three walls, is worked in red brick, is fitted with six double-section sliding doors, each of which is 12.5 feet wide and 15 feet high. In addition thereto a 4-foot door leads into the reception room whence visitors of the plant are conducted to the specific department with which they have business to transact. The wall facing the uncovered yard has four sliding doors of the same construction and dimensions as the front side. The other two walls are not interrupted by doors and, as reference to Fig. 3 shows, all the wall area excepting the structural supports is taken up by large windows which afford ample general illumination throughout the working day.

In a building of this size the selection of suitable systems for lighting and heating it is an important and not an easy problem. As to the question of illumination, electric light is, of course, the sole method applicable in an establishment of this kind, but it, too, offers a choice of various systems. Among the possibilities of arc, incandescent and Cooper-Hewitt illumination, the company chose the most widely used method, namely, the incandescent light. Throughout the building, tungsten electric lamps of the Mazda type are used, which are dropped from the ceiling by means of cables, much in the manner used in offices and garages.

To provide full utilization of daylight, the four walls of the building are practically all glass, except for the structural supports; but these, as reference to the shop illustrations show, decrease the entrance of light very little. All the windows are composed of an upper and lower half each, which again consist of nine approximate squares. Not only do these windows permit of plenty of light to reach the benches and machine tool shop, but they also provide full light for the men working on complete automobiles positioned in the middle of the shop, a large skylight which extends also over part of the office-and-supply room section, is used. Another skylight serves to light the cloak room. Both skylights are shown by cross hatching in Fig. 3.

A similar problem as the selection of the best-suited lighting system is that of an advantageous method of heating the building during the cold season, hot-air and steam circulations being the options in this case. It was perhaps because the first-mentioned system, which is now finding its way into many factories, calls for equipment too large and elaborate for a service plant, that the company preferred the steam-heating system. A series of coiled pipes, which are laid along the walls of the building, form the passageways for the steam which is generated in the boiler room.

Structure is Fireproof

The building is largely what is generally referred to as fireproof, being all steel and brick, except the concrete floors, and save the substructure of the roof, which latter is made up of strong wooden beams. To increase safety against conflagrations, all the rules of the fire department concerning water, hose, pails and chemical extinguishers are being observed carefully.

All electricity is obtained from the central station which is located about 1-2 mile away from the Alco building. This electricity is used for lighting and whatever power is used in the building for driving the shop equipment as well as the ventilating fans which are stationed throughout the establishment. By this expedient, the boiler room is made to serve the heating system exclusively, which, of course, facilitates its operation and reduces the otherwise greater force of men needed in this portion of the plant.

The inside of the building is divided into three sections by two fire-walls, which extend from front to back wall. By this arrangement the three departments of the service building devoted to repair work, office and supply operations and storage, respectively, are effectively separated. These departments are dimensioned as follows: Repair shop, 146 feet wide and 89 feet deep; central section containing office and supply departments, 98 feet wide and 95 feet deep; storage or garage department, 36 feet wide and 98 feet deep; the depths being calculated as averages, as they vary from end to end in each department, due to the converging shape of the building along its longer dimension. The rooms formed in each of the three sections are separated from each other by partitions finished in oak.

Taking up the departments in turn, the repair shop with its 13,000 square feet commands prime attention. It is entered by trucks through the four sliding doors, already mentioned, and by individuals by way of a small door leading through the fire-wall, from the office department of the building. The shop department has a concrete floor formed with twelve pits provided for working under automobiles. In one corner it is lowered as a centrally inclined square which serves as a wash rack. The roof is of the horizontal type and is carried on a network of steel beams and a wooden substructure supported by three longitudinal rows of posts spaced about 20 feet from one another.

As the floor plan, Fig. 3, shows, ten of the twelve pits are located in two rows in the center of the repair shop and in alignment with the second and third doors. They are, therefore, arranged so that they are equally easy to reach from any part of the shop, without necessitating a great deal of space to be spared for passages. Each pit is 3 feet deep. Work on cars themselves is done in that portion of the shop which is shown by dotting in Fig. 3 and which comprises more than three-fourths of the floor space. The only portions of the shop where no cars are placed are a long and narrow field extending

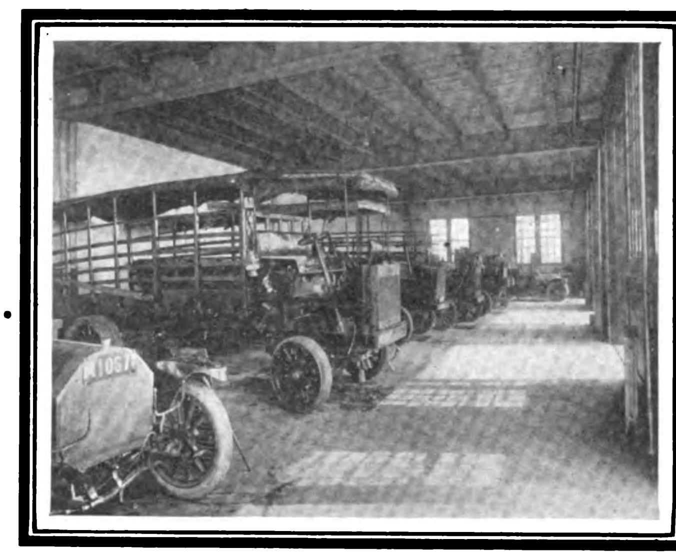

Fig. 2—Interior view of the garage where cars and trucks stopping for quick repairs are stored

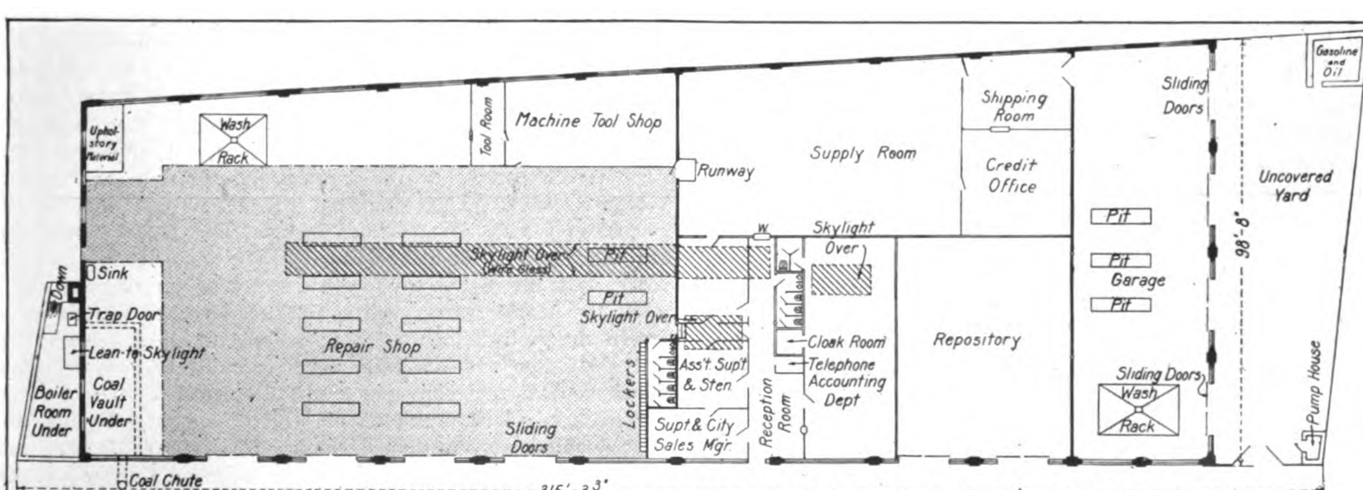

Fig. 3—Floor plan of new Alco service building in Long Island City, showing the division of the brick building into three departments, serving as shop, office and supply room, and garage, respectively. The shop is shown by dotting, while the cross-hatching denotes skylights supplying ample access of daylight throughout the building

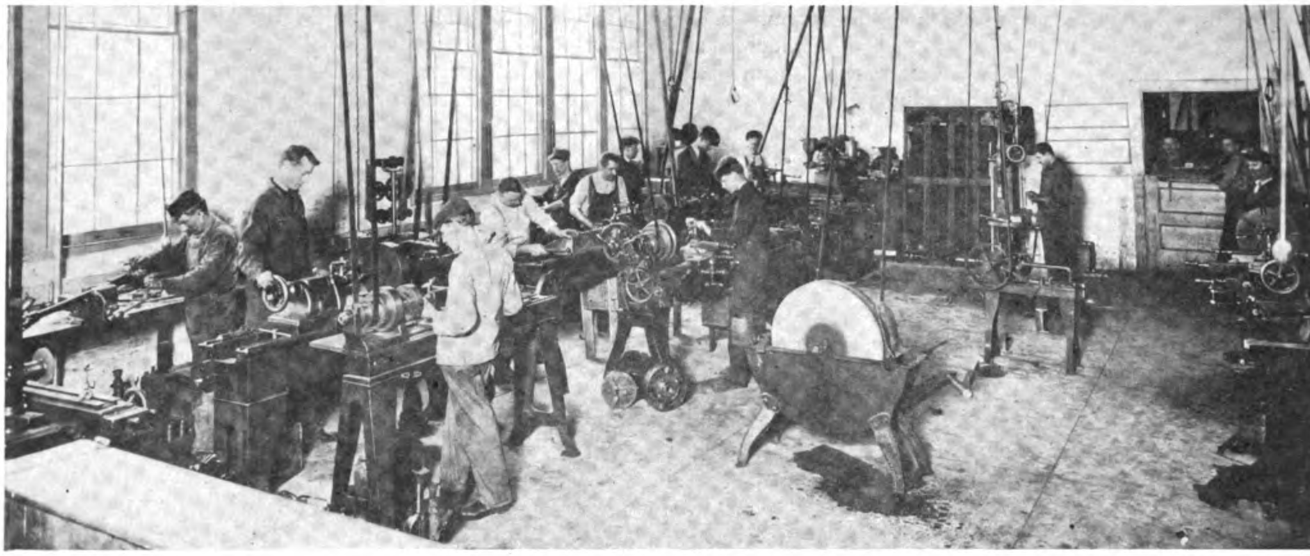

Fig. 4—Inside of machine tool department of the repair shop which is equipped with every desirable facility

along the back wall of the building as well as the left front corner. The first-mentioned portion holds the machine-tool shop and tool room, as well as the benches, wash-rack and upholstery-material storeroom. The corner at the left end of the building front contains the forge, which forms the principal part of the blacksmith shop.

The machine-tool shop is separated from the rest of the shop by a screen partition; another partition divides it into two sections, the larger of which contains the machine tools and the smaller one the tools proper, which are used in the machine tools and in bench work. The entrance is by way of a door leading from the main repair shop into the machine tool department, whence another door opens into the tool room. A window between the latter and the bench department permits of handing tools out and in between that department and the tool room.

Equipment of the machine-tool department consists of a large and a small lathe, several drilling machines, drill presses, grinders, emery wheel, arbor press, planer, shaper and a few other shop tools. These tools are all very neatly arranged, as Fig. 4 shows, and they are driven by belting from shafts extending along the back side of the repair department. One motor is used to drive the shafts, it being located halfway

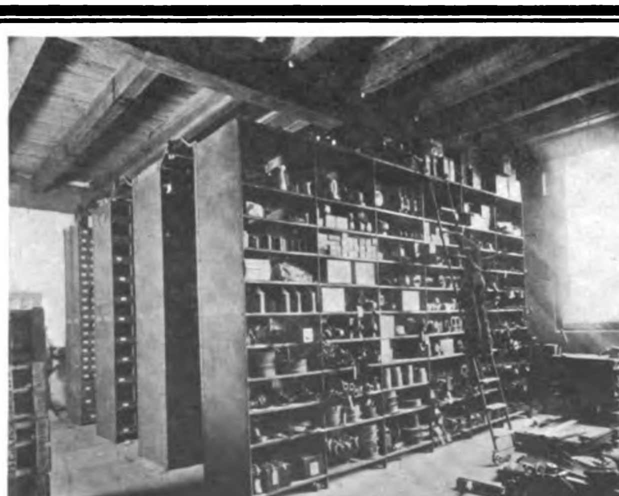

Fig. 5—View of sheet-metal shelving in stock room of Alco service building, Long Island City. This room will hold $80,000 worth of parts

between the tool room and the wash rack. Close to the motor and driven by the same an air compressor is mounted on the cross-beams carrying the roof, being connected to two tanks having a combined volume of 30 cubic feet, approximately.

In the left front corner of the machine tool shop the foreman's desk is in place. Outside of the screen partition and directly in front of his station is the recording clock and the time-card rack. Fig. 3 also shows a door, the upper hall of which is formed as a window, between repair shop and supply department, also located in close proximity to the foreman's quarters. Farther in front along the same fire-wall, the lavatories and workmen's lockers are arranged.

Shop Has Two Main Sections

The central portion is divided all along its length into two sections, the front being the office department, which is 49 inches deep, and the rear the supply room having a depth of 46 feet. The office section in turn is subdivided into manager's, stenographers' and telephone department, accountants' office and repository for supplies used in the building. The cloak room is located adjacent the telephone switchboard. The passageways and doors are clearly shown in Fig. 3.

The supply room contains $50,000 worth of stock. Its details appear in Fig. 6, showing the floor plan and arrangement of the contents of the room. The supply room, as situated between the two fire-walls and the lengthwise partition separating it from the office department, has one door piercing each of the fire-walls and one through the partition. The door between the supply room and the repair shop, as has been stated before, is formed as a window through which materials may be passed from the supply room to the shop. A second window of the same type is shown at W, opening into the extension of the reception room. The equipment of the supply room is arranged in a very advantageous manner, the shelves containing the repair-part stock being located in six double-shelf rows directly in front of the window between supply room and shop, while the heavier parts, such as motors, wheels, materials coming in sheets, bar stock, etc., are orderly arranged between the last shelf row and the right subdivision of the supply room which contains shipping and credit departments. The shelves are of a standard multiple-unit steel design, and besides the four double rows mentioned, another row is located along the partition between this room and the office, and these shelves are used to store tires and their parts. Rims are assembled in a group in front of these shelves and radiators form a similar group. The location of the supply-room clerk's desk and of his files is also shown here.

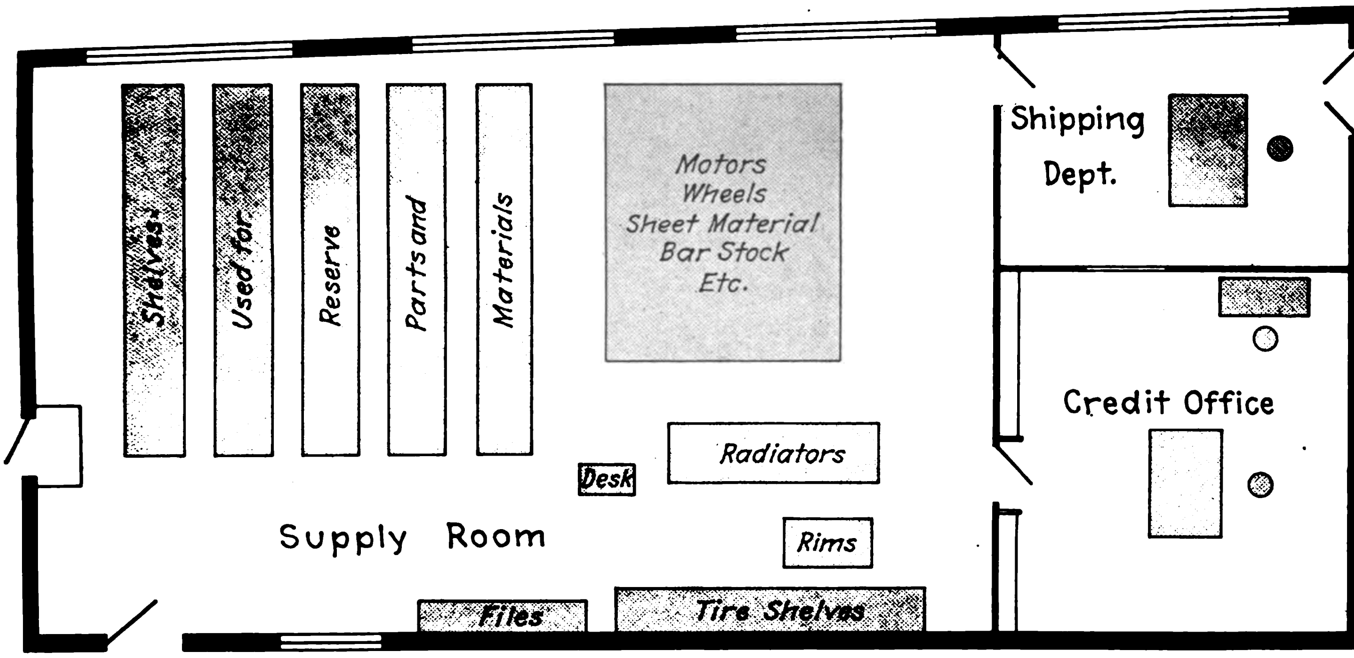

Fig. 6—Floor plan of Alco stockroom, showing layout for storage of various parts

Parts returned to the company are delivered to the credit office before going back to stock, while outgoing parts are recorded and charged by the shipping department. Since the business of these departments is closely interwoven with that of the supply room proper, their location in immediate proximity of the stock is a good stroke of efficient arrangement work.

The repository, which is also part of the central section of the building, serves for storing cars that remain at the service department for some time, either before or after being repaired. In this department is also kept the overflow of supplies from the supply room proper. The two sliding doors leading to Jackson avenue and the interior doors, inside the building, appear in the floor plan, Fig. 3.

From the shipping office, the only door between the central and the right-hand section of the building leads into the garage. The latter serves as a stopping place for the companies' cars which commute from Manhattan as well as for cars which have been repaired and are just about to be delivered to their owners. The garage is 36 by 98 feet in size, and is equipped with three pits of the same size and shape as the repair-shop pits. The three doors leading into the uncovered yard, which has a width of 30 feet, permit of free entrance and exit of the cars in the garage. In the front portion a large wash rack is provided, above which washing apparatus are fitted.

Certain parts of the equipment of the service department are stored outside the building, principally for reasons of safety, but also to save space inside the walls. Among these units is the boiler room shown in the floor plan, at the left front corner of the building. The boiler is stationed underground and is located next to the coal vaults which are charged from the street.

Ninety persons constitute the force which is employed in the entire service department. Two-thirds of these, or, to be exact, sixty-two men, work in the repair shop; the latter are ordinarily distributed about as follows: Five men on benchwork, from eight to ten men in the machine-tool shop, four doing blacksmith work, and the rest operating on the floor of the shop. In the supply department about six men are constantly employed, while the garage requires the services of two men. The boiler-room attendant, doormen, gasoline-tank man and about eighteen men in the office make up the rest of the force.

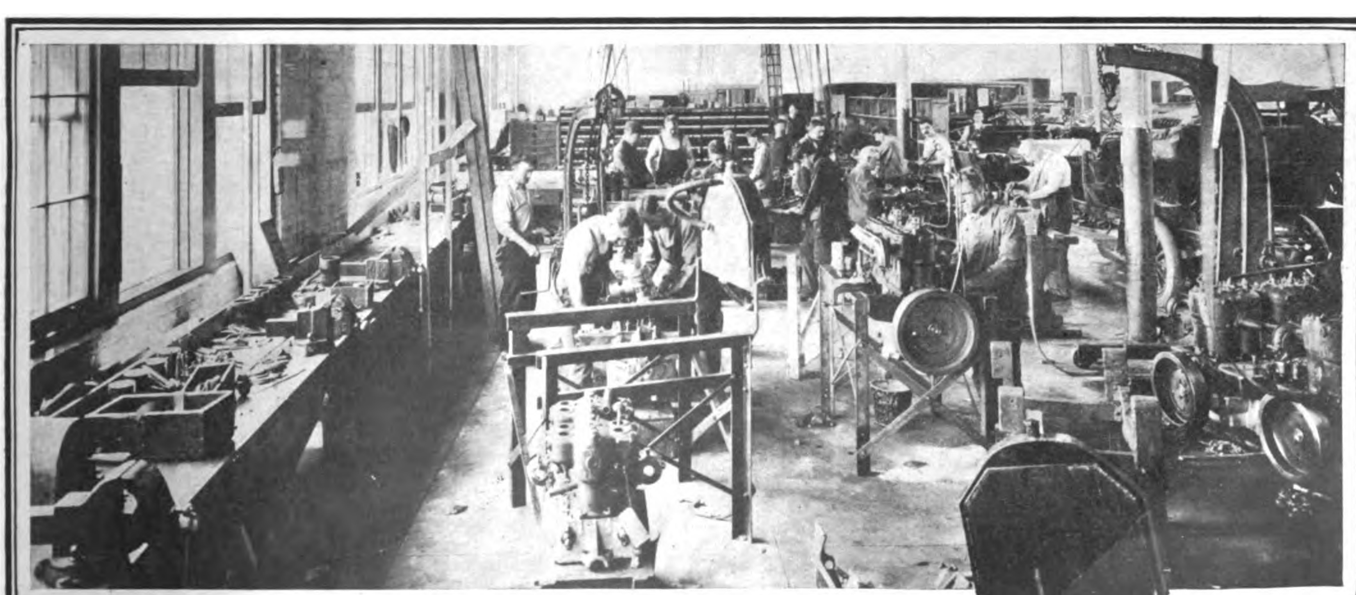

Fig. 7—Bench-room department of repair shop at Alco service building

Automobile Frame Steel

Heat-Treatment Applied to Straight-Carbon Steels of Suitable Composition Greatly Enhance Their Value

Many Manufacturers Should Give More Attention to Their Frame Specifications to Insure Durability

Paper presented by C. M. Hall, Sales Manager of the Parish Mfg. Co., at a recent meeting of the Detroit Section of the Society of Automobile Engineers.

IN order to fully understand the factors entering into the choice of materials of construction of the automobile frame it is necessary to consider the following points: First, the relation of the type of frame design of tne material; second, untreated steel as against heat-treated steel; third, the dynamic strength of the steel.

Automobile frame design may be broadly divided by the manner in which the shocks and strains caused by bad roads and by the vibration of the engine are to be absorbed. The material to be used will depend upon this design to a very large extent. The shock and vibration may be (1) deadened; (2) overcome by mass; (3) mitigated by springiness; (4) absorbed by sturdy construction. The first class makes use of a wooden frame, the argument of the manufacturer being that the wood kills or deadens the vibration. With the increased size the strength demanded by the greater load and power of the new cars, this material has been very nearly eliminated from the field, and does not pertain to this discussion.

The second class may be likened to the bed of a heavy planer or milling machine. The mass of the frame is so large and heavy in comparison with the vibration that the automobile negatives the latter. Such is the argument of the manufacturers of this type of car. In general, we may say that the first class is prone to weakness, while the second class is characterized by an extremely heavy or unwieldy car, necessitating additional driving force. Both of these divisions are now in the minority.

Frames Are Often Springy

The third class may be best described by the following incident: A party was riding in an automobile of this class with one of the company officials. While passing over some street car tracks the front wheels caught in the track. The front part of the frame was twisted out of line for the moment, but upon the release of the wheels it sprung back into alignment. The official remarked that the incident explained the principle of the design of the frame of that particular car; that is, springiness. This class is generally characterized by a light frame, with the side bars usually of small section. In order to make this design at all feasible under hard running conditions the steel should be of the very best—heat-treated alloy steel. Only too often is this requirement disregarded by the manufacturer. As the major portion of the strains to which the frame is subject enters through the hanger end of the side-bars they reach the front cross-member practically unimpeded. As the cross-member acts as a stay, or brace, at this point, there must necessarily be a focus of the separate forces at this section of the side-bar. This results in a tremendous strain at this point. If the section is not of sufficient size, nor of suitable steel, a break results. This is not a rare, but a common occurrence.

The fourth class is generally typical of the larger and higher-powered cars, which have what we may term sturdy construction. The side-bars are of suitable section, and usually of heat-treated, chrome-nickel steel. The frame is substantial, but not unwieldy, the higher physical properties of this particular steel making an extremely heavy frame unnecessary. The shocks are to be entirely absorbed by the springs and frame, so that only a very small proportion shall actually reach the body of the car. Engineers are divided as to the relative merits of these last two classes, as is shown by the numerous automobiles of each type. But whichever of the two is used, the character of the steel entering into the frame construction must be carefully considered. As will be shown later, alloy steel without heat-treatment is of little value, while heat-treatment applied to straight-carbon steels of suitable composition greatly enhance their value.

The motor truck is now entering the market in a most aggressive manner, so that mention should also be made of it. The design of a suitable frame for a motor truck is a much simpler affair than that of the pleasure car. Leaving aside the actual design, the two important features to be considered—as far as the materials of construction are concerned—are the use of the I-beam or of the heat-treated channel section. Metallurgically, there should be no hesitation at all as the former cannot compare with the latter. The rolling mills of many steel companies producing these I-beams and rail sections aim for quantity rather than for quality. The steel is generally crushed down to size with as few passes through the rolls as possible, giving a structure which is absolutely unfitted for the use in view. Among the manifold causes of failure there was shown in New York City last winter the crystallization set up by cold weather and its disastrous results. Although no steel will entirely resist this tendency to cold crystallization, the structure of heat-treated steel is such that the influence of cold is many times less upon it than upon the coarsely crystalline I-section.

A decade ago, when the automobile steel frame was in its infancy, cold-rolled, low-carbon Bessemer steel was the only metal on the market for this sort of construction. This steel generally analyzed from 0.07 to 0.10 per cent. carbon. From this statement, however, it must not be assumed that such steel was ordered to specifications. Far from it. Indeed, in the eyes of the automobile manufacturer at that time, steel was simply steel. Then, with the ever-increasing ascendency of the open-hearth process and the decline of the Bessemer process, open-hearth, cold-rolled steel was specified. The steel mills, using the argument of the better quality of the open-hearth steel, increased their profits charging $2 or $3 more a ton for their steel if open-hearth was specified; otherwise the purchaser probably was given open-hearth steel anyway. Prices were soon equalized, however, and at the present time all sheet steel used in automobile frames is open-hearth. (There are only four Bessemet sheet mills now in operation in this country.)

Cold-rolled steel was specified at first simply for the bright finish obtainable. Having obtained this foothold, for many years its was practically the only steel in use. With the lowering prices 2 years ago hot-rolled steel came into use, and will probably supplant the cold-rolled material within a short time.

The growth of the steel frame business was somewhat hampered in the beginning by the difficulty experienced in obtaining sheets of sufficient length and width. The sheet mills were formerly rolling at a maximum width of some 8 inches, while a frame of 100 inches in length was considered large. Educational methods have now resulted in sheets double the width, while a side-bar requiring a 350-inch sheet is not at all unusual.

With the increasing weight and size of the car came the demand for a better and stronger steel. This requirement was filled for the time by the use of a higher carbon steel, giving an elastic limit of some 30,000 pounds per square inch. Then, in 1905, came the revolutionizing process of using alloy steel, together with a suitable heat-treatment, with the formation of the Parish Manufacturing Company, at Reading, Pa. This company experimented with various types of nickel, chrome-nickel and manganese steels—heat-treated—which resulted in the present types of chrome-nickel steel and special carbon steel now used by them. The true worth of this chrome-nickel steel as against carbon steels may be appreciated by noting the dynamic strength and quality figure given in the last part of this article.

Selection of Steel for Frame

The problem of selecting the proper steel for an automobile frame is an all-important one, for upon the strength and proper construction of this frame will depend the safety and lives of the automobilists. Moreover, a faulty frame necessarily results in a useless machine. A large part of the frame troubles probably never reach the ears of the manufacturer. The owner of a broken frame will often have it repaired in some crude way by a blacksmith rather than forego the use of his car for some weeks. If the automobile manufacturers were aware of, or would admit, the large percentage of frame failures they would pay more attention to their frame specifications.

The steel must be chosen with a view to the metallurgical and mechanical treatments in mind, and with due regard to the peculiar conditions to be met with in finished car or truck. It is well known that various elements, such as carbon, manganese, phosphorus, sulphur, etc., affect steel in divers ways. Some are injurious; others confer added elasticity, hardness or toughness and increase the efficiency of the steel for certain usages peculiar to automobile frames. In short, this means a special steel, which upon further treatment will be the best for the existing conditions.

Metallurgists will tell the uninitiated that raw steel resembles granite, in that it is made up of innumerable crystals, often too small to be seen with the unaided eye. A little thought will convince one that the qualities and properties of the steel will be directly dependent upon the size and arrangement of these crystals. The closer the crystals interlock with each other, the stronger the steel. Also, the smaller the size of the crystals, the greater the number of crystal faces which will fit into each other. Upon this internal structure will depend the physical properties of the steel. The control of the structure—assuming a proper chemical composition—is vested in the metallurgical treatment which is given the steel. Chemical composition—special steel—must go hand-in-hand. One is useless without the other.

This heat-treatment is not to be a hit-or-miss affair, but must be conducted rationally and in a technical manner under the direction of a competent metallurgical engineer. For each heat of steel a separate treatment must be worked out. Steel of high quality—and such only should be used in frame construction—is very susceptible to a few degrees of heat at high temperatures. This is easily demonstrated by the use of a testing machine in conjunction with accurate pyrometers. Heat-treatment such as should be used in connection with the heat-treatment of automobile frame steel must be most accurately adjusted and carried out. This, of course, will necessitate very careful work on the part of the metallurgist and of those under him. The results obtained will amply justify the efforts expended. Heat-treatment in general is as yet in its infancy, but specialization in this particular branch of metallurgy will have a rapid growth.

Let us consider the effect of heat-treatment properly adjusted upon the frame steel. A strip of straight carbon open-hearth steel was pressed into a channel. Photomicrographs were then taken of a section of this channel. This steel is characterized by the laminations given it by the rolling operation; by very coarse crystallization (inherent to raw steel); and by lines of weakness due to the crushing of the crystals in the forming operation. That is, the steel is so strained and stressed that it is wholly unsuited—in its present condition—to frame conditions. And yet many manufacturers persist in using such steel and wonder why their customers complain that the frame is unsatisfactory!

The channel was then heat-treated by the Parish process and photomicrographs taken of the same section. A great contrast between the untreated and the treated steel was observed. A fine, even grain has replaced the coarse crystallization and all signs of weakness have been obliterated. The working strength (elastic limit) of the steel has been nearly doubled, as is shown by the following results:

	Untreated	Treated
Elastic limit, lbs. per sq. in.	28,950	57,300
Tensile strength, lbs. per sq. in.	50,600	85,000
Elongation, per cent in 2 in.	37	28.25

The effect of using untreated stock for frames is that the structure of the steel is very uneven and shows much weakness. Many other examples illustrating the advantage of heat-treated steel over untreated steel might be given. From both the technical and practical point of view, heat-treated steel—of suitable composition and physical properties—has no equal.

An automobile frame is subject to two general classes of stresses: static and dynamic. By static stresses are meant the weight of the dead load, such as machinery, body, passengers, etc. It is upon this total load and its distribution that the design of the frame with its component members is usually arrived at, allowing for a certain factor of safety. But there are also other extremely important stresses to which the automobile frame is subject on account of its inherent make-up and which are too often neglected in selecting material for the frame. These stresses are set up by the vibration of the engine and by the constant bumping on uneven ground. The latter may be partly or wholly taken up by the springs, but the former can but pass into the frame itself. These continual shocks and alternating stresses, though primarily small in amount, soon play a very important part in the life of the car. To these complicated kinematic forces and fatigue-resisting power are given the name of dynamic stresses. That these are not a direct function of the static strength is shown by numerous every-day failures in all lines of steel construction, and which cannot be attributed to any other cause by dynamic weakness.

THE RULE for finding the piston displacement of a motor cylinder is that of finding the cubic contents of a cylinder, which is as follows: Multiply the area of one end by the length of the cylinder, the product will be the cubic contents of the cylinder. The rule for finding the area of a circle consists in multiplying the square of the diameter by .7854. The formula for finding piston displacement is: $D^2 .7854\, S\, N =$ piston displacement, in which D is the diameter of the cylinder, S length of stroke, N number of cylinders.

Therefore, to find the piston displacement of a motor with 5-inch bore, 6-inch stroke and four cylinders, substituting the numbers for the letters of the formula, it would read: 5^2 (five square) $\times .7854 \times 6 \times 4 = 471.2$ cubic inches.

Modern Repair Service

An Outline of Its Functions and a Standard on Which Departments May Be Organized

Every Man's Work Must Be Laid Out and Clearly Defined to Permit of Efficient Operation

From a paper by C. Roy Watson, published in the September Bulletin of the Society of Automobile Engineers.

THE function of the car service department is to take care of the cars after they are sold; to supply repair parts; educate repairmen; supervise the character and extent of agents' repair shops and policies; settle claims for defective parts, and operate a local branch for repairs, etc.

DUTIES OF THE CAR SERVICE DIVISION

ORDER DEPARTMENT. General foreman of car service	A Repair stock...	(1) Manufacture and storage of repair parts. (2) Handling, packing, shipping.
(1) Records, lists, prints, etc., of parts, tools and material. Pricing (2) Ordering, accounting and maintenance of repair stock..........	B Claims	(1) Receiving and cleaning of specimens. (2) Investigation and judgment. (3) Storage. (4) Adjustment, allowing stock or credits.
(3) Correspondence ..... (4) Ordering of shop. Outside repairing and work	C Educational N..	(1) Class room. Models. Car and instructor. (2) Compiling of instruction book. Educating agents' men. Answering technical queries, and directing apprentices in repair and shop work. (3) Traveling repair organizer and overseer.
	D General repairs.	(1) General repairing and overhauling, shipped in from outside.

ORGANIZATION OF CAR SERVICE DIVISION

General foreman of car service division.....		
(1) Order clerk......... (2) Stenographer .... (3) Stenographer	A Repair stock foreman	(1) Manufacturing foreman. (2) Stock renewal man. (3) Order clerks. (4) Order checker. (5) Packer. (6) Shipper.
(3) Records man.........	B Claims foreman.	(1) Clerk. (2) Handyman.
(4) Accountant	C Instructor	(1) Traveling overseer.
(5) Typewriters .... (6) Errand boy	D Repair shop foreman	(1) Repairmen. (2) Repair apprentices.

A—Repair Stock.—The main requirements in connection with the repair parts stock are that the parts be reliably and promptly supplied, properly ordered, equitably priced, and interchangeable. Two or three sub-stocks for storing, at suitable shipping distance, are necessary for promptness, as very few agents can finance a complete stock which in several cases runs as high in price as $50,000.

As time passes and men whose minds are storehouses of facts leave, the lack of thorough records, generally neglected in the rush days of the industry, calls for a thorough supply of drawings, lists and records of supersedence, interchangeability, etc. All the plans, tools, and a wisely estimated stock of the special materials and intricate process, parts and assemblies made by outsiders should be bought and stored when it is suspected that the supply of such repair parts will be neglected or stopped in the future.

B—Claims Department.—The claims department of an automobile factory is distinctly an item of expense, but a necessity; and when equitably and diplomatically managed makes a quiet bid for happy loyal owners.

C—Educational Department.—The educational work is, first, to supply trained repairmen, and post agents and their foremen on new models; also to oversee and develop agents' repair shops to a high standard. Of course, this work is a direct expense, but when really productive pays indirectly many times its cost.

The instructor, a thorough man in both general information and the lore of the car, with teaching and managing ability a classroom with sectional models and a car.

Overheating During First Few Miles; Method of Adjusting the Schebler Model L; Tapping Sound from First Cylinder; Mercer Cars Are Overslung; How To Shift Gears Readily; Best Non-Freezing Solution

Engine Overheats in 2 Miles

EDITOR THE AUTOMOBILE:—I drive a 1911 Hudson 33, and I find in running the first mile or two the engine gets very hot, but on a long run it seems to be all right.

1. Can you suggest anything that would cause this or is it a natural consequence? The 1911 Hudson's fan is in the flywheel, that being the only cooling fan. Also, can you suggest any preparation that would tend to keep the temperature down in the engine, such as something to mix with the water.

2. Also, I would like to know what is a good thing to keep the water from freezing in the radiator, and is it necessary to use lighter oil in cold weather, or can the oil I am using be thinned down?

Hartford, Conn. S. F. FRENCH.

—1. This is a very strange case and the first time that THE AUTOMOBILE has heard of a motor that would overheat in 2 miles and be all right in 10. The overheat, since it is of such short duration, will not harm your motor and you may disregard it unless it becomes more serious. It might be that owing to your location you have to climb a steep hill when starting out or that you travel with your spark retarded too far. Keep your spark advanced as far as you can without permitting the motor to knock.

2. The answer to this question will be found elsewhere on these pages in answer to another inquiry. Do not attempt to thin down your oil. Medium cylinder oil will give you satisfaction. It is a big mistake to endeavor to thin down thick or heavy oil by adding oil of a lighter grade. The only place where it is safe to use mixed oil is in the gearset or the differential.

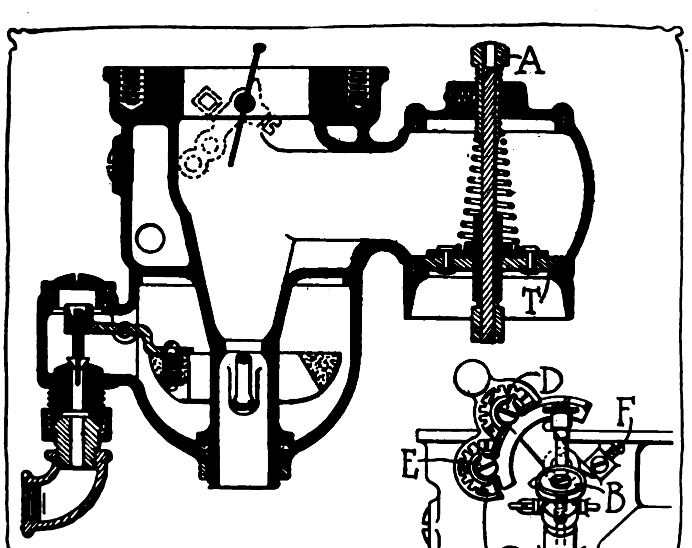

Fig. 1—Adjustment points on the Schebler model L carbureter

Adjusting Schebler Model L.

Editor THE AUTOMOBILE:—How can I adjust a new model L Schebler carbureter to my car so it will run well at all speeds? I have had the carbureter some time, but have never attached it as I did not know how the adjustments should be made.

Toronto, Canada. FRED. BLACKSTONE.

—First make sure that your ignition is properly timed, and

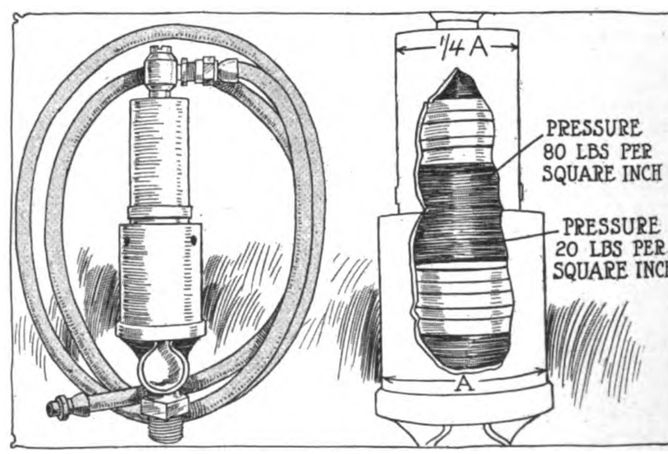

Fig. 2—Use of the differential piston, showing Mayo spark plug pump

that you have a good hot spark at each plug; that your valves are properly timed and seated, and that all connections are tight, and that there are no air leaks of any kind in these connections.

Adjustments on the auxiliary air valve A, Fig. 1, are made first so that it seats firmly but lightly at T; then close your needle valve by turning the adjustment screw B to the right until it stops. Do not use any pressure on this adjustment screw after it meets with resistance. Then turn it to the left about a turn and a half and prime or flush the carbureter by pulling up the priming lever C and holding it up for about 5 seconds. Next, open your throttle about one-third, and start the motor; then close your throttle slightly and retard your spark and adjust throttle lever screw F and needle valve adjusting screw B, so that the motor runs at the desired speed and hits on all cylinders.

When a good adjustment with your motor running idle is secured, do not touch your needle valve adjustment again, but make your intermediate and high-speed adjustment on the dials D and E. Adjust pointer on the first dial D, from figure No. 1 toward figure No. 3, about half way between. Advance your spark and open throttle so that the roller on the track running below the dials is in line with the first dial. If the motor backfires with the throttle in this position, and the spark advanced, turn the indicator a little more toward figure No. 3; or if the mixture is too rich, turn the indicator back or toward figure No. 1 until you are satisfied that your motor is running properly with the throttle in this position, or at intermediate speed. Now, open the throttle wide and make your adjustment on your dial E for high speed in the same manner as you have made your adjustments for intermediate speed on dial D.

It is found that in the majority of cases in adjusting this carbureter the tendency is to give too rich a mixture. It is suggested and recommended in adjusting the carbureter, both at low, intermediate and high speed, that you cut down the gasoline until the motor begins to backfire, and then increase the supply of fuel, a notch at a time, until the motor hits evenly on all cylinders. Do not increase the supply of gasoline by turning the needle valve adjusting screw more than a notch at a time, in your low-speed adjustment, and do not turn it any after your motor hits regularly on all cylinders. In making the adjustments on the intermediate and high-speed dials, do not turn the pointers more than one-half way at a time between the graduated divisions or marks shown on the dials. By following these instructions the adjustment should be satisfactory.

The Best Non-Freezing Solution

Editor The Automobile:—Will you kindly advise us of some chemical which you know to be good to add to the radiator water to keep it from freezing where the temperature never reaches zero.

Norfolk, Va. D. M. Bell.

—There are three well-known anti-freezing compounds which

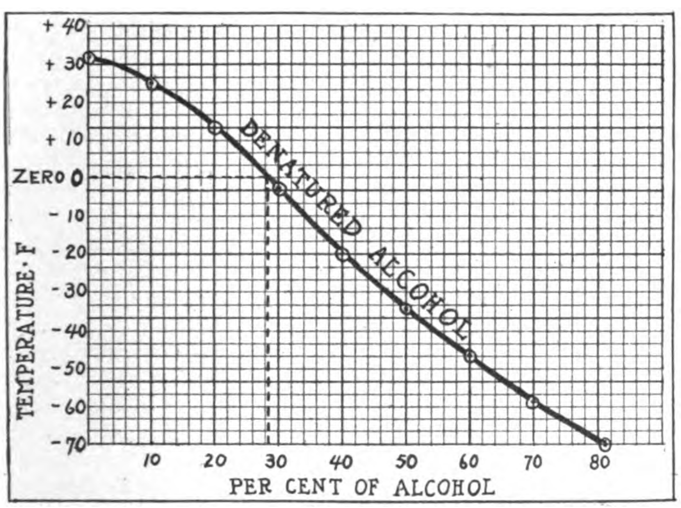

Fig. 3—Freezing points of various solutions of denatured alcohol and water

have been used extensively and which have proved themselves to be valuable for this work. They are alcohol, glycerine and calcium chloride. Besides these there are many others that are good, but they nearly all have some drawbacks that prevent them from being as useful as would otherwise be the case.

About the most popular of all the solutions to use in the motor is the alcohol. Wood alcohol or denatured may be used. The cost is small; denatured alcohol may be purchased for 60 cents per gallon and the price of wood alcohol is about the same. The advantages of alcohol are that it is very easily handled and that there is no action on the metallic parts of the circulating system. The denatured alcohol is especially perfect in this respect, while the wood alcohol has a tendency of developing formic acid under the influence of heat when in the presence of oxygen. Formic acid has a mildly corrosive action which will harm the metal in the radiator if the action continues for a long period of time. The danger of the formic acid, however, is so slight that only the most particular of automobilists need worry about any deleterious effects from its use.

The freezing point of the wood alcohol is lower than that of the denatured alcohol, as may be seen in Fig. 8. It would seem therefore, that less of the wood alcohol would be required, but the objection to this is that the boiling point is also less than that of the denatured alcohol and therefore more of it is required in order to counteract the evaporation. When wood alcohol is added to glycerine, however, in the proportion of half to half, the boiling temperature is raised considerably as will be seen in Fig. 7, which shows the boiling points of the pure wood alcohol and the alcohol and glycerine when added to the water at different percentages.

The specific gravities of the wood and denatured alcohol solution will also vary considerably and, although this is not an important feature in many respects, it may be brought out as illustrating another point of difference between the action of wood and denatured alcohol. It will be seen that the wood alcohol has the lower specific gravity as well as the lower freezing point for a mixture of a given percentage.

Taking wood alcohol alone the following solutions may be used:

Freezing Point	Wood Alcohol	Water
+ 5 degrees Fahrenheit	20 per cent.	80 per cent.
0 " "	25 " "	75 " "
— 5 " "	27 " "	73 " "
—10 " "	31 " "	69 " "
—15 " "	35 " "	65 " "
—20 " "	38 " "	62 " "

When using denatured alcohol the freezing point will be as shown in the diagram at Fig. 3. In tabular form for temperatures between 5 above and 20 below zero Fahrenheit, the denatured alcohol solutions will be as follows:

Freezing Point	Denatured Alcohol	Water
+ 5 degrees Fahrenheit	24 per cent.	76 per cent.
0 " "	29 " "	71 " "
— 5 " "	32 " "	68 " "
—10 " "	34 " "	66 " "
—15 " "	37 " "	63 " "
—20 " "	40 " "	60 " "

Glycerine possesses many characteristics which would seem to stamp it as the ideal non-freezing agent. The boiling point is high and, as will be seen in the diagram Fig. 7, does not change the boiling point of the mixture regardless of the percentage added to the cooling water. Glycerine reduces the freezing temperature materially when added to the water, but does not do so as rapidly as wood or denatured alcohol, as may be seen in Fig. 5. When reducing the freezing temperature to such an extent

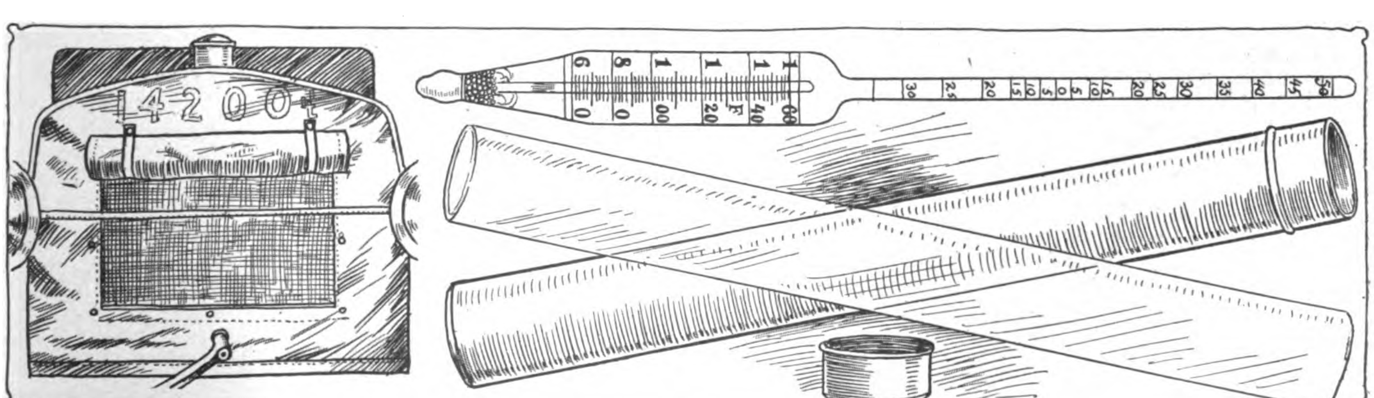

Fig. 4—Useful form of radiator cover; freezometer for determining freezing point of alcohol solution

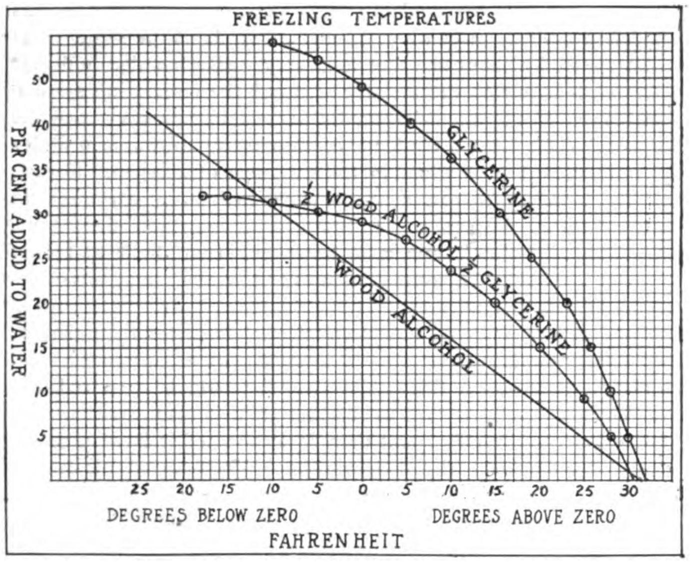

Fig. 5—Freezing points of glycerine and glycerine-and-alcohol solutions

that the water will not freeze in a cold climate it is necessary to add so much that the water tends to become gelatinous and for this reason it has been mixed very often with wood or denatured alcohol in a very successful attempt to combine the merits of the two. When glycerine alone is used the mixtures that are required for different temperatures will be found in the following table:

Freezing Point	Glycerine	Water
+28 degrees Fahrenheit	10 per cent.	90 per cent.
+15 " "	30 " "	70 " "
+ 5 " "	40 " "	60 " "
0 " "	48 " "	52 " "
— 5 " "	54 " "	46 " "
—10 " "	58 " "	42 " "

It will be seen from the above table and from a study of Fig. 8 that the enormous quantity of glycerine which has to be added at the lower freezing points will naturally stand in the way of the success of the use of this material where the climatic conditions are such that temperatures below zero will be reached. It is for use under such conditions that the addition of alcohol to the solution has been recommended by many, and which has become decidedly popular in the last few years. When the glycerine and alcohol are used together they are used in equal quantities. This mixture, which is purely mechanical, has not as great a tendency to rot the hose connections as a pure glycerine solution would have. It has more water in it than would the latter and is thus more free to pass through the radiator and other parts of the circulating system without doing harm. On the other hand, there will be less alcohol in this solution than there was in the pure alcohol solution and the result of this is that there will not be so much evaporation and necessary replacement of the cooling fluid after the motor has been run for a time. The glycerine and the alcohol are stirred up together and added to the water in the following proportions:

Freezing Point	Mixture	Water
+20 degrees Fahrenheit	15 per cent.	85 per cent.
+15 " "	20 " "	80 " "
+10 " "	24 " "	76 " "
+ 5 " "	27 " "	73 " "
0 " "	29 " "	71 " "
— 5 " "	30 " "	70 " "
—15 " "	32 " "	68 " "

A study of Fig. 5 will show that the freezing curve of this mixture drops off very rapidly toward the end. When a 32 per cent. mixture has been reached the line of freezing is almost vertical and a very slight change in the mixture will cause an enormous drop in the freezing temperature. It is remarkable that while a 30 per cent. solution of the mixture will have a freezing point 10 degrees higher than a 30 per cent. solution of the alcohol alone, still a 32 per cent. solution of the mixture will have a freezing point about 10 degrees below that of a 32 per cent. solution of the alcohol. When using the mixture the quantity of glycerine will remain constant for a couple of months, although the alcohol will have to be frequently renewed to make up for what has evaporated.

We now come to calcium chloride, $CaCl_2$, and water. This compound has been recommended by many and is very good, although it has its dangers in the difficulty of securing the chemically pure article. In buying the calcium chloride for use in the cooling system of an automobile the crude article costing about 10 cents a pound should not be purchased. The chemically pure article costs about 25 cents a pound and is very satisfactory. The objections to the use of the material is its tendency to set up an acidic action in the radiator. Chloride of lime, which should be kept out of the radiator, is often a constituent of the commercial calcium chloride and care must be used in getting the chemical from a reliable concern who will guarantee the purity of their products. With the calcium chloride solution the percentages are given by weight instead of volumes as are the other tables:

Freezing Point	Calcium Chloride by Weight	Water by Weight
+10 degrees Fahrenheit	15 per cent.	85 per cent.
+ 5 " "	17 " "	83 " "
0 " "	19 " "	81 " "
— 5 " "	21 " "	79 " "
—10 " "	22 " "	78 " "
—15 " "	23 " "	77 " "
—20 " "	25 " "	75 " "

In Fig. 8 the specific gravities of this mixture are given. These would be of use if the motorist had a hydrometer. He could then take a sample of his solution from time to time and test it for its specific gravity; from this he would know the freezing point which corresponds to it. He could then add more calcium chloride if it were necessary to lower the freezing point. For instance, if the specific gravity were 1.12 by looking at the curve, Fig. 8, it will be seen that the freezing point is 10 degrees Fahrenheit. There is an interesting instrument on the market called a Freezometer which is a hydrometer especially adapted for use with denatured alcohol. The readings are directly in terms of the freezing point. The appearance of the device is shown in Fig. 4. It is used as follows:

The scale in the stem of the Freezometer reads from plus 30, or 30 degrees above zero Fahrenheit, to —50, or 50 degrees below zero Fahrenheit, and indicates the freezing point of the solution tested. Take a quantity, either of the fresh solution before filling the radiator, or if a test is desired of that in use, draw from the radiator sufficient to float the Freezometer in the test tube supplied with each instrument. Put the Freezometer in the solution and read the line on the stem to which it sinks. This point will show the degree at which the tested solution will freeze, provided the thermometer, in the lower part of the body of the instrument, shows the temperature of the solution to be 60 degrees Fahren-

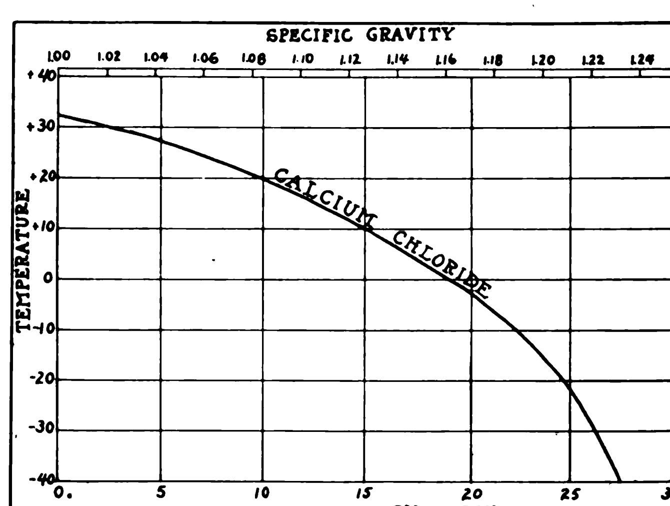

Fig. 6—Freezing points and specific gravity of CaCl and water solutions

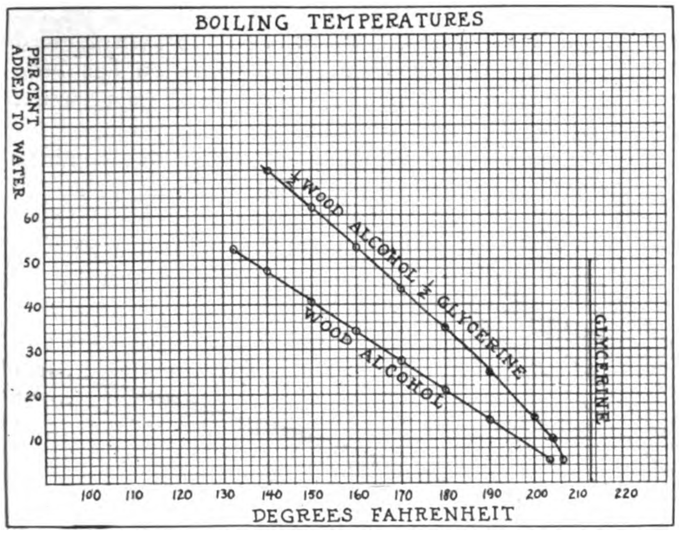

Fig. 7—Showing temperature of the mixture of alcohol and glycerine boils

heit when the test is made. If the thermometer shows a temperature below 60 degrees Fahrenheit hold the test tube closely in the hands until the solution is warmed up to 60 degrees, which will require but a few minutes, when the correct reading of the Freezometer can be taken. If the thermometer shows a temperature above 60 degrees Fahrenheit, the correction table, which is also printed on the reverse side of the thermometer scale in the bulb of the instrument, should be used.

The use of blankets over the radiator when the car is standing will keep it warm for a long time. The curtain-like device shown in Fig. 4 has been adopted by some. It is of very neat appearance and can be rolled up as shown in the illustration. Others place a sheet of newspaper across the front of the radiator permitting the suction of the fan to hold it in place and allowing the motor to run while the car is standing to keep the water continually warm. When leaving the car in a cold garage a cluster of electric lights placed beneath the hood of the car and a blanket thrown over the hood and radiator will often keep the motor warm for a long time while the owner is occupied elsewhere.

Any of the above devices will keep the water from freezing and they have all been tried and found all that has been stated above by numerous automobilists. There are no experiments in the above list of solutions, every one being practical.

Simple Way to Shift Gears

Editor The Automobile:—I have read with much interest the different means suggested for shifting from a higher gear to a lower one, all of which are practically the same except the different means used to obtain the result. I am of the opinion that the simple instruction to shift to neutral, allow the clutch to engage for an instant, throw out the clutch and instantly shift to the lower gear, all of which can be done in 3 seconds and on the steepest hill without any clashing of gears or material loss of speed, is the best instruction to give. This leaves the driver to learn from experience the required speed of car and motor. .

San José, Cal. Willis.

Tapping in Front Cylinder

Editor The Automobile:—I am driving a four-cylinder gas car, one of the best makes. I have noticed for some time a tapping in one of the cylinders and have taken it up with the local people who have a good machine shop, but they do not seem to be able to get it out. I was speaking recently, with a view of purchasing, to the manager of one of the best make six-cylinder cars; he told me at the time that a tapping might be expected in a six-cylinder car, but did not mention a four-cylinder. He stated it was usually in the cylinder next to radiator, and caused by cold air striking the more exposed cylinder causing a contraction or expansion of the metal. Will you kindly advise me if such is the case and if there is any known way of taking it out.

Baltimore, Md. C. Summers.

—The idea of air striking the cylinders and causing a tapping sound from any expansion, contraction or any other cause is absurd. The fact that the sound you hear is a tap and not a knock would seem to indicate that it is somewhat in the nature of a valve. In The Automobile for October 17 the adjustment of the valve was explained and it might be well to follow the directions given therein to see if this will eliminate the trouble. Should the tap still continue after the valves have been adjusted up as closely as they should go, look at the cam followers to see if they are worn. If so, the parts which are gone will have to be renewed. It very often happens that the exhaust will leak through an opening in the pipe with a sound that is sharp enough to be mistaken for a tap. The correction of this is obviously in closing up the opening. This will have to be done by the means which are best fitted to the particular case in point. If you are mistaken in the sound and it is after all a knock, look for a loose connecting-rod bearing, carbon in the cylinders, loose wristpin bearing, broken piston rings or loose main bearings. Sometimes a rapping sound is caused by the fan striking the radiator or by a broken circulating pump.

Mercer Cars Not Underslung

Editor The Automobile:—Will you please tell me how the Mercer cars are hung? I claim they are overhung and my friend says that they are underslung.

Hoping you will answer this, I remain,

Andover, Mass. J. D. Crary, Jr.

—The Mercer cars are not underslung, both the frame and the springs being above the front axle.

Use of Differential Piston

Editor The Automobile:—In a recent issue of Thf Automobile I noted a spark-plug pump which was condemned by the Editor because it did not use a differential piston. Would the pump have operated if such a device had been used?

Elyria, O. J. S. Smith.

—The pump would no doubt have operated successfully as there is now such a pump on the market, it is illustrated in Fig. 2. It will be realized that the pressure follows the law brought out in the diagram in the same illustration. Total pressure divided by area will give pressure per square unit. Therefore since the pressure in any part of the vesel must be the same, when it is divided by a smaller area a greater pressure per square unit will result.

Paraffin Motor Fuel

THE use of paraffin as a motor fuel instead of gasoline is receiving much attention in Europe today because of the excessive prices charged for gasoline, which during the last year reached the high mark of $1.12 per gallon. In a recent test a motor car was given an official run of over 2,000 miles with paraffin as a fuel but with provisions made to start on gasoline and switch to paraffin when ready, the switch being accomplished from the driver's seat as easily as turning from the battery current supply to the magneto in an ignition system. The test demonstrated that paraffin is a fairly satisfactory fuel: The engine after stops of 20 minutes was re-started on paraffin although it was customary to re-start on gasoline and switch to paraffin. The motor demonstrated flexibility by propelling the car for 1.5 miles at 6.14 miles per hour and also accelerating to 40 miles per hour in 51 seconds.

The Englishman in particular is quite desirous of seeing the paraffin carbureter developed; in fact, to such an extent that a public competition of paraffin carbureters has been called for and an American citizen living abroad has offered a prize of $2,500 for the best design. He is nevertheless somewhat skeptical as to how long paraffin will remain at its present low price. He has had a lesson during the last year on how the oil interests can advance prices when public attention turns to a certain product such as crude oil, which has more than doubled in the last 13 months since its consumption has been considerably increased by the more general introduction of the Diesel heavy-oil engines.

But the cost-of-fuel argument is not entirely confined to Europe; it has reached our shores and complaints are coming more from owners of high-powered cars than from the cheap-car owners. The complaints are being heard from those who are getting but 7 or 8 miles per gallon out of gasoline and not that much. Now that fuel is selling in metropolitan garages at 25 cents per gallon it brings the fuel cost alone for operating such a car up to over 3 cents per mile. The owner of the small light-powered car is getting 25 and 27 miles per gallon or an expense of less than 1 cent per mile.

There is no question but that the American car owner is going to face higher fuel prices during the touring season of 1913 and when that condition comes public attention will be focussed on the carbureter makers more than ever before. With them it will then be economy first. Up to the present the car owner and the maker, as well, have been demanding speed. Carbureter makers were demanded to make special adaptations of their stock product for different cars in order to get higher speeds, without any special regard to consumption. Now this is changing and already two or three American concerns have been abroad picking out the most satisfactory carbureters for the American field with the object of pushing their manufacture in this country. In nearly every case fuel economy is one of the big essentials of the foreign device.

That there is room for vast improvement in fuel consumption in America is admitted on all sides. Every engineer admits it, the car owners admit it, the carbureter makers admit it, all admit it. It would have been better today for the industry if the fuel economy tests of 3 or 4 years ago had continued and had developed as the hill-climbs, the road reliability runs and the road races. But makers scoffed at them. Who cares about fuel consumption? The bigger question was, could you go over 60 miles per hour and could you climb all hills on direct drive? But the lane is turning, and the owner who today is paying for his follies of 3 years ago is alert to what must be available a year or two hence and he is goading the car maker and the carbureter maker on. Both of these parties have made good in the past and there is not any reason why they will not make good in the future.

The necessity for carrying a supply of gasoline for starting purposes when using paraffin or other heavier fuels cannot be considered any difficulty in that the small tank capacity necessary for the gasoline supply can be made as a compartment of the standard fuel tank. Owing to the fact that greater mileage per gallon has been obtained from paraffin the net result is that with mixed fuels there is a greater fuel capacity in a given cubical space than with gasoline alone.

The present trends of attention towards heavier fuels again impresses the automobilist with the fact that while heavier fuels offer certain difficulties in carbureting, yet pound for pound, they give more power than the lighter fuels. The troubles in starting with heavier fuels in cold weather have been, to an extent, overcome by the self-starter.

Elbert Hubbard on Ideal Salesmanship

"When You Sell a Man an Automobile You Do Him a Benefit," One of the Messages in the Fra's Recent Address to the Convention of General Automobile Sales Association at Indianapolis

"WHEN you are out with very learned people, if you don't know what to talk about, just talk about electricity," he says. "You will never shock anybody. If you are out to a dinner party and there comes a little lull in the conversation, here is what you will say:

"'Electricity, speaking of electricity—of course it is not really what you are talking about. Speaking of electricity; that is the great mystery. Nobody knows what it is. All we see is its manifestation!' You are perfectly safe in saying that. If you don't know anything about electricity you will have to back up and sidetrack and start something else, but usually it goes all right."

And in the presence of that man, casting around in the vacuum which I am pleased to call my mind, seeking something to say, it came to me all at once: "Electricity, the great mystery, nobody knows what it is; all we see is its manifestations," and was just going to say it, when he said it himself! He beat me to it. "Good-by," I said, and I ran down the steps, caught a trolley car, jumped on the front end and over the head of the motorman I read a sign, "Don't talk to the motorman." That suggested an interview, and so I said: "Partner, what is electricity?" "It is the juice," he said. He knew. I said: "Where do you get it?" "Everywhere," he says; "it always was. Edison didn't invent it; it is God's best gift to man." I said: "I thought woman was God's best gift to man." "Same thing"—a great mystery. Nobody knows what it is. It is very dangerous if you don't know how to handle it." I said: "Does electricity make this car go?" "Sure," he said. I said: "Tell me how." He told me. I had not known before and I do not know now. I said "How do you know so much about this subject?" He said: "I have been taking an International Correspondence School course. I get $65 a month for holding down this job. I am going to have charge of the electric light station next month at $125 a month." I says: "I get off there at the corner," and the car stopped within a foot of where I wanted to get off and as I stepped off the car I said: "Good-by, my friend." He said: "Good-by, old man," but he never looked up at me. He was just intent on carrying that car through in perfect time, at proper speed and getting me off on terra firma. And as the car moved away I said to myself, "There goes an educated man. He is onto his job and he is getting ready for a better job."

If you don't like that definition of education, then you take the definition of President Eliot, of Harvard, who says that **that man is best educated who is most useful.**

Can you imagine a better man than a man who has a good job, who holds it down, and who is getting ready for a better job? You get your business organization going and the office runs on momentum. All you have got to do is to go along and look in once in a while, scare the boys a little, cut them down, fire a few and put in a few more, and the thing goes.

Not so with salesmanship. You deal with humanity. Humanity is a strange thing. Nobody ever got beyond the sky. You don't know what it is. Man is an electrical manifestation. That man, that motorman, was right. Man is an electric phenomenon, a generator. He takes up energy into his system and gives it off again. He is only here for a day. Life is motion. We are doing things, making things, interesting humanity.

Ten years ago it would have been impossible to have got this number of men together—men in competition with each other. We were all afraid of each other a few years ago. Ah! we had trade secrets. Now, here we are all together. I look into your hearts; I look into your happy, smiling faces, and I feel this afternoon here that there is but one atmosphere, there is but one feeling—brotherhood.

We come into life without our permission. We are being sent out of it against our will, and over the vision of our dreams there steals a thought that we have been used by an unseen power for an unknown purpose. We guess what that purpose is. We are here for a mutual benefit. We will not be here so very long. You help me and I will help you, and soon Death will come and rock us all to sleep. In the world where Death is there is no time for hate.

We are business men. We grow by elimination, by discarding things, and we know now as sensible men, leaving the question of ethics and morality absolutely out of the proposition, we know **the only way we can help ourselves is to help humanity. When you sell a man an automobile you do him a benefit.**

If you want to make money don't cut down expenses, but increase your income; increase your efficiency. And any man who owns an automobile is a better man than the one who does not. I say plunge; yes, mortgage if necessary to get the machine, and you will work out all right.

The other day I went into Tiffany's trying to sell them space in a magazine. Says the advertising man away down deep: "We are not selling any jewelry now. People are not buying any shiners." You remember how our old friend Hinky Connors, of Buffalo, launched upon the world an immortal epigram, to wit: "Them as has shiners wears them."

Now, the question is whether you will spend your money for shiners or automobiles. You are going to blow it in some way, anyway. So then I went to Sherry's and tackled their advertising man, and when I did he said: "The people are going out in the country." And I find it is so. I own a hotel. I feed the automobilists at a dollar a meal. We have them from one week-end to the other at East Aurora, and every Saturday and throughout the week. They don't go to the lobster palaces in the cities; they go to towns like East Aurora, where they can get a single meal for 75 cents—and the automobile increases the efficiency of the man.

Most of us go through life on one cylinder. We overeat. We underbreathe. We are full of hate and doubt and fear and apprehension, and the result is that we are about 33 per cent. sick 33 per cent. of the time. Anything that takes people out in the country, out away from the gases and noises and smells of the city, out through the green fields—that thing is a benefit; and so I repeat, when you sell an automobile you do him a benefit.

The man who buys the automobile and runs it gets his money's worth, and the man who makes one gets a profit on it always and forever, and the fellow who writes advertisements insists on getting his pay, but the **dealer is up against it a good deal of the time, and I think one reason is this: The dealer is isolated. He lives by himself. He is not in communication with other people. He does not get together with people in conventions like this.**

A convention like this enlarges your view. You get the perspective from both ends. You get acquainted with people. You get rid of your fears, your doubts, your grouch —and I want to see the dealers get together. I want to see a combination of dealers that will put the makers on their knees. I want to see you salesmen get what you are worth, and only a few of you do.

Everybody profits by good roads. I was delighted to hear the plea made for this road to run from the Atlantic to the Pacific. Why not? Do you know that in America we have only one railroad that runs from tidewater to tidewater? That is the Panama railroad, 46 miles long. It has one engine. I want to see an automobile road from tidewater to tidewater, and I expect to see it.

The proposition is a good one, that every automobile manufacturer should pay 1 per cent. of his gross income for a year into this project, and if they will do that this project will go through. I dont think there is an automobile manufacturer in America who can afford to stand out on that question. He will have to come in to save his face. This thing will go through.

Salesmanship Headwork

Boost All Products, But Boost Your Own Products Best Is the Theme of John G. Jones at Indianapolis Sales Convention

MAKING a selling talk is a hard job when you are talking to salesmen, but when you talk of four and six-cylinder motors surcharged with energy it is a dangerous job unless the rules of the game, the traffic rules, are obeyed. I am told that the one big problem of the dealer is in the making of profits from his distribution. I am further told that the manufacturers of the country are manufacturing today successfully and at a fair profit. There is a reason.

The manufacturers have found that they must do everything along scientific lines, and they are following the practice of sensible business methods. They have gotten down to as low an overhead as it is possible for them to strike.

Efficiency is prominent in every department, and the corelation of the various departments is one harmonious whole. That is why they are successful.

A great part of the trouble of the dealers has been in rebating or commission cutting. It is only poor salesmanship that must cut the advertised price for the good article. There may have been times when you were forced to give expensive joy rides to poor prospects. I believe that time is past. There may have been times when you would almost have to give the buyer the whole of the commission in order to get the game started and to get the people into the habit of using your product. But that time has passed.

There is no business man in the United States today, if he is approached by a real salesman imbued with the excellence and the value of his product, and knowing it from every angle, who is not willing to talk business. This convention is the keynote of a new era in the management and conduct of the dealers' organization.

Dealers must realize that they, as well as the manufacturturers, must have efficient organization; but it is up to the manufacturer to help the dealer; not only to help him in the way of giving him supplies and sending an efficient salesman around to visit him and to give him the talking points of his special product, but it is up to the manufacturer to get a central body. I would suggest that the 419 manufacturers in the United States to-day get together and take up the problems, not of each individual manufacturer, but the problem of the distribution of the automobile.

The bankers are training young men in their ranks all over the country in the economics of banking, in banking principles, in commercial law, in corporation finance, and they are doing it by a standardized course. I think if the 419 car manufacturers would put up $50 apiece a year they would be able to have an organization that would send out efficiency information to the dealers; it would tell them how to get the best results out of their territory, whether that territory were a city, state or county; it would teach them how to organize; it would teach them what kind of salesmen the manufacturers were finding making successes in their own organization.

This would not interfere with competition. **The cleaner and higher class the competition is the greater the demand for that product.** And that is the one point that I want to drive home to the dealers today; that is, the education of their salesmen. **If you have a large territory to cover, an important territory, don't take a salesman on your staff unless he gives you his whole time.** The automobile is too important, and you have to learn too much about it, and you have to be keyed up to too high a pitch to be able to do anything else and sell it successfully. The automobile is deserving of the whole time of a salesman.

In the choosing of the salesman I would suggest a few qualifications that are absolutely necessary to the success of your organization.

First of all, natural qualification; then the prime condition of the salesman: Personality, ambition, honesty and courage; acquired qualifications, confidence three ways, enthusiasm, earnestness, application, preparedness, observation, self-analysis.

As a business proposition it pays to be honest with one's self, with one's firm and with one's customers. In that way only will the salesman retain his own self-respect and the confidence of his customers.

There are salesmen who are known as one-trippers. They cover the district and they have told so many untruths about the product that they are selling that they are not able to go back.

Then there are those other salesmen who inspire confidence in themselves and in the product that they are selling. That kind of a salesman can go back and sell his customer a second car; he will go back and sell him a third car—because the buyer knows that the integrity and the honesty of the man that he is dealing with are back of that product which he is buying, but no honest man can sell a dishonest product.

Courage—It takes courage to be honest under all circumstances, and courage is one of the prime qualifications of the salesman; courage to go up against a man when you know that someone else has offered him a cut in commission on his product; courage to go up there with the enthusiasm based on the knowledge that your product is so much better that it is just the thing that that customer wants; so much courage that that little obstacle in your way, in the way of making the sale, is forgotten and wiped away. If it is wiped away in your own mind there will be no impression left in the mind of the man to whom you are trying to sell.

Acquired Qualifications—They are a little different from the natural qualifications. All men are not born salesmen, but every man with innate ability to get hold of true business principles, and with enough personality to meet his fellowmen, can train himself to be a salesman. After all, selling is nothing more than making the other man believe that he wants what you have got to offer; make him believe that he wants it badly enough, or, rather, well enough to get his name onto the dotted line and pay over his hard cash.

You can train salesmen, and in so doing train them first of all in honesty; then train them in courage; then train them in the essential qualification of the business, which is enthusiasm.

It matters not whether a salesman be selling an $800 car or whether he be selling a $10,000 limousine, if he is himself satisfied, if he believes that the product he is selling is the best there is to be had for the money and the most serviceable that his prospect can buy, that man can come pretty near making the other man believe that a $1,500 car is as good as a $10,000 car at the time. It is not a question of price in the selling. It is a question of sizing up the product to the amount of money you are going to ask for it.

With the dealer first of all is the product; with the salesman first of all the customer that he is going to sell and serve. There is not a man in this convention today, if he goes out in the morning imbued with the idea that he is going to sell some man or woman the best automobile that there is in Indianapolis or that there is in Detroit or in any other town, he is going out to make a clean-cut sale because he has, first of all, a belief in his product.

Earnestness—A man can be enthusiastic without being earnest. There is a manufactured enthusiasm that does not ring true in all cases. But earnest enthusiasm—not too earnest to permit a smile once in a while when you are telling all the fine qualities of your product; but that earnestness that drives home the point; that drives it home every time the salesman makes it—that is the selling qualification that they can't get away from. I don't care how strong the opposition is that you meet with, and I don't care how much another dealer is cutting and rebating. **Meet your prospect with honesty and courage and confidence in yourself and in your product, with enthusiasm, with earnestness,** and your prospects will forget the little rebate that has been offered to them.

Have patience with men whether they are in the market for your kind of a car or not; one may want a $2,700 car and another a $5,000 car. Don't get sore at those fellows that buy Fords. Ford is doing the best work for you automobile dealers today that has been done in the country. He is educating the people to buy automobiles.

The first watch that my father gave me was an Ingersoll. The Ingersoll keeps time, but I am making a little more money now and I can afford to pay more than $1.90 or $4.60 for a watch today, and the Ingersoll is in the discard. If you could see the discard corners of automobile buyers in America you could start a Ford second-hand shop; so don't knock Ford—boost him, and boost every other car that comes into competition with your own product. **A boost gets more than a knock anywhere, and a knocker only belongs on the outside of the door and not on the inside of a prospect's home.**

Don't think for a minute that all that the salesman must know is just enough to be able to go out and discuss just one thing, just the automobile. **The more interesting a salesman can make himself in his community the more re-**

spect he can command from the people with whom he expects to do business—the easier it is for him to get next to them.

It is important that the salesman be a broad-minded business man, an efficient business man, with a knowledge of the laws of supply and demand; with a knowledge of credits; with a knowledge of advertising; with a knowledge of money; with a knowledge of investment. He should be a man with all men. He should be able to talk banking with a banker. He should be able to talk manufacturing with a manufacturer; and he should be able to talk those subjects intelligently. That is efficiency. And when a man gets hold of business principles and grasps them tight he will soon find out that when he meets men he is gaining their respect. He has added to personality an irresistible force of a broad education along tangible business lines, and that commands respect.

When you have told the story of your car have you said all, or are you ready to go on talking about your prospect's business? Are you able to interest him, if he has not bought that car, to such an extent that when the next man comes around to try to sell him he will remember you, and he knows that you are coming back?

The last point—that is specialization. Take a prospect and go after it. Don't go after ten men at the same time. While you are going after ten men there is some salesman tacking close after each one of them, and while you are only giving each man who is a prospect one-tenth of your selling qualifications and power, there is some one else there who may not be as good a salesman as yourself, that is, if you systematized your work, who is getting the order from him.

Don't let salesmen run riot over your territory. Take your Bradstreet, your Dun and your directory and inform yourself until you have the names of all the persons in your territory carded up, and when your salesmen come in in the morning, say to John Jones, "Here are six names. I want you to see those parties today. They are on the east side of town." And when Tom Smith comes in, say to Tom Smith, "Here are six names over in another district. They have seen our advertisement. They have inquired about our car. They are interested. Go out and see them and don't see another man in that county."

Systematize and hustle along the right lines, and if you hustle along the right lines you will see your efficiency is growing, and you will see that the manufacturers will soon be coming after you for pointers. That is the game. Systematize the work of your salesmen. Don't send salesmen out who you don't think are qualified in every respect to represent you.

Don't knock the product of any other manufacturer. Boost them all.

The automobile industry has come to stay. There have been more good things killed by knocking than by any other one means. When you begin to suggest a negative idea to a buyer, by telling him that the Cadillac is not good, or the Chalmers is not good, you are putting that prospect into the frame of mind where he says, "My God, is there a good car?"

Boost, but boost your own product the best.

Taxis Form an Export Element

NEW ORLEANS, OCT. 18.—Taxicabs form a large percentage of the motor cars exported to Latin America through this port. With the increasing amount of smooth-surfaced streets in that section of the world, taxicabs are taking the place of the time-honored coach. In all Latin American cities the public coach service is an institution that was inaugurated shortly after the coming of the Spaniards and has flourished despite the advent of street-cars and automobiles.

Coach fares are very cheap, being regulated by the municipal governments. The best coaches, really elegant equipages, are hired for 50 cents per hour, but the medium class, which is more generally used, can be had for 37 cents an hour. This low rate has made it necessary to quote almost as low rates for taxicabs and as there is little variation in the coach rates throughout Latin America, it will be found that taxicabs usually may be had at a slightly higher rate than is charged for the first-class coaches. The low rates and the time saved have made this class of motor car very popular and most Latin American cities, where the streets are improved, has doubled or tripled the number of taxicabs found in American cities of the same size.

Freight Cars Are Scarce

Present Shortage of 31,000 Will Probably Increase to 60,000 at the Crest of the Crop Movement, Says J. S. Marvin of N.A.A.M.

WITH a net shortage of freight cars reaching beyond 31,000 reported by the railway associations for the fortnightly period just past and in view of the probability of a still greater shortage during the next month, the automobile industry is interested to know whether conditions are going to improve before the height of the shipping season of the industry.

James S. Marvin, traffic manager of the National Association of Automobile Manufacturers, has returned from a trip through the manufacturing centers and states that shipments are moving, but that in the event of a general stringency of the freight car situation the automobile industry would have to take its chances with other shippers.

Mr. Marvin said: "Since May 1 I should say that the railroads have added about 5,000 wide-door freight cars to their equipment and that the total number of automobile cars on the American railroads on January 1, 1913, will approximate 50,000.

"Conditions this fall have no parallel in the history of the world. The demands for cars to move the unprecedented crops and the general demands of business are sharper than ever before known. The busiest part of the automobile shipping season is still some distance in the future and if the weather remains good there is a prospect that the traffic demands may be satisfied. The movement of the crops has not reached its crest, but the agricultural wealth of the country is moving in tremendous volume right now.

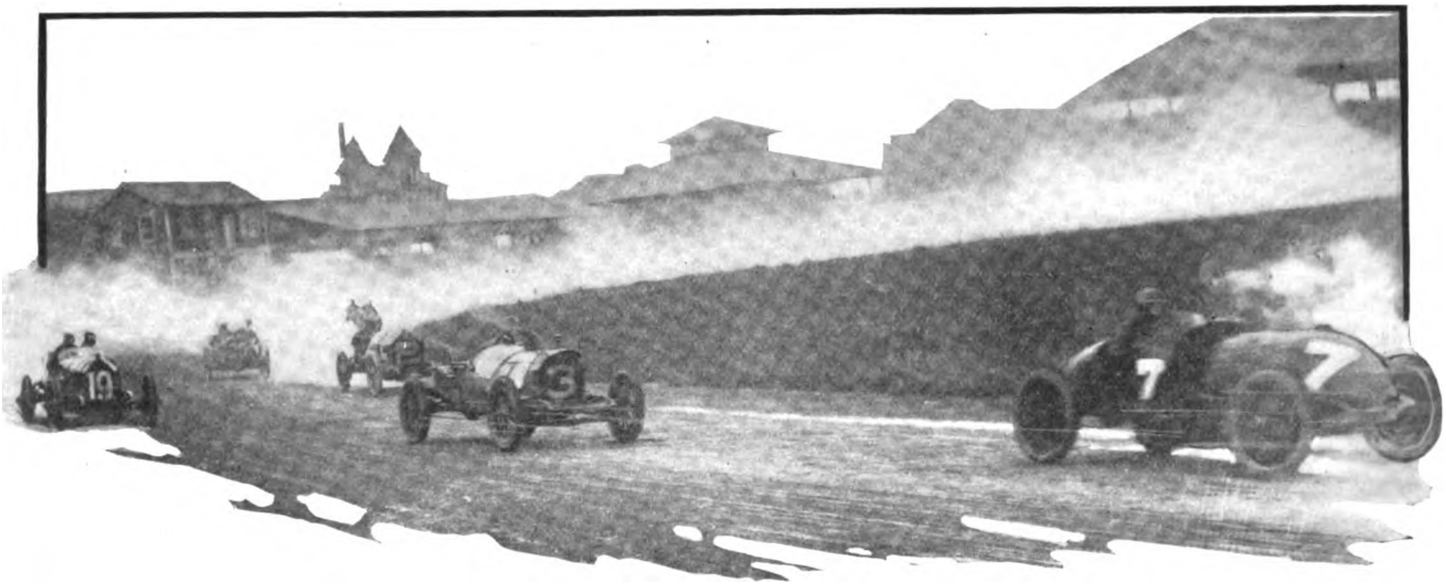
"The railroads are doing everything in their power to prevent congestion, to give them due credit. They are quite as anxious as the shippers possibly can be to keep their cars moving under profitable loads and have adopted special rules for quickening terminal work.

"Reports have reached us that automobile freight cars are being used for other kinds of traffic. I will say that in the case of an eastern road, for instance, where there are thousands of automobile cars in the equipment, it is exceedingly difficult to regain possession of cars that have been consigned with freight to some section where the demand for rolling stock is feverish. The existing plan of interchange in the use of cars is far from the ideal and the solution of the problem is still to be met.

"The elaborate car service departments installed by all the railroads have frequent records of cars absent from the service of their owners for months at a time. It is hardly to be expected under present conditions that a western road would go out of its way to return cars of an eastern colleague at a time when the demand for cars in the territory of the western road was far in excess of the possibility of supply."

It is considered quite likely that the total net shortage of cars at the crest of the crop movement will approximate 60,000. After passing the crisis the volume of shipping has usually decreased slowly but steadily for a month and then rapidly for another month. At that rate the car situation should be cleared by February 1, when the season for shipping automobiles is at high tide. If the country enjoys good weather in December the traffic men look for a natural development of the situation, but an early blizzard at a time when the shipments are still extraordinarily heavy might serve to produce a congestion the like of which has never been known.

Possibly with such a contingency in view the great producers of automobiles have made an early start with their shipments. The annual report of General Motors shows that its receipts for the first two months of the fiscal year were $1,000,000 in excess of last year. The Overland company has adopted methods to accelerate deliveries of sold cars and Ford shipments have made an entirely new mark as to volume for this time of the year. In addition to these precautionary measures, indicated by the increased volume of early shipment, every large producer has endeavored to provide for a supply of cars to transport its output. The railroads have assumed a hopeful atitude as to general results and promises and agreements have been made by them to avoid a repetition of last spring's congestion.



Getaway of the George H. Robertson Trophy, 25-mile free-for-all, at Brighton Beach, which was won by Neil Whalen in a National

Brighton Races Success

Eight Interesting Events Run Off—Wishart, Lewis and Whalen All Star—Over 4,000 Spectators

DESPITE lowering clouds which kept down the attendance, the race meeting staged at Brighton Beach Saturday was the best presented to metropolitan lovers of speed in many a long day. There was a sharp brush in each event run off and the suspicious circumstances of some former meets were delightfully absent. The promoters probably lost a little money because of the clouds, but the impression made on the public was distinctly favorable to future meetings.

The card was divided into eight events and two exhibitions and the running was done in precise accordance with the schedule and rules. The first event started sharply at 2:30 o'clock and the interminable delays of other days was absent.

The feature race of the day was the George H. Robertson Trophy event at 25 miles, free-for-all which was handily won by the National driven by Neil Whalen. At the start the Buick Bug made the pace, closely accompanied by Wishart's Mercer Special. The hot gait they pursued resulted in the retirement of both before the midway station had been passed. The National had been laid off the pace in the early stages and when the Bug went out with a blown tire and Wishart's mount faltered, Whalen came along with the blue car and tin-canned to the wire. The National was chased determinedly in the last 5 miles by Ferguson's Mercer and the speedy Stutz came booming at the end, but the National had been aided in establishing a wide gap by reason of the sprint of Wishart's Mercer which had lost a lap earlier in the race. Wishart tried to pass the winner and in the duel that followed the other cars were lost.

A full score of cars participated in the various events and a national tinge was imparted to the card by the appearance of such names as Mortimer Roberts, William Chandler, David Lewis, Ray Howard, Neil Whalen, Spencer Wishart, Ralph Mulford, Caleb S. Bragg and others in the list of

The handicaps were well filled, a dozen starting in the 5-mile event and eight in the 10-mile contest and the class events drew good fields. The allotment of handicaps proved to be a good job as the finish in each of the condition races was uncertain until the final lap.

The opening sprint was for cars having a total piston displacement of less than 230 cubic inches and drew a field of six, from which the R. C. H. entry was scratched. This event did not develop much of a struggle, but was interesting from the fact that the winner was a Mason Special, which was making its metropolitan début. The distance was 5 miles and the Mason, under the handling of M. Roberts, jumped into the lead after one false start and set a winning pace to the wire. The E-M-F was a handy second and the Hupmobile, running very steadily, was third.

The second event was for cars of 231-300 cubic inches piston displacement and had five entries originally. To these was added at the post the Mercer Special, handled by Wishart. It was known that the car exceeded the class limit by a small amount of piston space, but this fact was overlooked in the rush before post time. The Special got away smartly and cut out a rapid pace, accompanied by Ferguson's Mercer. A bigger Mason driven by Roberts made a bid in the early part of the race, but carbureter trouble soon made its appearance and the car retired to the background. The Bergdoll kept up with the procession throughout and in the final mile passed all but the Mercer pair. The finish showed Wishart's car in front with Ferguson's second and the Bergdoll third. Protest was immediately lodged with Referee Pardington and Wishart admitted that his car was outside the class. The official disqualified the Wishart Mercer and placed Ferguson's mount first and the Bergdoll second.

The third race was at 10 miles for the Poertner Trophy for cars of 301-450 cubic inches piston displacement. It brought out only four starters, Stutz, G. J. G., Pope Hummer and National. The National started well but retired after making 1 mile because of a blown tire in front of the grandstand. This left the Stutz out in front, where it stayed to the end. The Pope kept going until it had made 9 miles, but was unequal to the task of standing off the rush of the G. J. G. The Pope was not in good condition, but the G. J. G. ran a creditable race. The Stutz had the speed of the party and as subsequent events proved might have beaten the National even if there had been no tire trouble.

The Borax Trophy at 5 miles came next with a field of four: a Mason, Mercer, Buick and National. The National again suffered a blow out, but managed to finish. The Buick retired after tire trouble at the head of the stretch, where its disablement almost caused a disaster to following cars. The Mercer, driven by Wishart, had a nice trip landing in front, the length of the stretch ahead of the Mason, which was handled by Mulford.

The Whiting Trophy, an invitation race for Mercer cars at 5 miles brought out a field of four and Ferguson's mount took first from Wishart's car, while Mitchell was third and Wolf fourth.

The 5-mile handicap developed a fine race. The Buick Bug was given the position of honor on scratch because of its past history. The Stutz and National started 10 seconds ahead; Ferguson's Mercer, 20 seconds, which was the same rating given the Bergdoll. The remainder of the field was given various handicaps, the limit man being the Flanders (Wood), who had 75 seconds.

The Bug failed to catch the field and was not prominent at any period of the race. It was a duel between the Stutz and the National until the last mile, when the latter lost some of its speed and allowed the Bergdoll to nose it out for second money. The Stutz made fast time and finished the race in 4:27.50, or 67.29 miles an hour.

The last race of the day was the 10-mile handicap, with the penalizations rearranged to correspond with the performances in the preceding race. This placed the Stutz on scratch with the National and Wishart Mercer at 25 seconds, the Ferguson Mercer at 45 seconds and the rest spread out to the limit, which was given the E-M-F, 75 seconds. Wishart's car made the pace, picking up the cars that started in front of it after the third mile. The Stutz carried too much of a burden and while it keept shooting at the Mercer, it was never able to cut down the handicap so as to bring Wishart to a drive. The finish found the Mercer Special in front with the Ferguson Mercer second and the Stutz third 3 furlongs back.

A. R. Pardington acted as referee, Fred J. Wagner starter and the promoting organization is known as the Motor Dealers' Exhibit Company. The money prizes aggregated $1,450 and five handsome bits of plate went to the winners of the important races. The summary follows:

Class C, 5 miles, under 230 cu. in.

Car	Driver	Time	Car	Driver
Mason	M. Roberts	5:18.55	Herreshoff	S. Casey
E-M-F	W. Chandler		Flanders	F. Wood
Hupmobile	E. Meyer			

Class C, 10 miles, 231-300 cu. in.

Car	Driver	Time	Car	Driver
Mercer	A. Ferguson	9:33.15	Mercer	P. Thebaud
Bergdoll	E. Homan		Mason	M. Roberts
Correja	J. Quinlan		Mercer	S. Wishart

Mercer (Wishart) finished first but was disqualified as out of class.

Class C, 10 miles, 301-450 cu. in.

Car	Driver	Time	Car	Driver
Stutz	D. Lewis	9:32.50	Pope Hummer	R. Howard
G. J. G.	P. Thebaud		National	N. Whalen

Class E, 5 miles, under 600 cu. in.

Car	Driver	Time	Car	Driver
Mercer	S. Wishart	4:46.25	National	N. Whalen
Mason	R. Mulford		Buick	R. Howard

Class D, 25 miles, free-for-all

Car	Driver	Time	Car	Driver
National	N. Whalen	24:54.85	Mercer	S. Wishart
Mercer	A. Ferguson		Mason	M. Roberts
Stutz	D. Lewis		Buick	R. Howard
Mercer	C. Wolf		Hupmobile	E. Meyer

Class E, 5 miles, invitation

Car	Driver	Time	Car	Driver
Mercer	A. Ferguson	4:56.85	Mercer	L. Mitchell
Mercer	S. Wishart		Mercer	C. Wolf

Class E, Handicap, 5 miles

Car		Driver	Time	Car		Driver
Stutz	(10)	D. Lewis	4:27.50	Mason	(30)	M. Roberts
Bergdoll	(20)	E. Homan		Correja	(50)	J. Quinlan
National	(10)	N. Whalen		Hupmobile	(60)	E. Meyer
E-M-F	(35)	W. Chandler		Flanders	(75)	F. Wood
Mercer	(15)	A. Ferguson		Buick	(scr.)	R. Howard
G. J. G.	(25)	P. Thebaud				
Mercer	(25)	C. Wolf				

Class E, Handicap, 10 miles

Car		Driver	Time	Car		Driver
Mercer	(25)	S. Wishart	9:30.15	E-M-F	(75)	W. Chandler
Mercer	(45)	A. Ferguson		Mason	(65)	M. Roberts
Stutz	(scratch)	D. Lewis		Mercer	(55)	P. Thebaud
Mercer	(55)	L. Mitchell		National	(25)	N. Whalen

English High-Gear Tests

Royal Automobile Club Tries Out Pathfinder on 1,934.75-Mile Run with High Gear Continually in Mesh

LONDON, Oct. 17—Under the observation of the Royal Automobile Club, a 27-horsepower Pathfinder car weighing 2,975 pounds was driven over a course of 1,934.75 miles with the high gear in mesh at all times. The car traveled from Land's End to John O'Groats and back; the course includes a number of hills, all of which were taken, though sometimes with difficulty, as in the case of Berridale Hill, which the car mounted, but at the seventh attempt to do so. Another factor which made travel difficult at times was inclement weather. The automobile is of the standard Pathfinder make, its engine having been measured by the R. A. C. officials as 105 by 133 millimeters, and the machine has traveled some 7,000 miles before the test. After the trip was over the car was taken to Brooklands track for some speed demonstration work, and attained a speed of 55.92 miles an hour. This latter performance was conducted independently of the high-gear test and no credit was given for it in the official R. A. C. certificate, which covers only the factors entering into the original tests.

A similar test was made about 3 weeks ago on a 59.9-horsepower, six-cylinder Napier car, having cylinders of 127 millimeter bore and 127 millimeter stroke and weighing 5,472 pounds. The high-gear ratio, which was used throughout the trip, is 2.7 to 1 and the full wind area 10.3 square feet; the tires used on the car were 35 by 6 inches. Over a course of 795.875 miles, from London to Edinburgh and back, the car was driven in high, excepting for a short distance, where the driver had to drop in low gear due to the presence of troops in the road. The car was also put to a test on Brooklands track and went at the rate of 75.69 miles an hour. During the London-Edinburgh-London trip the car consumed 23.1 gallons of gasoline, being 29.1 gallons per mile.

Rain Spoiled Sport at Rockingham Park

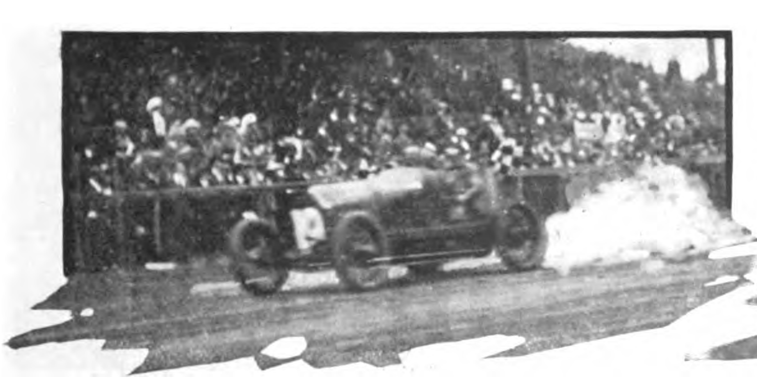
BOSTON, MASS., Oct. 19—Rain put an end to the automobile race at Rockingham Park, Salem, N. H., today, after seven of the ten events had been run. There were more than 5,000 people at the track. When the rain set in the race was called off permanently, having been postponed once before. Iselin and Higgins were the heroes of the day. The summary of the races follows:

5-Mile, Non-Stock, Under 300 Cu. In.

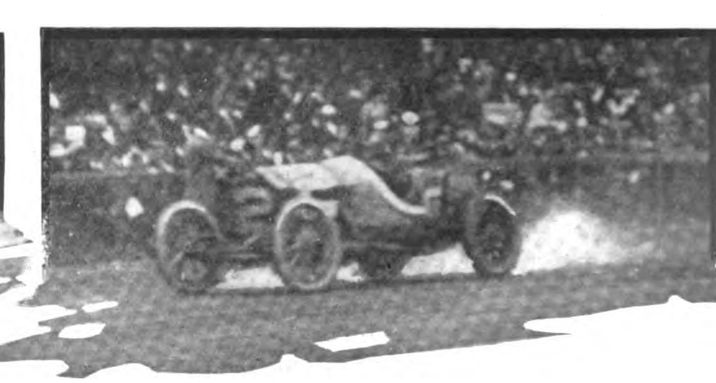
Car	Driver	Time
Mercer	C. O. Iselin, Jr.	5:30
Mercer	H. Cutting	
Buick	S. S. Bigelow	
Hudson	C. Smith	

10-Mile, Non-Stock, Under 300 Cu. In.

Car	Driver	Time
Studebaker	D. Higgins	13:15
Penn	J. Pugh	
Hudson	H. Warren	
Mercedes	A. D. Young	



Spencer Wishart, who won two of the Brighton races in a Mercer



David Lewis, who won two events in a Stutz

Six Cars Still Perfect In Lake Michigan Run

Heavy Rain Converts Dirt Roads Into Morasses and Causes Withdrawal of Four and Points on Five

ESCANABA, MICH., Oct. 22—**Special Telegram**—Rain falling yesterday and today put a period to the hopes of four of the contestants in the Chicago Motor Club reliability run around Lake Michigan and only 2 days of the schedule have been run off. It turned some of the dirt roads into swamps and made the going on the improved roads uncertain and difficult. The 18 and 20-mile an hour schedule in force today was too much for all but six of the contesting cars. In addition to the three cars that withdrew, another has not been reported at a late hour tonight and five were penalized for work or lateness. The perfect score division in the touring class includes: Case 2; Staver 4; Abbott 6 and R. C. H. 7. In the roadster division the only clean scores are carried by the Moline pair.

Only One Penalization At Oshkosh

OSHKOSH, WIS., Oct. 21—**Special Telegram**—Fourteen cars finished the first day's run in the sixth annual reliability contest of the Chicago Motor Club with perfect scores. Only one of the fifteen contestants which lined up at the start of this strenuous run around Lake Michigan fell by the wayside. When the cars had checked in here tonight after their first leg of 171 miles from Chicago the only car missing was National No. 8, entered by Chicago Spring Wheel Motor Company, equipped with spring wheels made by the entrant. This car had trouble with its rear axle in the morning and failed to check in at the noon control at Milwaukee. A wire received here says that the National is on the way and will be in Oshkosh before the morning start.

R. C. H. entry No. 7 broke its rear axle just before lining up at the start this morning. The press car, also an R. C. H., was started as No. 7 and probably will continue in the contest in that capacity. Another R. C. H. was started out from Chicago to carry the press men about 3 hours after the rest and by spectacular driving caught the tour here only a few hours late.

The threatened arrest of N. H. Van Sicklen, Sr., one of the judges in the pilot car, was the only incident of the day. The Oshkosh chief of police considered it his duty to arrest the pilots for throwing confetti on city streets, but was talked out of it.

Starting this morning under a cloudless sky, the tourists found good roads all the way to Milwaukee. From there on the quality of the road varied from best to bad. Most of it was fine gravel, and near Fond Du Lac a stretch of about 4 miles of cement was found which enabled the tourists to make up lost time. A driving rain was the only uncomfortable feature of the afternoon, but it lasted only an hour. It was sufficient to make mud roads for the rest of the way to Oshkosh. Tomorrow's run takes the tourists of Escanaba, in northern Michigan, a distance of 177 miles from Oshkosh. Noon control is to be at Oconto, 89 miles away. The road tomorrow includes some dirt which, with today's rains, probably will be mud. With the exception of a few miles the road is expected to average fairly good through Neenah and Green Bay to Oconto. Thence to Marinette. From there to Escanaba there is a stretch of fine macadam, 63 miles in length, built under bounty from the state.

ESCANABA, MICH., Oct. 22—**Special Telegram**—Six out of fifteen cars in the Around-Lake-Michigan tour completed the second day's run to Escanaba tonight with clean scores. Five received penalties today, one had not checked in at 10.30 o'clock and three have withdrawn from contest. Gray's National Number 8 withdrew at Racine, Velie, number 101, withdrew at Oshkosh this morning, and the R. C. H., 110, went out this afternoon with a frozen motor. Practically all trouble to cars receiving penalties was due to the rain which continued almost without cessation from noon yesterday till this afternoon. Roads which would have been good in dry weather were made so sloppy that mud and water splashed in magnetos and carbureters. There were two hills with mud so deep and so thick that cars stalled and had to be helped up.

About 50 miles of state-built macadam between Marinette and Escanaba and upon the stretch and west boulevard the cars could make 50 miles an hour. Much time lost in negotiating bad stretches was made upon these roads. Velie number 1 received two demerits for cleaning its carbureter which was stopped up with mud. Staver, No. 3, eight points for same; Bergdoll, No. 5, broke its steering knuckle near Green Bay but Monson, the driver, put in a new one and got into night control less than 3 hours late, sustaining 161 points penalties. Bergdoll, number 104, was stuck for 30 minutes in mudhole but pulled itself out with a winch driven by the motor, receiving 30 points for lateness. Stutz No. 109 came into Escanaba several hours late on account of battery trouble and its fenders bent by broken tire chain, sustaining 182 points. Stutz No. 102 has not checked in and is over 6 hours late. Branstetter's Kissel, acting as pilot had carbureter trouble at noon and the Case threw confetti for rest of day. The Staver pacemaker also had carbureter trouble from rain and mud and referee Root nominated the Velie as pacemaker for the day. The R. C. H. press car chugged through in good order but had a narrow escape from upset when it skidded to the edge of a 12-foot ditch. Skillful driving kept it from going over the edge.

The Midland, carrying starter Watts, was held up at Green Bay and both Watts and the driver Kavanaugh, were arrested for scaring a horse and wrecking a buggy. They were not detained long. Five cars finishing with perfect scores are: Koease, Staver No. 4; Abbott, R. C. H., No. 7 and the two Moline cars driven by Wicke and Salisbury.

Today's run of 177 miles from Oshkosh to Escanaba was covered at regular running schedule of 20 and 18 miles per hour. It took hard driving to maintain this schedule through the mud. Noon control was Oconto.

Hardest Run Is Wednesday's Schedule

Tomorrow's run from here to Newberry is expected to be the hardest of trip on account of the naturally poor road conditions and excessive rain, although the distance is only 125 miles with the running schedule reduced to 13 and 11 miles per hour, with noon control at Mantique.

The rules of the contest provide for penalities on account of work on the road and lateness at either of the daily controls. The points are reckoned on a basis of one for each minute spent in repairs or making adjustments for each man so engaged and also for lateness at controls a demerit is charged for each minute after the regular checking time of the car that intervenes before the car checks in. A leeway of 3 minutes is allowed at all controls. Larger penalizations are likewise levied for certain kinds of repair work.

SUMMARY OF 2 DAYS OF CHICAGO MOTOR CLUB RELIABILITY

No.	Car	Driver	Penalties 1st day	Penalties 2d day
1	Velie	John Brolley	0	2
2	Case	J. Hanson	0	0
3	Staver	E. Knudson	0	8
4	Staver	G. Monkmier	0	0
5	Bergdoll	A. Monson	0	161

Ford Wins Iowa Run Driven By Its Owner

Final Scores Not Announced, But Paige, Chalmers and Warren Are Placed First In the Various Classes

DES MOINES, IA., Oct. 21—The fourth annual Little Glidden tour of the Iowa Automobile Association which closed Saturday night after an 850-mile circuit over Iowa, was won by a Ford roadster, owned and driven by Dr. R. W. Soper, of Luther, Ia. The Ford won, in addition to the sweepstakes cup, the first prize for cars selling at $800 and less. The other prize winners and their classes were as follows: $800 to $1,200 cars, Paige; $1,200 to $1,600, Chalmers; $1,600, Warren.

No scores were announced by the referee but it is shown that the Ford came through with an almost perfect score. The only penalty imposed was caused by faulty gasoline which caused Dr. Soper to stop his motor. Penalties inflicted by Referee C. A. Knedler, of the American Automobile Association, were for time on magneto, time on steering gear, time on gasoline tanks and time on tires.

The Paige, winner in its class, was the same car and driver which recently finished well in the Buffalo run. The Chalmers winner was a 1909 veteran, driven by August Gronau, of Des Moines.

Postponements and fear of the weather so late in the season kept down the number of entries materially but outside of this feature the run was by far the most satisfactory ever pulled off in Iowa. Never before have Iowa towns along the route of an endurance run gone to such arrangements to provide entertainment and comfort for the contestants. All the towns and many of the farm houses along the route were decorated and the roads had all been dragged so that for the most part they were as level as a floor.

The White Pole Association, which is the good roads association back of the route from Des Moines to Council Bluffs by way of De Soto, gave the tourists probably the warmest reception of any received. The White Pole enthusiasts had provided a loving cup as one of the prizes and for this reason took unusual interest in the run. Many of the automobile owners along this road met the contestants at De Soto and went through all the way to Council Bluffs, which was the first night control. The second day out, the run traveled from Council Bluffs to Sioux City, following the west bank of the Missouri River. The third day brought the tourists into Ft. Dodge for the night control. Waterloo was the noon control on the fourth day; the motorists there met the tourists and a 2-hour stop was made while Waterloo and Waverly enthusiasts gave the visitors a banquet. Cedar Rapids was reached in plenty of time for the night control.

The final day gave the contestants a 200-mile drive into Des Moines by way of Oskaloosa, and the east branch of the White Pole road. The last car had checked in at 5.10.

The object of the Iowa reliability run is largely to create interest in good roads and the run this year certainly had proof of the fact that the Hawkeye state is a leader in the good roads movement. Almost every town along the 850-mile route has some sort of a good roads organization and many of these associations had provided some kind of a showing for the benefit of the contesting cars.

Blue Book Tourist Back at Denver

DENVER, COLO., Oct. 19—Trail-blazers who set out to secure data on the Denver-Salt Lake route in particular and Colorado roads in general, returned to Denver this evening after having covered 1,300 miles in a White six-cylinder car furnished by the White company, of Cleveland, for this particular expedition, which was carried out under the direction of the Official Automobile Blue Book. In the party were John P. Dods, of the Blue Book; Nathan Lazarnick, the New York photographer; James A. Harris, advertising manager of the White company, and D. Walter Rheineck, also a White man.

The party left here October 7 with the intention of laying out an official route to Salt Lake City, but after reaching Grand Junction, Colo., plans were changed and the return to Denver was made over the Rainbow route to Pueblo. The change in plans was brought about by the discovery that the Utah people have not completed their road work. They evidently have failed to realize the importance of improving the trail, so after a short trip into Utah out of Grand Junction, Dods and his party decided not to go to Salt Lake, delaying the routing of this stretch for another month, when it is the intention to send out another Blue Book car and secure all the necessary data to make the route complete.

On the outgoing journey the White six poked its nose along a trail that led through Buena Vista, Leadville, Wolcott, and Glenwood Springs to Grand Junction, a distance of 365 miles. Then, upon finding that Utah was not ready, the return trip was started, going through Gunnison, Salida, Canyon City to Pueblo, from which point the party went north to Denver, the distance on the return leg being 300 miles. In addition to the main expedition Dods covered several other stretches that connected with the main line, collecting road data.

"We took 450 photographs on the trip," said pathfinder Dods upon the completion of the trip. "When we reached Grand Junction we went out into Utah a few miles to find that no work had been done in the desert and that heavy rains had made the roads bad. On consultation with the Grand Junction people we decided to defer the rest of the routing for a month.

"On our way back to Denver we saw some wonderful sights. We saw the Black canyon of the Gunnison from the cliff road, 2,000 feet up. The new road over the black mesa was not completed and we had to use the old road, which has dangerous, sharp turns on a 28 per cent. up grade. It took us 4 hours to get up 5 miles, a rise of from 1,600 feet to an altitude of 10,500 feet. It's a wonderful country."

Stutz Wins Feature at Narberth

PHILADELPHIA, PA., Oct. 19—As an additional feature to the getaway day attractions of the Inter-County Fair, which has been in progress throughout the past week at the Belmont race track, Narberth, a series of automobile races was conducted this afternoon with several well-known local motorists as the contestants.

In a 50-mile free-for-all race the Stutz car, S. R. Blockson driving, romped away with the honors from a field of six cars, the event being declared finished at the conclusion of 48 miles owing to the withdrawal of all the other contestants but one, which car was too far behind at the time to figure. Time for the 48 miles, 45 minutes. The track was in excellent condition and the attendance was large. The time made in the feature race was considered remarkably fast.

Richmond Show to Be in Horse Arena

RICHMOND, VA., Oct. 21—The Horse Show building has been secured by the Richmond Automobile Dealers' Association for their first automobile show, which will be held February 16-23. The sum of $10,000 will be expended in putting on the exhibition, which promises to be one of the greatest events of the kind ever held in the South. There is a total floor space of 13,000 square feet and up to date there remains but about 2,000 square feet to be allotted, with quite a number of local dealers and accessories firms to hear from.

Thomas B. Hutchinson, of Nw York, is general manager of the association.

Mason Racer Analyzed

Winning Car in Two Milwaukee Races Photographed Immediately After Contests—Details of Motor and Chassis

Lubrication of Motor and Carbureter Details of Special Interest—Novel Valve Operation Used

NOW that the 1912 racing season has come to a close, it is time to compare notes. The American cars which have competed in the big events of the year have acquitted themselves most creditably. They have all shown themselves to be mechanisms of stamina of which we may well be proud.

In the small car races which have been held in conjunction with all the big racing meets this year, the Mason machines have excited much interest for their consistent performances. Early they began to get a name for themselves at the Algonquin hill-climb, in which they were the runners-up, winning in their classes; later at Galveston and Elgin they carried off the small-car honors, which their most recent achievements have been the winning of the Pabst and the Wisconsin Motor trophies races, held in connection with the Milwaukee program.

"What is there to these cars which causes them to perform so well?" was asked.

There are several things which help to make a good car, and one of these is undoubtedly the motor. The Mason Special motor is of peculiar construction and is exclusively the design of F. S. Duesenberg and his brother. The engine involves a number of principles upon which patents have been applied for. The most important are those which relate to the valve and rocker arm construction and to the method of oiling these.

The car in which Mortimer Roberts won the Pabst race is illustrated herewith. Perhaps the keynote of the success of this car, and the others of the Mason team this year, was struck by Mr. Duesenberg when he stated that "the machines are not built for extreme speed, but rather for durability under extreme conditions."

The motor is suspended from the frame at three points, the front support providing a swivel, allowing the engine to adjust itself to unequal road conditions, without strain.

The cylinder casting is a monobloc type, and the crankcase is made in one piece. The crankshaft is easily reached through the large opening, Fig. 10, and has two bearings, whereas the camshaft has three.

An idea of the overall dimensions of the motor may be gained from the monobloc cylinder casting dimensions. The length of this casting is 18.5 inches; the height 14 inches; and the width 6 inches; it being faced on top, both sides and bottom, the latter where it rests on the crankcase, and the other three facings to receive the water-jacket plates.

Looking at the two right side views, Figs. 1 and 2, of the motor as it appears in Roberts' car, the gases exhaust through the top of the hood, the four vertical pipes conducting them outside. Such a means of getting rid of the exhaust makes for least resistance to the outward flow. In Fig. 2 the extreme simplicity of construction is brought about through the use of the cover plate P completely inclosing the valve mechanism, and excluding all foreign matter and making possible the peculiar oiling of the valves and their parts, which is to be a patented feature.

Figs. 6 and 7, of the left side of the Duesenberg motor, show the two sets of spark-plugs arranged horizontally. The large diameter water connections are also illustrated.

The waterjackets deserve mention, as the cylinder casting is found open on both sides, and on the top. The left side open space is covered by the aluminum plate of which the inlet water connection WC, Fig. 7, is a part. The plate WP on the right

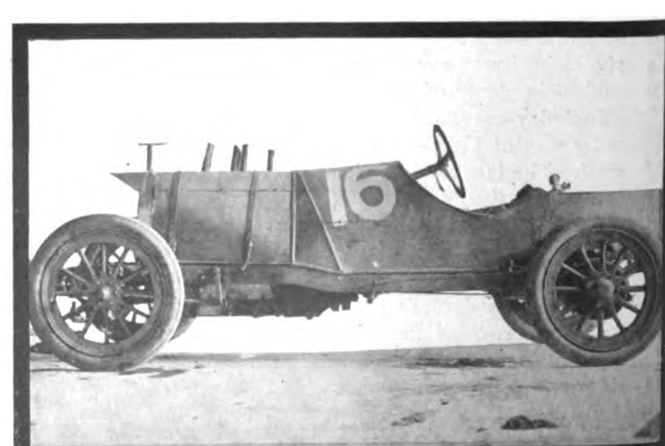

Fig. 3—Mason Special racer which won the Pabst Milwaukee trophy, showing vertical exhaust pipes in top of hood

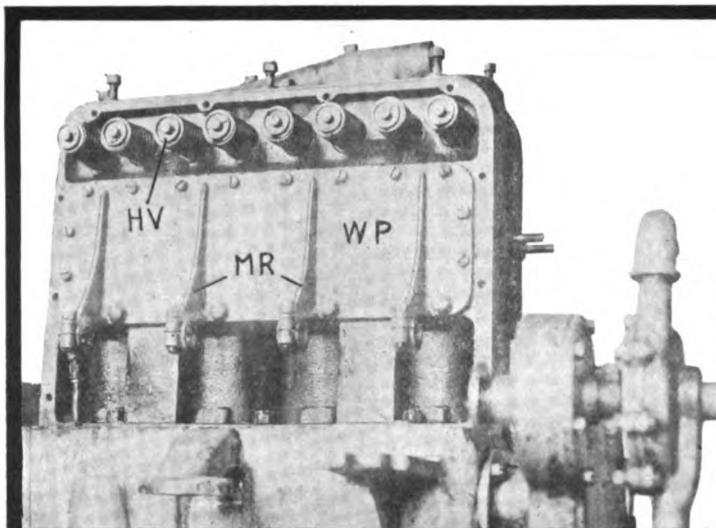

Fig. 4—Right side of Duesenberg-Mason motor, with cover plate P, Fig. 2, removed, and showing plate WP forming the side of the water-jacket, and having bearings MR for the shaft carrying the valve rockers shown in Fig. 5

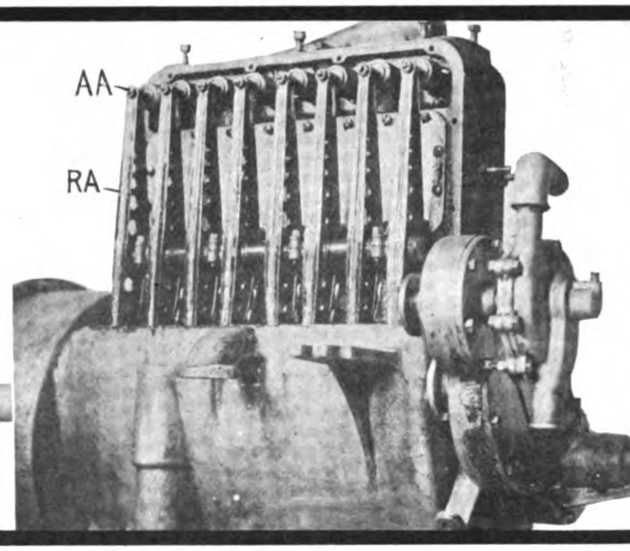

Fig. 5—Right side of motor, showing long valve rockers RA, the lower ends of which bear on the cams and the upper ends on the valve stems. Adjustments AA in the upper ends make provisions for wear and necessary valve timing

side, Fig. 4, carries the four supports MR for the rocker arm shaft. The top jacket opening is covered by the plate which also forms the water outlet manifold to the radiator.

The motor has a bore of 3.875 inches, and the long stroke of 5 inches, giving a bore-stroke ratio of 1:1.29. The valves are placed horizontally, opening directly into the explosion chambers, thereby eliminating valve pockets. The inlets have a diameter of 1.875 inches, and the exhausts are .0625 inch less. The lift of both is .34375 inch. In placing the valves horizontally over the cylinder heads, the designer's idea was not only to reduce the wall area of the combustion chamber, but to put the exhaust openings in such a position that the burnt gases would have a very much freer exit than could be obtained by any other arrangement.

On the opposite side from the valves, plugs are placed, Fig. 6, in the centers of which the spark-plugs are located. These plugs or valve caps make it possible to inspect the cylinder heads and the piston faces and to remove carbon therefrom.

The valves are of the conventional poppet variety with a 30-degree bevel. The stems are 5 inches in length and .4375 inch in diameter. The stems are of carbon steel electrically welded to the 3.5 per cent. nickel steel heads. The ordinary type of coil spring serves to close them, but opening is accomplished through the use of long rocker arms, Fig. 4. The lower ends of these rockers rest against the cams, which are an integral part of the camshaft, and the upper ends are in contact with the ends of the valve stems. These ends are provided with adjustments which allow for taking up of wear, and for fixing the clearance between stems and arms.

The contact points of the rocker arms are hardened. These arms have a length of 14 inches. The distance from the point of cam contact to the center of the arm pivot is 6 inches, while from the rocker shaft to the valves is 8 inches. This greater length above the rocker shaft gives quicker cam than valve action, making for quiet cams.

The peculiar piston construction is illustrated in Figs. 8 and 10. There are three piston rings which are placed in each groove. One is twice as wide as the other two, and is placed inside the two narrower ones. The ring joints are beveled. The pistons have a length of 4 1-2 inches, only 3 1-4 inches of which length is in contact with the cylinder walls, the center being a broad shallow groove, done to decrease the wear, and to aid in oil distribution. The pistons are of gray cast iron; the cylinders of cast iron; the connecting-rods of carbon steel.

Another peculiarity is the method of conveying the explosive mixture to the intake valves. Looking at the views which show the valve side of the motor, Figs. 8 and 9, the inlet N is integral with the crankcase, and the inlet passages are cast as a

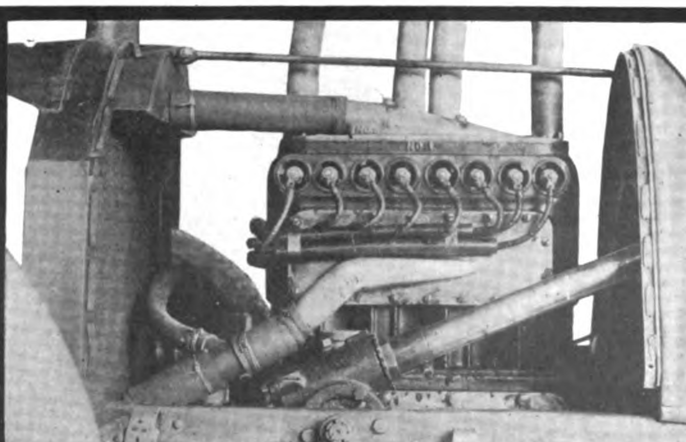

Fig. 6—Left side of Duesenberg-Mason motor, showing spark plugs mounted horizontally in plugs in the sides of the combustion chambers. The large water connection pipes appear

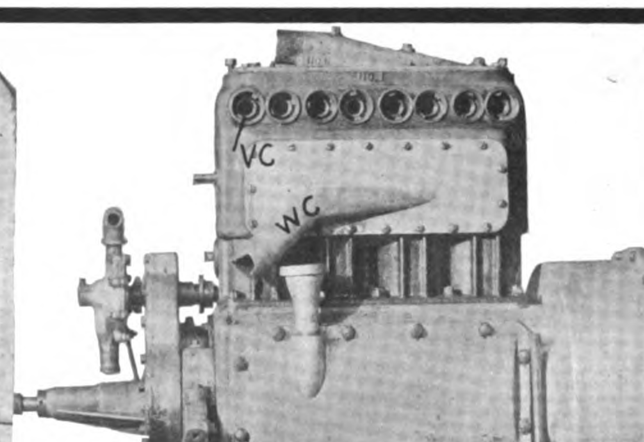

Fig. 7—Left side of motor removed from chassis of Robertson's car after the Pabst race. The large crankcase inspection plate is shown with its oil filler

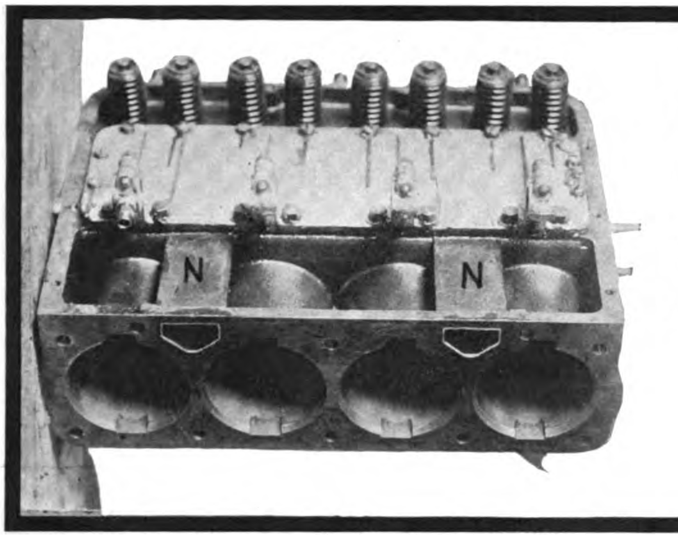

Fig. 8—Duesenberg-Mason motor with intake passages N which connect with the integral manifold in the crankcase and deliver direct to the cylinders. These passages register with openings N in the crankcase, Fig. 9

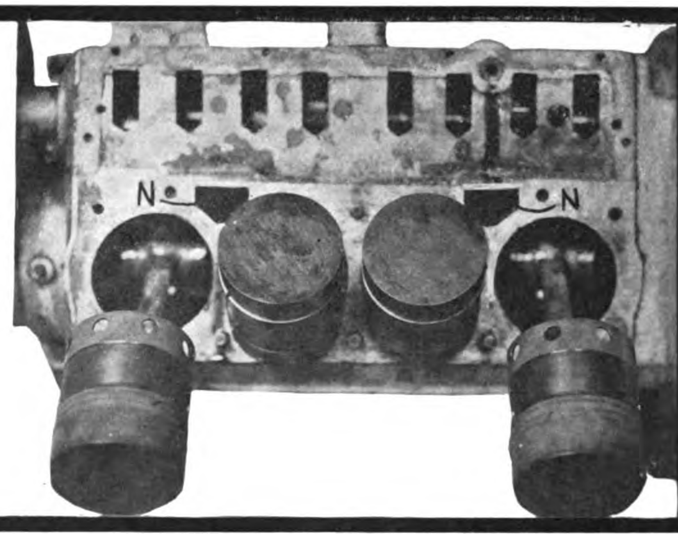

Fig. 9—Details of pistons in motor, showing recesses in central portion, perforations at lower ends and the use of two rings, each of which is a compound one made up of one full-width outer ring and two narrow inner rings side by side

part of the crankcase, and pass from them into other passages cast integrally with the cylinder casting. Part of the cylinder passages are seen at N. After entering the crankcase at M, Fig. 2, the gas is split up into two parts, passing upward to the intakes, one integral passage going to each two cylinders, thus the gas passes back of the rocker arms, and up to the valves.

The oiling of the motor is interesting. The main crankshaft bearings, connecting rod bearings, and cylinders are provided with lubricant by splash from the dipping of the ends of the connecting-rods into oil troughs. There is a trough for each rod end. The oil flows into the base of the motor which has a capacity of 2 gallons. From this point it is pumped up into the hollow rocker arm shaft and to the four rocker arm shaft bearings and the bronzed-bushed rocker arm bearings. From the latter, it is forced to the cams through oil leads which pass down the rocker arms from their bearings. From the cams the lubricant flows again to the oil troughs under the connecting-rod ends, and its cycle is complete. The four troughs are provided with outlets or regulating tubes which govern the level in them. These regulating tubes are so arranged with slots that by raising or lowering them, the level of the oil may be varied from .25 inch to .75 inch. For racing purposes, the level is regulated for 1 inch.

The feature of the oiling scheme on which the patent is asked is the lubrication of the valve stems. The aluminum coverplate P, Fig. 2, is oil tight, and when the motor is running is considerable speed, the splashing of the connecting-rod ends into the troughs creates a mist of oil which rises through the slots in the top of the crankcase through which the rocker arms pass, and on up to the valve stems, lubricating them. The idea of this scheme is that wearing of the valve guides is prevented, giving the stems perfect contact with the guides. This lubrication of the stems also serves to keep the exhaust valve stems cool, preventing their becoming blue black for more than .25 inch into the valve guide when seated.

Passing from the power plant to the transmission system and running gear, the gearset has three forward speeds, and is mounted at the rear axle, being contained in a special case bolted to the axle housing. The gear ratio is 2.6 to 1. The differential carriers are a part of this case. Special axle shafts are used, the flanges which bolt to the rear wheels being integral with these shafts, F, Fig. 12. This was done with the idea of increasing the strength, thus increasing the factor of safety for high-speed work. The axle shaft flanges F have nothing to do with the holding of the wheels in place, their function being simply to drive.

The propeller shaft is inclosed within a torque tube the rear end of which bolts to the forward end of the gear-box. Two radius rods extend from the front end of the torque tube to the axle housing, in the conventional way.

The front axle, an I-beam type, has a 3 1-2-inch central drop. Front springs are half-elliptic; rear, elliptic. The frame has a 2-inch drop at the dash, and 4.5-inch drop at the rear. Its rear width is 34 inches, and it narrows to 30 inches in front.

The car carries 32 by 3.5 inch tires. Its wheelbase is 104 inches, and its weight about 2,000 pounds.

—

In cases where it is desired to attach rubber to metals, this end may be obtained in the following simple manner, given in *Brass World*. To prepare the metal for the securing to it of rubber, it is first electroplated in a suitably concocted solution. The latter, proposed by Leo Daft, Rutherford, N. J., is composed of water and copper, zinc and antimony salts mixed in respective proportions of 60 to 38 to 2. To obtain the salt, the metals are mixed in the given proportions by weight, dissolved in nitric acid and precipitated by a sodium carbonate solution, after which they are redissolved in cyanide. The metal to be plated serves as cathode, while a piece of alloy in the given proportions of the three metals named is the anode. After the metal has been electroplated, the rubber is vulcanized in place.

M. A. D. A. Holds Up Cash Prize to Bragg

Milwaukeeans Refuse To Settle Until Driver Pays Entry Fee—Loss at Meet $43,000—Bank Account Attached

MILWAUKEE, WIS., Oct. 21—Bart J. Ruddle, manager of the recent Milwaukee road race, said today, that the M. A. D. A. refuses absolutely to turn over to Caleb S. Bragg the $5,000 in gold offered as first prize in the Grand Prize contest, until such a time as Mr. Bragg pays in cold cash the balance of the entry fee of $1,000, upon which he has made a deposit of only $125 and there is still due $875. Bragg claims he will refuse payment of this fee because no fee was exacted from David L. Bruce-Brown, now dead, and Manager Ruddle declares that this is a poor subterfuge.

The M. A. D. A. lost approximately $43,000 on the speed carnival, and its officers regret deeply that the association's poor position should be taken advantage of by two of the participants, Bragg being one and Ernie Moross being the other. Moross late last week filed a claim for expenses for 14 days for himself, Burman, Horan, Decourcey and Toney, but payment was immediately refused because the Moross outfit played 1 day stands in Pittsburgh, St. Louis and other cities during the time it charged for expenses at Milwaukee. Moross also filed a protest against the award of fifth place in the Grand Prix to George Clark's Mercedes, because he claims Burman was running as well as Clark when the race was called off. It develops from this claim that no fifth place was awarded, Referee A. R. Pardington having placed only four cars which actually finished the race. The M. A. D. A. did, however, make a gift of $500, equal to the fifth place prize, to Clark, who was 40 miles ahead of Burman when the race was called.

The expenses of the meet were approximately $118,000 and the total receipts only $75,000. While no financial statement will be issued to the public, for the reason that the affair is a private matter of the association, it is stated that the principal expense was the construction of the course, upon which $55,000 was expended. The prize list amounted to $20,500, which added to the road expense equals the total revenue.

A garnishee of about $375 placed on the bank account of the M. A. D. A. several days after the races has caused considerable inconvenience, but President Isaac G. Hickman says he is confident that this will be only temporary and the embargo will be lifted before the end of the week. The garnishee served to delay payment of a number of checks, among them that of Starter Fred J. Wagner, whom Manager Ruddle wired on Friday to be patient until early this week, when the matter will be cleared up.

"No one will lose a cent, though our deficit is enormous," said Manager Ruddle. "We are going to pay penny for penny, and what is more, we are going to have the international cup races in Milwaukee in 1913. The matter of financing the deficit is well under way and it will be a matter of only a week or so before we will be able to liquidate every debt contracted legally."

Manager Ruddle will go to New York late this or early next week to make preliminary arrangements for the running of the big cup races on the Wauwatosa course next summer.

Outside of the expenditure of $10,000 by the M. A. D. A. for improving the course for next year, Milwaukee county will put $60,000 into one road forming the course early in the spring. This work will consist of paving the North Fond du Lac road from the city limits to the Town line road with concrete having a roadbed of 25 feet. The work will be started April 1 at the latest and be ready by June 15 or July 1.

It will be news to some people that the proposed improvement of North Fondy road was to have been done this year, and in time for the running of the cup races, but because no assurances could be given by County Highway Commissioner H. J. Kuelling, that the stretch would positively be ready by Sept. 10, the M. A. D. A. requested that the work be held off until the spring of next year.

Ralph De Palma, who was seriously hurt in a collision with Caleb Bragg's Fiat in the last lap of the Grand Prix, is driving a wheeled chair around Trinity hospital and the neighborhood these days. He made his first public appearance on Saturday night, when he wheeled himself into the banquet hall.

ENGINE DIMENSIONS OF THE MASON SPECIAL

Crankshaft bearings:
- Front—1.875 inches diameter; 4 inches length.
- Rear—1.875 inches diameter; 4½ inches length.

Camshaft bearings:
- Front—1.125 inches diameter; 4 inches length.
- Center and Rear—1.125 inches diameter; 2 inches length.

Connecting-rod lower bearings—2 inches diameter; 2¼ inches length.
Wristpin bearings—1.125 inches diameter; 2.625 inches length.
Jacket space—.375 inch thick.
Cylinder, and jacket walls—.25 to .3125 inch thick.
Connecting-rod length, center to center, 10.1875 inches.
Length of pistons—4.75 inches.
Piston rings (three of bull-ring type)—inside ring .625 inch wide; outer rings .3125 inch wide.
Flywheel—15.25 inches diameter; weight 60 pounds.
Crankcase opening—5.5 by 16 inches.
Horsepower—58 at 2300 revolutions per minute.
Bore—3.875 inches.
Stroke—5 inches.

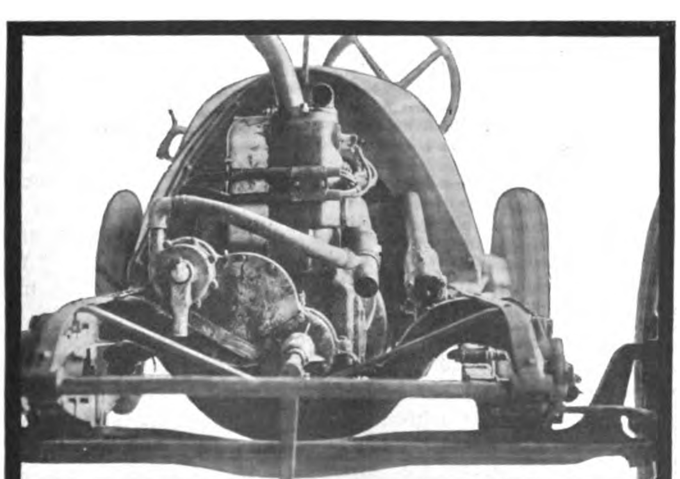

Fig. 11—Front view of Duesenberg-Mason motor with radiator removed. The waterpump location is shown, and also the water intake pipe connections

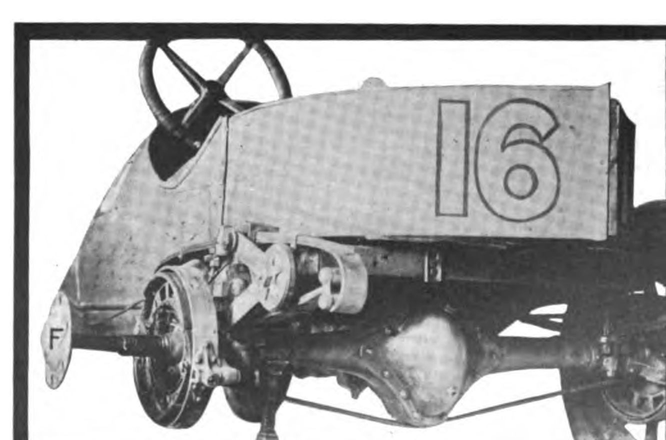

Fig. 12—Rear axle details of Mason racer with axle drive shaft withdrawn, showing integral, drive shaft flange F, which simply drives the wheel

Cadillac Coupé Design

—

Three-Passenger Design for 1911 Cadillac Runabout for $1200—Drawings To Scales Shown

—

By GEORGE J. MERCER.

NOW that the approach of winter is in sight, car owners who are not already provided for are busy with ideas as to the best method to pursue to make the machine comfortable for use during the cold weather. The question of the cost of a new body or the cost of alterations to the old body and other expenses that a new body design may bring about, such as larger tires, new rear mudguards, changing the dash and gasoline tank, repainting the chassis, etc., resolves itself into these expenses being added up and balanced against what would be a fair increased valuation of the car as a finality. In other words, the business proposition is: If money is to be spent on a new body to be used on an old chassis, how much money should be spent to make the investment profitable?

The present market price of the car, the use and the treatment that the machine has received, which, of course, determines its present usefulness, and the plans of the owner regarding the style of body required, all tend to make the query one that must be answered individually. Therefore, it is proposed to give several successive body designs of coupés and shown on as many different makes of cars. Most of these cars will be of a uniform size that will permit of many of the designs of bodies being transposed to another make of car than the one selected.

The immediate subject in hand, however, and the idea to which this article will be confined, is the description of a coupé body design that is shown mounted on a 1911 Cadillac runabout chassis. This body design has several distinctive features that will be taken up and described in detail as the article progresses, and an early model of the Cadillac car has been chosen because the visible features are not radically different from the latest model. Also, this article is intended to assist the owner who will be most appreciative, and to assist him in making something that is old look like new is consistent with this intent.

The features to be considered when rehabilitating a car of an earlier model are: First, the general condition of the motor, springs, tires, etc., and assuming that these are fairly good, the next step is the consideration of the new parts that are to be added. This model is made to take a coupé body and is so specified in the maker's catalogue, therefore the springs and tires are ample, as the design of body here illustrated is very light and will weigh, when finished, about 550 pounds.

The new parts added to the chassis are the mudguards, front and rear, and a new design of hood. It can be assumed that any car that has been in use for two seasons will have guards and hood that show service, and the replacing of these parts is a cost that can in part be charged up to depreciation. Especially is this true of the guards.

The positions of the gear change and brake levers, the foot pedal and the steering wheel remain normal. The gasoline tank wil require to be shifted toward the rear on account of the seating arrangement. It is moved back about 6 inches or until the seat covers it, or it can be placed in the rear compartment back of the body. The old dash can be made over to the shape of the cowl, provided it is not needed for use when the summer body is replaced. In this instance it will be best to use a new dashboard, and cheaper wood can be used that is customary, because it will be out of sight at all times.

One of the essentials of a body design for a pleasure car is that it be so constructed as to fulfil the requirements specified for the comfort of the users.

A design of body that is intended for use in winter is naturally made heavier than one intended for summer. It must protect the occupant from cold and storm and therefore it is closed in with a permanent and substantial framework and panelling. The proportions inside should be ample and yet no room wasted, and the exterior proportions must not be ungainly.

Common custom has established proportions for the interiors of closed bodies, and these proportions are suitable for the majority of normal persons. The design shown herewith is made in accordance with this rule, and Figs. 1 and 2 show the dimensions for head room and seating arrangements.

This coupé body is designed to carry three people inside, all seats facing forward and each seat is individual, this being accomplished by offsetting the seats as illustrated on the plan view, Fig. 2. The body is made as wide as an ordinary limousine, or 58 inches overall, measured across the widest part, but the taper toward the back and front, as illustrated in the plan, Fig. 3, is sufficient to prevent a bulky end appearance. The extra width in the center of the body is necessary, because the steering wheel in the standard car is so positioned that the seat for the driver must be placed with the inside of the seat approximately in the center of the car, and he occupies the whole right half of the body, however wide it may be. In this case the driver's seat is placed 3 inches toward the right side from the center. The seat on the left side, which is a counterpart of the driving seat, is placed with a space of 10.5 inches between, and this is the width allowed for the knees of the person seated in the middle. This latter seat is set back 7.5 inches and the width necessary for comfortable seating is gained by this offsetting back of the middle seat. The width of the seat-room allowed is 18.5 inches for the driving seat and 17 inches for the other two. The depth is ample to allow of thick upholstery at the back and the seat cushions slope toward the back, the thickness of the forward seat cushion being 5 inches and of the middle seat 8 inches. Extra room on the right side of the driving seat provides ample working space for the change and brake levers, and the entrance to the car on the right side is fairly comfortable, only the levers presenting some difficulties.

A further general description of the interior measurements shows that the head-room allowed over the cushion is 40 inches. This is maximum height for average people, but as the stretch for the limbs is also maximum, the forward seat being back 30 inches from the dash, the height from the top of the cushion to the floor has been made only 15 inches, or 2 inches less than regular. This is a gain of 1 inch off the total height of the body and helps to give a low, rakish appearance. Of course, the arched roof contributes to the low effect. With this the maximum height is obtained at the entrance and the contour of the roof follows a line that approximates the slanting line of the top of the seat cushion.

The windows are a part of the body that require space inside for pockets or grooves to receive them when lowered. On this body design the maximum room inside is required for seating, so the windows are lowered only part way. Line A-A, Fig. 1, shows these side windows in the lowered position. The frameless glass for windows is used on both sides and back, while at the front the glass is bound with a wood or metal frame and made to swing outward as a visor in the customary manner. The method of using the frameless glass has been described in a previous issue of THE AUTOMOBILE and will not be repeated at this time. In regard to its use, there are several good points in its favor, one being that the body is made to look very much lighter. Also, if a good workmanship job is made of assembling the glass into the body, they should last longer and look better when old than those with wood frames, because these latter depreciate quickly. It is no doubt possible to provide for and make tight against the entrance of rain, but this up to the present time is largely an experiment. The appearance of the frameless glass is so striking, however, that it is bound to come into public favor. The glass at the rear of the body is stationary and the front glass is made to swing as previously mentioned.

The lines of a body design that give it a distinctive character and make it stand out as individual are those that depart from the straight horizontals and perpendiculars. There are always enough of these foundation lines in evidence, and, while it is not an absolute rule, nevertheless it is a very general one, that a body line is improved from an artistic point of view whenever it deviates from the direction of these two standards.

A very good illustration of this is the ready acceptance by the public of the sloping hood, as illustrated in Fig. 1. This line is not only more pleasing to look at than the one generally used,

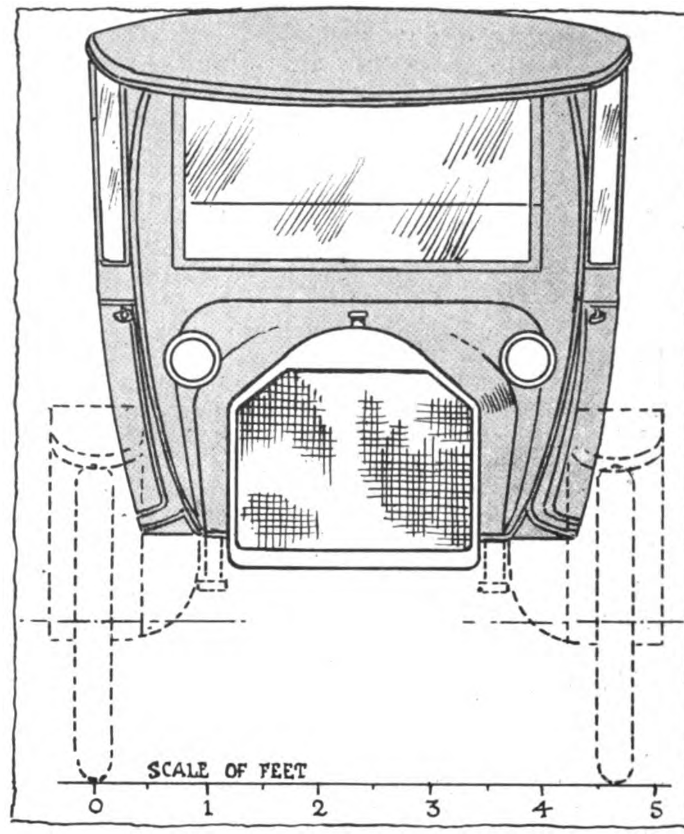

Fig. 3—Front view of Cadillac coupé design

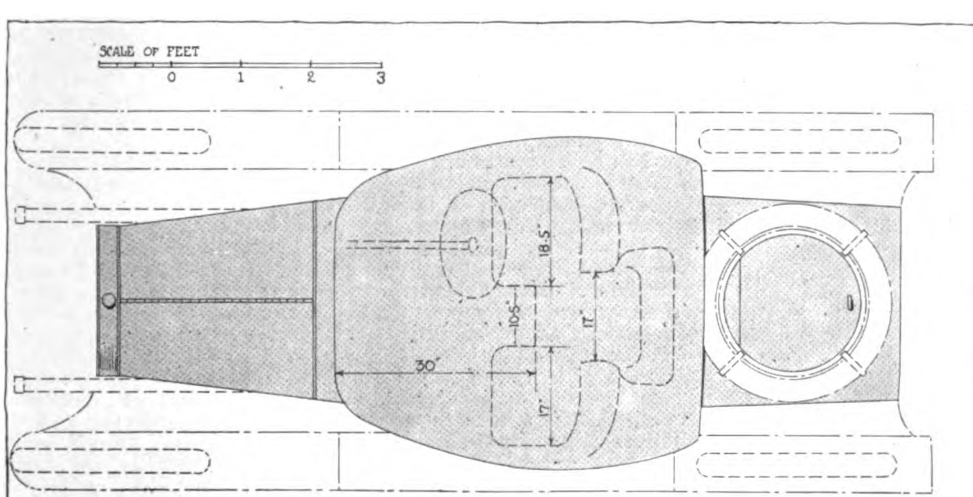

Fig. 2—Seating plan of suggested Cadillac coupé

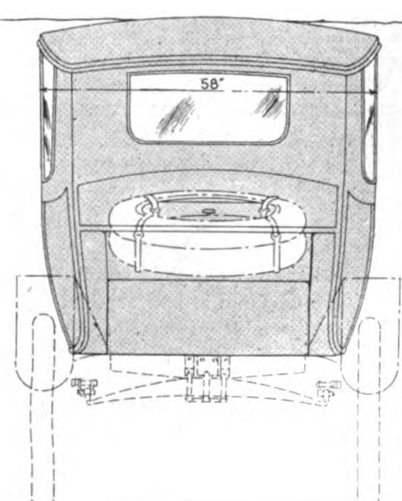

Fig. 4—Rear view of coupé

but it serves the additional purpose of making possible the elimination of the wood dash from sight and decreasing by so much the wind-resisting surface.

With the design as illustrated the upward line of the hood is continued beyond the dash and, to the body proper, this cowl is quite long, because the runabout steering wheel column is long and the body is placed back to accommodate this. If the touring car chassis, which has a shorter column, is used, the cowl will be proportionately shorter. In the sides of the cowl are recesses to receive electric dash lamps, which are of the standard pattern in general use and, together with the dome lamp in the roof of the body, are supplied from a battery located under the seat, the installing and wiring being attended to at the time the body is made.

Attention having been given to the general description of most of the body parts except the rear compartment, it can be briefly summarized as having a carrying space of 38 inches long with an average height of 12 inches and a width of 30 inches. It serves the purpose of a general catch-all and, as in the case illustrated, it may be made tight against rain and water from the washer. Moreover, it may be locked, so that it should be useful and safe to carry all that the owner desires. The top is made strong to carry two tires and the door for entrance is made within the space of the rim. Individual requirements will take up the details of this part, as it may be made in any form that the owner desires.

The question of cost depends to a large extent upon the method of construction, style of trimming, appointments, etc.

The body as designed has the lower panels and the cowl and rear compartment of metal, either steel or aluminum; the framing of good ash; the upper panels of .375-inch whitewood, and the roof of laminated whitewood, with .25-inch plate-glass windows, electric dash and dome lights and battery under the seat. A choice of trimming materials in broadcloths or cords may be made from the best sample books, a choice of style of trimming, with pockets, silk curtains and toilet case to match, choice of carpet rug, a good, common-sense finish and method of workmanship throughout.

Painting the body and mounting on the chassis should cost approximately $1,200. Additional charge for new mud guards and new hood and painting the chassis would amount to approximately $200. Tire holders of a simple pattern should be furnished with the body without additional charge.

This approximate expense of $1,400 has to be mentally balanced against the possible extra service that the car will give, if it is so equipped. Is the car worth this added expense if sold in the open market? This and other questions will have to be answered individually. The field is a large one and this is presented as one of the possibilities. The design of body is sensible; it is roomy, and if built by a reputable builder it will wear well and give service for a long time, because the weight is under the average. As the design is well in advance of the general style it will even up until it is worn out.

The most appropriate colors for a design as illustrated will be either a dark green or blue with the trimming either of a shade to match or a decided contrast and much lighter. The silk curtains and the carpet should always match the cloth. This question of trimming and the colors for the painting are best selected from samples, which any bodybuilder could supply. The principal task is the decision of a suitable body design, and the one here presented is suitable for almost any car having a wheelbase of from 110 to 125 inches. Each seat being individual the car is capable of accommodating three people comfortably, thereby avoiding the unpleasant crowding of three people on one seat. A roomy carry-all is arranged on the space behind the body. The front need not be made with a sloped hood if the extra expense is a consideration. Having decided on a body design, close figuring can be used to trim out the fancy features, and while the body will not be as good as if more money was spent on it, nevertheless a great deal can be accomplished with a little money if the buyer is in earnest.

Progress in Automobilism

English Engineer Reviews Advances of the Year—Paraffin as a Fuel, Quietness, Lubrication and Cleanliness Featured

Extracts from Address of President T. B. Browne Before Institution of Automobile Engineers in England

IN London alone there were licensed during the year ending August 31 last 2,510 motor omnibuses as against only 533 drawn by horses; the number of motor cabs licensed for the same period was 7,860 with only 672 hansoms and 1,982 four-wheeled horse cabs.

That the cost of running commercial motor vehicles is being continually reduced, especially where efficient organization exists for their maintenance in large numbers, is shown by the fact that one of the largest motor omnibus companies has now reduced its running costs to about 15 cents per car mile, whereas when I read a paper on the subject of running costs before this Institution in February, 1910, the equivalent figure was about 18 cents, so that the motor omnibus is now in a better position to prove a very formidable competitor to the electric tramcar.

It is very difficult to arrive at an exact estimate as to the number of motor vehicles running in this country, as there is at present no arrangement made for striking off the register those vehicles which are worn out, destroyed by fire, etc., but the total numbers registered for Great Britain and Ireland have been given as follows:

November, 1910	Motor cars	124,860
	Heavy motor vehicles	7,406
November, 1911	Motor cars	150,697
	Heavy motor vehicles	9,195

As nearly a year has elapsed since the last figures, the approximate number of registrations at the present time might be estimated as follows:

Motor cars	170,000
Heavy motor vehicles	12,000

Excellent results have so far been obtainable with paraffin with engines running on steady loads, but the extremely irregular load of an automobile engine has so far proved a serious obstacle to the proper carburetion of paraffin and the heavier oils. There is also the possibility that the price of any substitute will rise as soon as the demand for it becomes great, just as has been the case with the price of the heavy oil used in the Diesel engine, which was sold not so long ago at 38s., or $9.50 per ton, whereas it has now risen to over $20 per ton. However, it cannot be gainsaid that the whole question is one of supply and demand, and therefore the greater the number of satisfactory substitutes for petrol that are found the lower the price is likely to be. The enormous increase in the number of commercial motor vehicles that we are about to witness should not tend to raise the price of petrol for pleasure cars, if we are able to use a heavier oil as a fuel for the propulsion of the former. Petrol is distilled off the crude oil at temperatures ranging from 50 deg. C. to 150 deg. C., but if we can use an oil distilled off at a temperature range of from 50 deg. C. to 200 deg. C. the supply would be increased threefold; so that it can readily be perceived how this would affect the price of the fuel to the consumer.

No serious attempt to use the Diesel principle for automobile propulsion has yet been made, and there are, of course, considerable difficulties in the way which must be overcome before it can be successfully applied.

In the first place, with the comparatively small powers required, it would be very difficult to reduce the weight sufficiently to enable it to compare favorably with the petrol motor, and the mechanical efficiency of these small sizes would in all probability be rather low. Then, again, great difficulty would be found in applying it to the irregular loads and speeds of an automobile, so that much experimental work would have to be done before success could be expected. The success which has resulted with the use of Diesel engines on ships where these objections do not apply can, therefore, be no guide as to its suitability for automobile work.

The use of solid fuel in the shape of carbon has been proposed for automobiles, and at least one vehicle has been built with a suction gas producer. This would have to be designed on much lighter lines, and of smaller dimensions, than those at present used so successfully and economically with stationary gas engines, but those who have made a special study of this system, and who are therefore qualified to know, have stated their opinion that it should be quite practicable to bring the dimensions and weight of the apparatus down to the required limits without impairing its efficiency, so that the subject is well worth the consideration of designers, at all events for the heavier types of motor vehicles, though difficulties will probably occur in regulating the gas supply to suit the irregular load experienced with an automobile.

At the recent meeting of the British Association some of the papers read were of the greatest interest to automobile engineers, and I might specially refer to those read by one of our past presidents, Dr. Dugald Clerk, F.R.S., on the subject of gaseous explosions and internal combustion turbines.

The interesting point with reference to explosions brought out was the difference in the time taken to explode a gas when in a state of turbulence, and when in a state of comparative rest. In the experiments quoted a fan was used to create a turbulence in a 10 per cent. mixture of coal gas and air, with a result that the time of explosion was shortened from 0.13 seconds to 0.03 seconds when the speed was raised from 2000 to 4500 revolutions per minute.

This result accounts for the fact that it is possible to obtain satisfactory ignition with motors running at high speeds.

Perhaps the work which has been done of recent years in studying the indentations caused by phonographic records may lead us to some definition of "amount of noise," but the fact is that no one has as yet suggested a definition for a unit of either noise or smell.

The noises in the transmission gear of an automobile proceed from several sources. The most troublesome of these is undoubtedly that caused by the gear wheels of the change-speed gear. With the universal adoption of direct drive on the top gear, this can only occur when recourse is had to the lower gears, when the drive is transmitted through two pairs of spur wheels in the gear box. The introduction of ball bearings has intensified the trouble from this source, as it is well known that plain bearings do not conduct the sound emitted by the gear wheels to anything like so large an extent as ball bearings. Some experiments which I conducted with ball bearing camshafts several years ago bore this out to a surprising degree.

Another serious source of noise has been that due to the bevel gear used in the transmission. In chain-driven cars great difficulty was experienced in quieting the bevel gear owing to the comparatively high speed at which it was run. Its removal to the back axle, with the introduction of the live axle, rendered the problem not quite so difficult, but it has still been found a very serious one. **It has also been found extremely difficult to prevent the teeth of the bevel gears from warping during hardening. Here again great improvements have been made by the adoption of a process for the local hardening of the teeth, leaving the disc of the wheel soft, and by making the back axle as compact and rigid as possible.** The fact remains, however, that no spur or bevel drive in the transmission of an automobile ever gives absolute silence, although by the methods mentioned above the noise can be considerably reduced.

For this reason there is a tendency towards the adoption of worm gear, which has been delayed in many cases by the fear that this would be less efficient than the bevel gear. In some instances where it has not been carefully designed, this has certainly been so, but some recent experiments carried out in America have proved that the difference in the efficiency of the two types of gear is negligible where properly designed gears are used.

The difficulty with the splash lubrication was chiefly due to the fact that the connecting rod big ends which dipped into the oil were of such comparatively large dimensions that a slight rise in the level of the oil by reason of the tilting of the car due to a gradient or the movement of oil due to its inertia, caused a very much larger amount to be thrown up than the normal.

At last a thoroughly efficient way out of the difficulty was found, and was first tried by one of the London omnibus companies. This consisted in fitting a small vertical pipe to the lowest point of each big end, the lower end of the pipe being arranged in the form of a small scoop. The level of the oil was reduced correspondingly, so that, the orifice of the scoop being quite small, a very little extra amount of oil was splashed up by the scoop on to the sides of the cylinders if the level were temporarily increased by tilting, etc.

The oil into which the scoops dip is usually carried in small troughs situated under each scoop, so that the tilting of the engine does not materially affect the level.

This method has been found most efficient, and since its adoption the unpleasant smoke from the exhaust of automobiles has become a thing of the past.

A very great improvement has been recently made in the cleanliness of the automobile by the prevention of drippings from gear boxes and axle cases by the provision of a vent in the shape of a small aperture in the top of the case fitted with a short length of tube open to the atmosphere. It was found that the rise of temperature due to the churning of the oil often resulted in a rise of pressure in the gear case of as much as 4 pounds per square inch, which accounted for the fact that, in spite of careful provision in the shape of stuffing boxes, the oil still worked out and dripped on to the road, or found its way on to the surfaces of the brakes.

One of the chief causes of the unpleasant odors emanating from the automobile in the early days of the movement was the imperfect mixture, resulting in the products of the partial combustion, including the deadly carbon monoxide, being expelled into the atmosphere.

With modern carbureters, the variations of which are innumerable, there should be no excuse for any emission of unpleasant exhaust. At the same time it must be stated that a good many cars are run to-day with a much richer mixture than is necessary for perfect combustion. It is well known that a certain percentage of mixture too rich for perfect combustion gives slightly more power than the perfect mixture, but the gain is so slight that it is certainly not worth using for any but racing purposes, and it has the further disadvantage of increasing the tendency to carbon deposit.

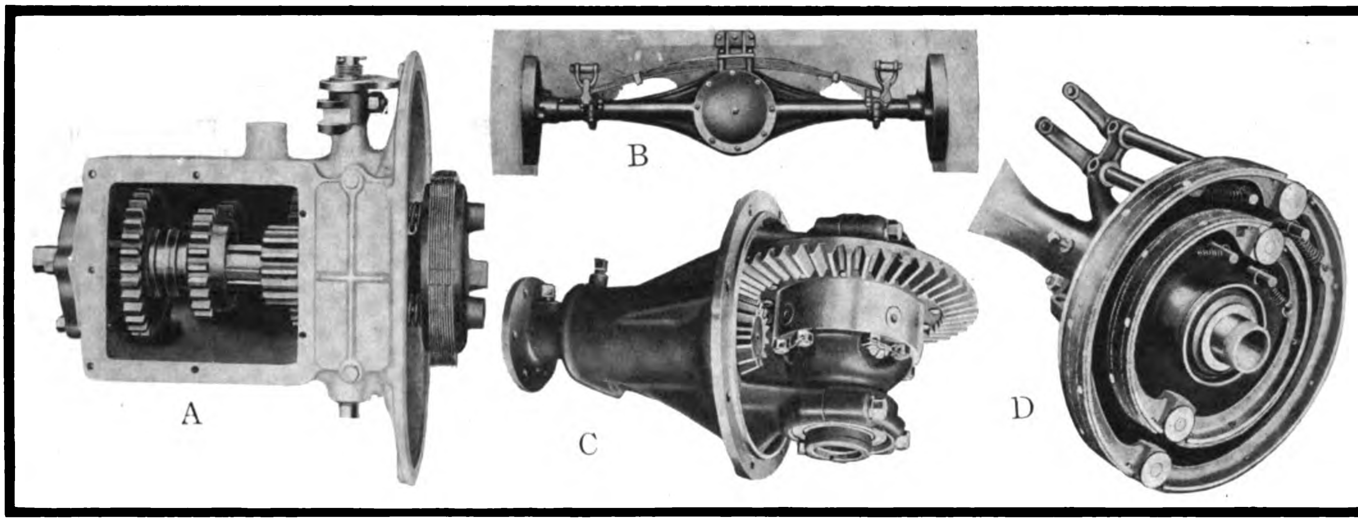
There is still, of course, room for improvement, and such parts as the tires and springs are obviously very far from having reached their final stage of development.—From *The Autocar*, October 12, 1912.

Harking Back a Decade

FROM *The Automobile and Motor Review*, October 18, 1902:

The great reliability run of the Automobile Club of America was finished at New York on Wednesday evening. There were seventy-nine entrants and sixty-five covered the route to the end. According to unofficial announcement there were twenty cars to complete the whole course without penalization. Of course, this list is subject to alteration when the judges, umpires, referees and officials have considered the results from all angles. In the honor list are four Whites, two Packards, two Grouts, two Stevens-Duryeas, two Searchmonts and one each of the following makes: Prescott, Lane, Haynes-Apperson, Knox-mobile, Stearns steamer, Oldsmobile, Fredonia and Foster. There were thirty-five different makes represented in the run. During the whole affair not a single serious accident occurred as the result of horses becoming frightened by the tourists. Entering Boston the column contained at least 300 automobiles. The run was from New York to Boston and return. The contestants were classified into three divisions according to weight in running condition without passengers. Class A was for cars under 1,000 pounds; Class B, 1,000-2,000; Class C, over 2,000 pounds. Of the clean score cars there was one in Class A; fifteen in Class B and four in Class C. There were ten steamers in the perfect score list and ten gasoline cars. Class A cars performed well, but the honors of the run went to those in the middle class. Practically all the disabling mishaps that occurred to contestants in this class were due to accidents. There was a big handicap on the heavy car class on account of the low average speed allowed by the rules. Poor workmanship and construction led to quite a number of penalties to some of the entered cars, but these were not very serious.

The new plant of the Winton Motor Carriage Company, at Cleveland, O., is located on a site of 12 acres. The four buildings, which are all of one story, cover an area of about 100,000 square feet. A feature of the building is the fact that the structural framework is raised in the center of each to provide windows and skylights from above.



F.g. 1—Gearset, axle, differential and brakes in the Detroiter car, showing principal features of each

Detroiter Embodies Latest Improvements

Left Drive, Center Control, Long-Stroke Motor, etc., Found in Product of 2-Year-Old Company

BEGINNING its second year, the Detroiter does not show any changes in a mechanical way. Some of the body lines have been straightened out giving a very graceful design which taken in conjunction with the long cowl gives the car an excellent appearance.

The motor is of the monobloc type, the four cylinders having the waterjackets cast integrally. The intake manifold passes through the casting in a unique manner, the intake pipe from each cylinder passing between the cylinder from which it leads and its neighbor and projecting from the opposite side of the monobloc casting. The passages are thus between the first and second cylinders and between the third and fourth; the pipes which pass between each of these pairs suffice for the two cylinders between which they pass. The passage is beneath the waterjackets and not through them so that the water circulation is not interfered with by this arrangement while all the advantages of a preheated charge are obtained. The intake manifold is Y-shape, each branch of the Y connecting to one of the intake leads. The carbureter is carried on the bottom of the Y as shown in Fig. 2. The short pipe above the intake is the water inlet.

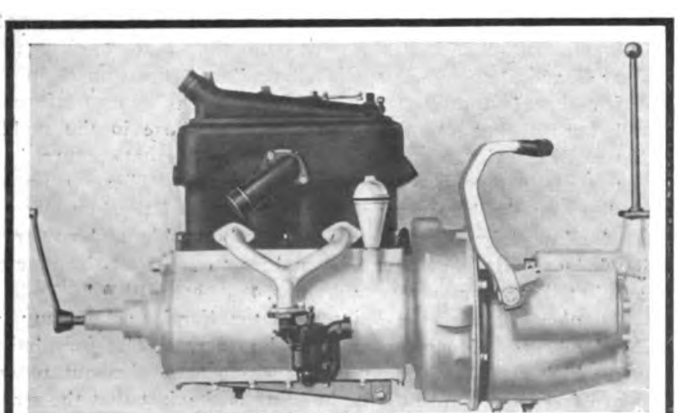


Fig. 2—Left side of unit power plant, showing carbureter mounting

The bore of the motor is 3 3-8 inches and the stroke is 4 3-4 inches. This gives a stroke-bore ratio of 1.4, which is somewhat higher than usual practice in the lower priced cars and should give good reserve power for hills at the same time making the motor economical as to fuel consumption. The material from which the cylinders are made is soft gray iron. The pistons also are composed of this material. A feature of the design of the Detroiter which is unusual is the reaming of the cylinders and the grinding of the pistons to exact diameter, 3.375 inches. The pistons are 4 3-4 inches in length and fitted with three concentric rings all of which are located above the wrist-pin. Before assembling the motor the complete set of four cylinders is weighed and balanced exactly to secure smooth running as far as this can be done by a static balance. A running balance is obtained on all rotating points cutting down vibrations to a minimum.

Other parts of the motor follow standard practice and design. The connecting rods are of I-beam section, and are carbon steel drop forgings heat treated. They are balanced in the same manner as the pistons. The connecting-rod bearing at the crank-pin end is of square projection, measuring 1 7-8 inches each way. The crankshaft is a high carbon steel drop forging carried upon two large heavy duty annular ball bearings. The grinding work at the bearing surfaces is done within extremely narrow limits to give a maximum life of both the shaft and the bearings.

Silence in the valve action of the Detroiter has been obtained by enclosing this part of the motor by oil-tight and sound-proof casing, Fig. 4. The valves are made in two parts welded together by a new process. The heads are of gray iron while the stems are of low carbon steel. They are all of the same size and interchangeable in every way. The action of the valves is adjustable in the usual way by turning a nut on the end of the valve stem. The nuts are of unusual size, however, to distribute the wear over a larger area and render frequent adjustment necessary. The push rods operate in bronze bushings which can be renewed when necessary.

Careful grinding is a feature of the camshaft, the limits being 1-1,000 inch throughout the length of the cam and bearing surfaces. The bearings are ground to .937 inch in diameter and the lengths of the bearings are 2 1-2 inches at the end and 1 1-4 inches in the center. The camshaft is actuated from the rear of the motor. The timing gears in the Detroiter being located at this end of the motor, it has been found easier to lubricate them in this position and they have also been rendered less noisy. The gears are cut helically and are three in number. The crankshaft and magneto gear are of steel while the central time shaft gear is composed of special gray iron. The gray iron timing gear is bolted to a large flange forged directly on the camshaft for this purpose to overcome the objections to keys.

The oiling system used is the circulating splash. The oil is carried in the lower part of the crankcase and is drawn from there by a circulating pump which sends the lubricant through a sight feed located on the dash. From the latter point the oil flows to the forward end of the crankcase and then passes through a system of four-splash troughs, one being located beneath each cylinder. The connecting-rods dip into the oil contained in these troughs and splash the oil to the cylinders, crankshaft, camshaft and all the internal bearings of the motor. In addition to this, the flywheel runs in oil and lubricates the clutch and gearset. Excess oil drains back to the reservoir through standpipes and is recirculated through the system after having passed through a fine mesh strainer.

The cooling system is thermo-syphon, operating through a vertical tube radiator having three tiers of copper tubes. The face area of the radiator is 24 by 26 inches. Large waterjackets are used in connection with this system to facilitate the circulation and make it as rapid as possible. A fixed spark Bosch high-tension magneto is used.

Power is transmitted through a multiple-disk clutch to the three-speed gearset. The clutch consists of twelve internal and eleven external crucible steel disks housed within the flywheel. It runs in a continual bath of oil and engagement is secured by three large helical springs. The gears in the gearset have a 3-4-inch width of face, a large engagement area being thus secured. The gears are of high carbon steel heat treated and hardened in oil. The main and lay shafts are carried on heavy duty annular ball bearings. Practically the entire gearbox can be disssembled through the handhole on the side. The gearbox is suspended by a sub-member to the main frame and forms the rear member of the three-point suspension.

From the gearbox, the drive passes through a universal joint to the propeller shaft and thence through another universal joint to the bevel gear differential. The differential and drive gear assembly are of unit construction, the bevel drive gear or pinion being capable of removal by taking the cap from the rear axle, shown at B, Fig. 1. The drive pinion shaft shown at C is mounted on a double-row ball bearing at the gear and next to the pinion and on a single-row ball bearing at the forward end. The differential set is carried on two large double ball bearings,

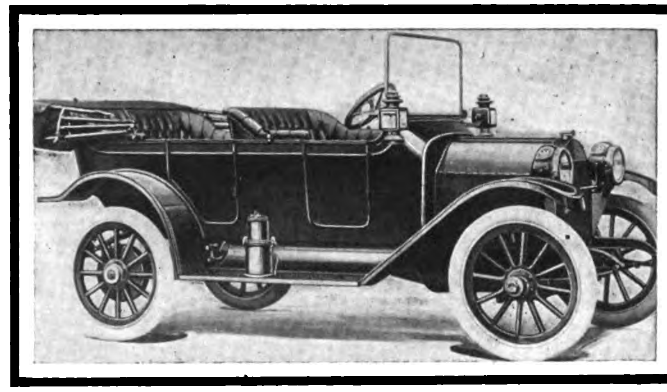

Fig. 3—Five-passenger touring car on the Detroiter chassis

one on each side of the gear. The ratio between the bevel gear and the pinion is four to one. The teeth are five diametric pitch with the short addendum formation and have faces 1-4 inch in width.

The rear axle is of floating construction with a pressed steel housing. The housing, which sustains the weight of the car in this construction, is designed to carry 3,000 pounds which is more than three times the weight that can ever be placed upon it when the car is loaded. The axle is shown at B, Fig. 1. As will be noted in this illustration, the rear spring is of the platform type. The springs throughout are 1 3-4 inches wide and supplied with rebound clips. The front springs are semi-elliptic, attached to swivel shackles, while universal shackles are used in the rear. All bearing points are taken care of by grease-cups.

Two sets of brakes working on double drums are employed. These are shown in Fig. 1 at D. Both brakes are of the internal expanding type. The service brake is 14 inches in diameter and the emergency brake 10 inches.

Heavy frame construction is used, the channel members being 33 inches wide in the rear and 29 inches in front, with a drop of 3 inches forward of the rear axle. The car can be turned in a 25-foot circle. Steering is taken care of by a worm and sector gear actuated by a 17-inch steering wheel. Left drive and center control are used in the Detroiter, a complete model of which is shown in Fig. 1. Tires are 32 by 3 1-2 inches and the color is Raven blue relieved by a light blue stripe.

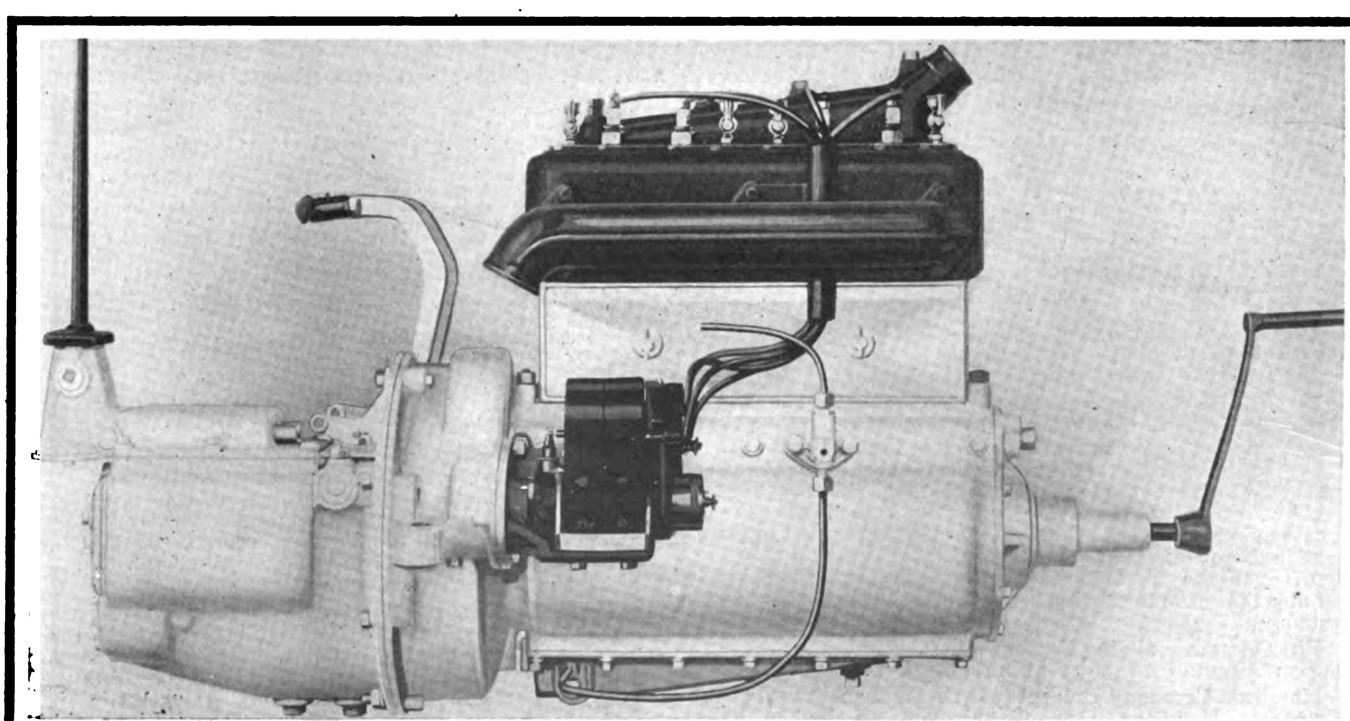

Fig. 4—Right of valve side of motor, showing magneto mounting and lead from oil reservoir to the crankcase

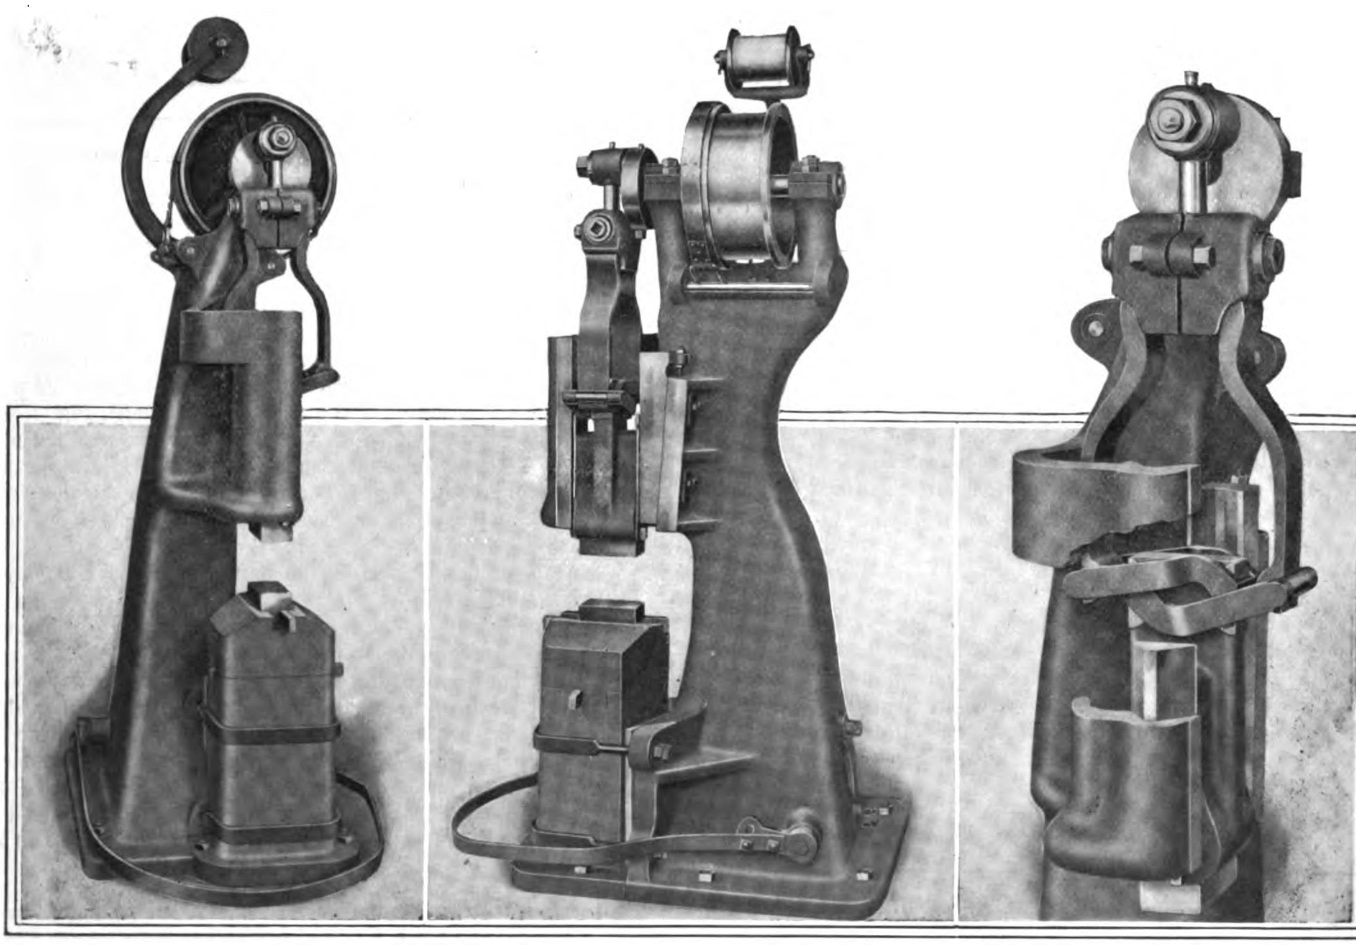
Factory Miscellany



Front, side and constructional view of the Beaudry Peerless ham mer which is especially adapted for tool making

In the accompanying illustration is shown a new hammer brought out by Beaudry & Company, of Boston. While also a hammer for general forging work it is especially adapted for plating and drawing steel. The feature of the hammer is its extreme quickness of blow. It is designed for continuous service and can be operated at a very high rate of speed. The hammer is made in seven sizes with rams which range between 25 and 200 pounds. The weight of the entire machine is from 1,200 to 4,400 pounds, according to the size. Another feature which distinguishes this hammer from most others is that it has no beam, coil springs, leather straps or rubber cushions. The hammer is started, stopped and regulated by a treadle which extends nearly all the way around the base, rendering it possible to operate the hammer from any side. A varying pressure on the treadle will give any desired speed or force of blow, thus allowing an experienced workman the greatest play. The anvil is a separate casting and is flanged at the bottom for the bolts which hold it to the frame. A wood filler is inserted between the anvil and the frame to eliminate vibration. As shown in the above illustrations the anvil is also secured to the frame by strap bolts and is offset so as to clear the main frame casting. The anvil has an independent and adjustable shoe die. The frame of the hammer is cast in one piece and is very rigid. It occupies but little floor-space, having a foundation of moderate size. The ram operates in V-shaped guides, it is composed of carefully machined steel and is adjustable on the connecting rod for varying heights above the dies. At all parts of the stroke the frame is contained within the guides to insure a true blow. The treadle works in conjunction with a belt-tightening pulley and a friction band brake which is capable of instantly starting or stopping the hammer. The hammer responds to the slightest pressure of the treadle and may be operated from any side. One man, of course, can take care of the hammer and do all the work with it. A highly trained man who has specialized on a hammer of this type can do wonders with it in the tool-making line, leaving very little for subsequent expensive grinding work to do. Such hammers as this are in everyday use in automobile factories all over the country.

BUSINESS Outgrows Baker Factory—The electric truck business of the Baker Motor Vehicle Company, Cleveland, O., has grown so rapidly that the business has outgrown the plant, and it has lately been found necessary to do part of the work in the open. The accompanying illustration shows several piles of pressed steel frames. The preliminary work of drilling and cleaning is being done here in the open. It may be seen in the illustration that about 100 feet of the embankment has been cut away and leveled off for the accommodation of the pressed steel frame shipments.

Fitzsimmons Building Factory—J. A. Fitzsimmons is building an automobile factory in Lindsay, Ont.

Hamilton Company Enlarged—The Tallman Brass & Metal Company, Hamilton, Ont., is preparing to double the capacity of its plant.

Wheel Company Adds—The Ideal Steel Wheel Company, Cincinnati, O., has bought the former plant of the Seufferle Cooperage Company, that city, for $41,000.

Wallis Company Working—The Wallis Tractor Company, capital $800,000, organized at Racine, Wis., by H. M. Wallis and other interests identified with the J. I. Case Plow Works, will engage at once in the production of tractors, tools, machinery and internal combustion engines. Temporary quarters have been arranged in the Case plow works, but a new plant will be erected as soon as possible.

Premier Adds to Plant—Two new additions are to be made immediately to the plant of the Premier Motor Manufacturing Company, Indianapolis, Ind. The company at first intended to wait until next spring before enlarging the plant, but it is stated that the demand for the new Little Six makes more room necessary before then. The additions will be two stories in height, one 40 feet by 140 feet and the other 48 feet by 140 feet.

Calendar of Coming Automobile Events

Shows, Conventions, Etc.

Jan. 2-10	New York City, Importers' Salon, Hotel Astor, Importers' Automobile Alliance.
Jan. 4-11	Cleveland, O., Annual Automobile Show.
Jan. 4-11	Montreal, Que., Montreal Motor Show, Drill Hall and 65th Regiment Armory.
Jan. 11-25	New York City, Thirteenth Annual Show, Madison Square Garden and Grand Central Palace, Automobile Board of Trade.
Jan. 20-25	Philadelphia, Pa., Annual Automobile Show.
Jan. 25-Feb. 1	Montreal, Que., Automobile Exhibition, R. M. Jaffray, Manager.
Jan. 27-Feb. 1	Detroit, Mich., Annual Automobile Show.

Oct. 31	Track—Phoenix, Ariz., Maricopa Auto Club.
Nov. 9	Sociability Run, Louisville, Ky., Louisville Automobile Club.

Proposed Contests

Oct. 26	Track—White Plains, N. Y., Geo. T. Long.
Nov. 3-5-6	Track—Shreveport, La., Shreveport Auto Club.
Nov 15-16	Track—Richmond, Va., Richmond Automobile Club.
Nov 28	Road Race—Visalia, Cal., W. H. Lipton.

Foreign

Nov. 2-3	Versailles, France, Splash Guard Competition.
Nov. 8-16	London, England, Olympia Automobile Show.
Dec. 7-22	Paris, France, Paris Automobile Show, Grand Palais.
Jan. 11-22	Brussels, Belgium, Annual Belgian Automobile Show, Centenary Palace.
April	Barcelona, Spain, International Exhibition.

Vulcanizing Plant—The Middletown Automobile and Bicycle Company, Middletown, O., is now receiving bids for a new vulcanizing plant.

Rim Company Building—The Jackson Rim Company, Jackson, Mich., has awarded a contract for a one-story factory to be 400 feet by 80 feet and to cost $40,000.

Maritime Company Building—The Maritime Motor Car Company has placed a contract to build an automobile factory at Coldbrook, N. B., at a cost of about $250,000.

Chalmers Plans Addition—The Chalmers Motor Car Company, Detroit, Mich., has plans in progress for a one-story addition, to be 140 feet by 60 feet, and to cost $20,000.

Electric Company's Factory—The Century Electric Company, St. Louis, Mo., is having plans prepared for a seven-story factory 75 feet by 110 feet. It will cost $150,000.

Indianapolis Company's Addition—The Motor Car Company, Indianapolis, Ind., has awarded its contract for the building of an addition to be 450 feet by 50 feet and of fire-proof construction.

Resilio Company Builds—The Buffalo, N. Y., Resilio Company, recently incorporated, will build a plant for the manufacture of resilio and other substances used in the making of tires for automobiles.

Lewis Acquires Detroit Plant—It is reported that the Lewis Spring & Axle Company, Jackson, Mich., has acquired a factory in Detroit, Mich., and will remove its automobile control department to the latter city.

Chain Firm Builds—The Whitney Manufacturing Company, Parkville, Conn., which manufactures chain drives for automobiles, is to erect a $40,000 addition to its plant. The new structure will be 40 feet by 180 feet and two stories high.

Plans Rubber Tire Factory—Rubber tires for all kinds of motor vehicles are to be manufactured by the St. Louis, Mo., Tire and Rubber Company. The company is to be capitalized at $150,000, and a site has already been chosen for the factory.

Bulldog Tire's Factory—The Bulldog Tire Company, Ltd., Toronto, Ont., has been incorporated with a capital stock of $300,000 to manufacture tires for automobiles, etc. Plans for a factory are being considered. William J. Tubman will be the manager.

Amesbury, Mass., Growing—The Walker & Wells Company, makers of automobile bodies at Amesbury, Mass., is having completed an addition to its factory of a building 40 feet by 100 feet, two stories high, to be used for the storage of lumber and metal.

Hardman Tire Plant Burns—The plant of the Hardman Tire and Rubber Company, Belleville, N. J., was destroyed by fire on September 26. The three-story brick building occupied an entire block, and was used, with the exception of one corner, by the Hardman company.

New Des Moines Factory—Des Moines, Ia., is to have a new automobile factory to be known as the Cannon Motor Car Company. The site of the new factory has not been determined upon. Two locations are already in view and a choice will be made in the near future.

Cutting Plant Enlarged—The Cutting Motor Car Company, Jackson, Mich., has made arrangements to double the size of the plant and additional land next to the factory has been purchased for that purpose. The new factory will probably be in course of erection by next spring.

Agner Company Moves—The Raymond C. Agner Company, Burlington, Wis., manufacturing adjustable socket wrenches, grease and oil guns and other specialties, is now located in its new factory, erected at a cost of $30,000. The output has been increased by 75 per cent.

Pope's Four-Story Structure—The Pope Manufacturing Company, Hartford, Conn., is completing plans for the construction of a four-story factory which is to be devoted to the production of a line of lower priced cars. It is said that this structure will double the capacity of the plant.

Amplex Will Enlarge—The Amplex Motor Car Company, Mishawaka, Ind., is planning to double its factory capacity so that all parts of its car will then be made at the Mishawaka factory, including the aluminum bodies. The company will in a short time put on a larger force of workmen.

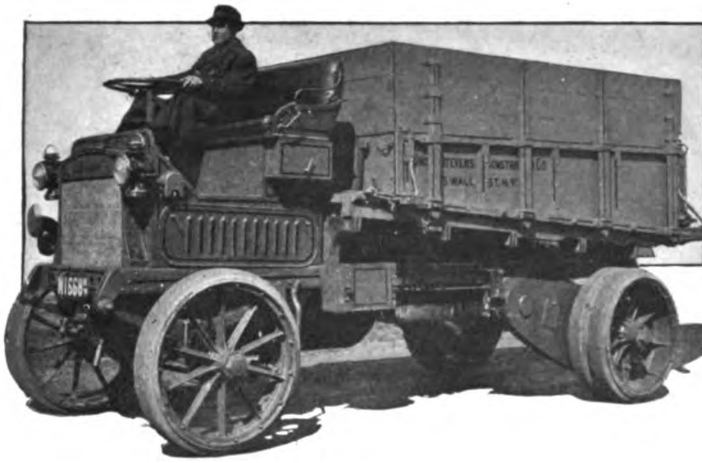
Body Plant Enlarged—The W. F. Stewart Company, Flint, Mich., manufacturer of automobile bodies, has awarded a contract for the erection of an addition to its plant. The new building will be 60 feet by 200 feet, two stories high, and will permit the company to double its capacity.

Kelly-Springfield Plans—The incorporation of the Kelly-Springfield Motor Truck Company, Columbus, O., recently, was the first step in extensive plans for the expansion of the company. The old plant at Springfield, O., is being considerably enlarged, and it is expected that the output for the next year will be in the neighborhood of 1,000 vehicles.

Federal's Building Plans—The Federal Motors Company, Indianapolis, Ind., is preparing to erect a large plant in Indianapolis, the plans having been received. The plant will consist of a one-story building several hundred feet long, to cost $150,000, exclusive of machinery. The construction will be of brick and steel and of the saw-tooth type.

Denies Failure—The temporary shutting down of the Bowling Green Motor Car Company, Bowling Green, O., for the taking of an accurate inventory, gave rise to the rumor that the company has closed permanently. This is denied by the management, which declares that even when the inventory was being taken an emergency force was at work rushing out a car load of trucks for shipment to western concerns. The full force will start to work again in the near future.

Business is so good at the factory of the Baker Motor Vehicle Company, Cleveland, O., that some of the work of drilling and cleaning frames is done outdoors



First Locomobile truck built after the installation of the new special machinery and tools in the truck plant of the company at Bridgeport, Conn.

FIRST Locomobile Truck—The Locomobile Company of America, Bridgeport, Conn., recently sold a truck to John F. Stevens. This truck was the first of standard construction, that is to say, the first to be built after the special machinery and tools had been installed in the new truck shop at the works of the Locomobile company. The above illustration shows the truck ready for usage.

Enforcing Street Regulations—The Chief of Police, Montreal, Can., has received instructions from the Mayor to enforce new regulations regarding street traffic.

Winton in Stage Service—A sixteen passenger Winton has just been put in stage service over the Olympia-Chehalis-Tenino route in the state of Washington, a distance of 26 miles each day.

Jones Heads Ford—A. W. Jones has taken charge of the Houston, Tex., branch of the Ford Motor Car Company as manager. He was formerly assistant manager of the Ford branch at Seattle, Wash.

Woodruff with Packard—C. H. Woodruff has become publicity manager of the Buick Motor Company, Flint, Mich., he formerly being connected with the Packard Motor Car Company, Detroit, Mich., in a similar capacity.

Express Uses Trucks—Twelve motor trucks are to be put in service in New Orleans, La., by the Wells-Fargo Express Company within the next year, according to advises from the general offices to the local agent.

Evans Resigns from Lozier—J. M. Evans has resigned his position as advertising manager of the Lozier Motor Car Company, which position he held for a year. In the future, the Lozier advertising will be handled by an advertising agency.

Minneapolis Show Plans—Construction of the Armory annex for the February automobile show in Minneapolis, Minn., is proceeding so rapidly that the management of the show is assured the building will be ready complete for the exhibition.

Chesborox Business Sold—The Chesborox estate at the corner of Main and Windham streets, Willimantic, Conn., has been conveyed to Fred D. and William P. Jordan, and they acquire with it the automobile business of the E. P. Chesborox Company.

Canadian Company's Contract—It is announced by the Legare Gadbois Automobile Company, Ltd., Montreal, Can., that they have contracted with the Keeton Motors, Ltd., of Brantford, Ont., for the largest number of cars ever contracted for by a distributing firm in Canada.

Humphrey with Oakland—S. H. Humphrey, who was formerly connected with the Peerless Motor Car Company, has taken the position of factory manager of the Oakland Motor Car Company, Pontiac, Mich., to fill the vacancy occasioned by the accidental death of T. W. Wilson on September 15.

Detroit U. S. Motors Moves—The United Motors Detroit Company has removed its headquarters temporarily from Woodward and Charlotte avenues, Detroit, Mich., to the Brush plant, where service will be provided owners of Maxwell, Columbia, Courier, Brush and Stoddard-Dayton cars.

Austin with Mais—L. A. Austin, who has been the sales manager of the Western Motor Company and its successor, Rutenber Motor Company, Marion, Ind., for some years past, has resigned to become the sales manager of the Mais Motor Truck Company of Indianapolis, Ind. Mr. Austin will enter on his new duties November 1, 1912.

Timken Sales Conference—The quarterly sales conference of the Timken Roller Bearing Company and the Timken-Detroit Axle Company was held at Canton, O., October 15. The following Timken men attended: W. R. and H. H. Timken, Heman Ely, E. W. Lewis, P. W. Hood, P. W. Doyle, E. B. Lausier, H. J. Porter, C. E. Gordon and E. A. Walton.

No Duty Charged—It is expected that the new ruling by the United States credit department relating to automobilists crossing the Mexico and Canadian borders, the effect of which is that there shall be no duty charged on the cars, the only requirement being that the machines must be inspected, will result in a great increase in this class of travel into Mexico. The new ruling fixes 6 months as the time limit set on this free return of the cars into the United States.

Columbus Arranging Show—The Columbus Automobile Club, Columbus, O., is arranging to give an automobile show some time during the winter. To that end a committee consisting of Herbert A. Mason, Nelson J. Ruggles, Lewis M. Brown, Ira P. Madden, M. J. Hanly, Charles C. Janes and W. E. M. Ranchous is making preliminary arrangements. The place will be decided soon and the time fixed. It is believed the show will be soon after the holidays.

Garages' Good Outlook—One of the straws indicating to the wholesale automobile dealers and the branch managers that the outlook for automobile sales is good in the Northwest is the heavy contracting for new garages in Northwestern states. Weekly reports from architects, contractors and building exchanges show that the activity is heavy, and that in all the smaller cities not supplied with good central garages buildings are being remodeled for automobile purposes.

Steel Bodies Growing—If the plans which are now under way culminate, a $200,000 automobile body building concern will be located in Detroit, Mich. H. D. W. Mackaye, secretary to the president of the Keeton Motor Company, is negotiating with certain interests in the East regarding the contemplated venture. He stated recently that the eastern capital was willing to go ahead with it, the matter at present resting entirely with himself. The idea is to manufacture all-steel stamped bodies.

St. Louis Formulating Road Laws—Good roads enthusiasts from all parts of Missouri met at the headquarters of the Automobile Club of St. Louis, Mo., recently to formulate plans crystalizing the good roads enthusiasm which has been aroused, into some definite action. It was decided to call a mass meeting to be held in Jefferson City, on November 13, for the purpose of revising the road laws and to formulate effective road regulations which will be the means of giving Missouri the best roads of any state in the Union.

Columbus Plans Speedway—A special committee of the Columbus, O., Automobile Club is canvassing the situation as to the building of a motor speedway in Columbus. The committee consists of N. J. Ruggles, chairman, Lewis M. Brown and Dr. J. W. Means. To finance the undertaking a stock company will be formed and stock will be sold to motor enthusiasts in Columbus and central Ohio. It is proposed to have a speedway of either 1.5 mile or 2.5 miles. The committee will make a preliminary report soon.

Louisville Purchases Truck—The Louisville, Ky., Board of Public Works will purchase a 5-ton truck in the near future. This vehicle is to be used for the hauling of broken rock and bricks to be used in the making of streets.

With Grinnell Electric—O. R. Hardwell has shifted from the position of advertising manager of the Paige-Detroit Motor Car Company to one of similar duties with the Grinnell Electric Car Company, Detroit, Mich.

Newby Traveling Representative—A position as special traveling representative, with territory in eastern Indiana, with the A. and M. Sales and Service Company, Indianapolis, Ind., has been taken by J. A. Newby, formerly manager of the United Motor Newcastle Company, at Newcastle, Ind.

License Tags Out Early—The first issue of Pennsylvania automobile license tags for 1913 will be made by the automobile division of the state highway department in December, almost two weeks ahead of the time of issue in the past, and it is expected to break all records for the first issue.

South Bend Forbids Speed—The Board of Public Safety of South Bend, Ind., has adopted resolutions forbidding the drivers of motor vehicles of the police and fire departments from driving their machines at a rate of speed greater than 30 miles an hour. The order of the board goes into effect immediately.

First Adams Fire Truck—The first automobile fire truck ever built by the Adams Brothers & Company, of Findlay, O., is just now being completed in the company's shops. It will be shipped within the next few days to Kittaning, Pa. The truck is of the one-and-a-half-ton model and has a 35-horsepower motor.

Employ Prison Labor—The Kent County Good Roads commission is planning to employ prison labor on the construction of roads in Grand Rapids, Mich. The plan successfully has been tried in Kalamazoo County. The commission is busy on the new roads for which the county recently bonded for $600,000.

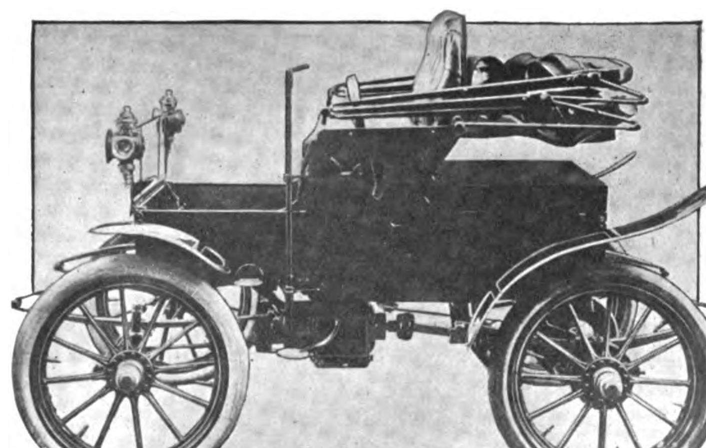
Abandon New By-Law—In consequence of an opinion from the city attorney, Montreal, Ont., that the new civic by-law prohibiting the use of steam driven traction engines in Montreal streets is ultra vires, Mayor Lavalle has given instructions to Chief Campeau to suspend further actions against those not complying with the said regulation.

Automobile Service Established—A daily automobile service has been established between Paducah and Roaring Springs, Tex., a distance of 40 miles. The Quanah, Acme & Pacific Railroad is now being extended from this place to Roaring Springs and the automobile service will be operated between the two points until the railroad is finished.

Motorists Give Talks—The Boston Y. M. C. A. directors have asked the Boston dealers to supply its motor school with men who can give talks to the students on motor construction during the winter, and the first talk was furnished by Charles Howell, of the J. H. MacAlman Company, agent for the Stearns and Columbia cars, who described the Knight motor.

Van Duesen Promoted—W. H. Van Duesen, assistant sales manager of the Abbott Motor Company, Detroit, Mich., and formerly connected with the Chalmers Motor Company and the E. R. Thomas Company, has tendered his resignation. O. F. Schreiber has been promoted to fill the vacancy in the Abbott sales organization. He was connected with the Chalmers Company at one time. M. L. Buck succeeds to Mr. Schreiber's former position.

Racine Wants Fire Engine—The city of Racine, Wis., which is in the market for a motor fire engine, is this week conducting a series of thorough tests, on the basis of which a purchase will be made. Among the companies which have sent models of their apparatus to Racine are the Nott Fire Engine Company, of Minneapolis, and the Ahrens-Fox Fire Engine Co., of Cincinnati, O. W. S. Goodland, mayor, and a party of officials, recently made a tour of the east to determine the efficiency of various types of motor-propelled fire-fighting equipment.



Shaft-driven electric runabout built by the Woods Motor Vehicle Company in 1904 which the company claims is the earliest model shaft-drive electric now in operation. The makers believe that it is the first vehicle of this type ever manufactured and sold in the United States. It took part in the parade of old models held by the Chicago Automobile Trade Association recently, running 12 miles and carrying two passengers

Martin tractor manufactured by Knox Automobile Company, Springfield, Mass., attached to a 15-ton capacity ash wagon, the combination being 12 feet high and 26 feet long

Buffalo Company Moves—The Buffalo, N. Y., Hudson Sales Company has moved into temporary quarters at 1133 Main street, opposite Summer street.

Kempton with Remy—P. E. Kempton, San Francisco, Cal., branch manager for the Splitdorf interests, has resigned to become San Francisco branch manager for the Remy Electric Company.

Building Branch House—The Fisk Rubber Company, of Chicopee Falls, Mass., is building a new branch house and service station adjoining its present quarters at 456 Milwaukee street, Milwaukee, Wis.

Orders Pathfinder Ambulances—An order for two Pathfinder ambulances has been placed with the Motor Car Manufacturing Company by the Board of Health and Charities of Indianapolis, Ind., the contract price being $5,500.

Y. M. C. A. Automobile Course—Arrangements have been made by which the South Bend, Ind., Young Men's Christian Association educational department will conduct an automobile course of 35 lessons, covering a period of 12 weeks.

Hold Lancaster Fair—Automobile dealers in Lancaster and Columbus, O., took advantage of the large crowds which invariably attend the Fairfield County fair and had large exhibits of automobiles at the fair, which was held the week ending October 5.

Bradfield Newspaper Representative—C. W. Sedwick, manager of the Indianapolis, Ind., Motor Speedway, has recently announced the appointment of H. C. Bradfield as traveling newspaper representative and chairman of the press committee of the speedway.

Warren's Factory Branch—The Warren Motor Company has announced the opening of a factory branch in Des Moines, Ia. R. E. Gresham will be manager of the branch. The service department will be featured and two experts from the Warren factory will be sent to Des Moines.

Sternberg Service Branch in N. Y.—The Sternberg Manufacturing Company, of Milwaukee, Wis., manufacturing the Sternberg commercial car, has established a direct factory and service branch at 285 East 137th street, New York. The New York branch will be known as the Sternberg Motor Truck Company.

Smith Succeeds Huylar—E. B. Huylar has resigned as manager of the Milwaukee, Wis., branch of the Diamond Rubber Company, 132 Oneida street, and is succeeded by R. W. Smith, who comes from Indianapolis, Ind. A. G. Laugher is traveling representative in Wisconsin, with headquarters at the Milwaukee branch.

Inspecting Repaired Road—State Highway Commissioner Marker has started on an inspection trip of the highways of Ohio which were improved during the present season. Commissioner Marker is using an automobile for that purpose, finding it quite a time saver over the use of railroads. It will require traveling 3,500 miles for a complete inspection trip.

Wilmington Club Elects—The Delaware Automobile Association, Wilmington, Del., held its annual meeting recently and elected the following officers for a year: President, T. Allen Hilles; first vice-president, Joseph Bancroft; second vice-president, A. B. Richardson; third vice-president, A. Greenbaum; secretary, Charles G. Guyer; treasurer, William Staniar.

Restrict Paris Operations—Announcement is made that the English Daimler Company will restrict its operations in Paris, France, at the end of this month. The central showrooms are to be closed and the headquarters of the English company confined to the repair departments in the suburbs. The retail sales department, in the hands of the various agents, remain unaffected.

In Financial Difficulties—An order in bankruptcy has just been filed by Leonce Girardot, for one time manager of the English Daimler Company in Paris, France, and earlier a member of the C. G. V. firm, now the Charron Company. For the past 12 months M. Girardot has been agent for Darracq valveless motors and the Panhard-Levassor Company, with a store in the Champs-Elysees.

Proposes Odd Ordinance—An ordinance is being prepared by Councilman Bohnert, of the Columbus, O., city council, which provides that the car of people charged with violating the speed law be locked up for a certain length of time as well as the chauffeur be jailed. Mr. Bohnert is of the opinion that locking the car up for a few hours or days in extreme cases will solve the problem of speeding.

Improves 4,700 Miles of Roads—Since the Pennsylvania state highway department took over 8,000 miles of highways in the state June 1, the department has improved 4,700 miles of roads. This total includes those that have been rebuilt under the 79 contracts so far let under the Sproul act and those that have been repaired by the road superintendents, 47 of which have been named out of 50 the law calls for.

Acme in Difficulties—William Vincent, president of the Acme Motor Car Company, 22 Commercial street, Worcester, Mass., has placed an attachment on the company's property for $1,200. He alleges that the company is indebted to him that amount for services. This is the second attachment placed on the garage stock, the first one being put on by the Worcester Trust Company. The company is still doing business despite its legal tangles.

In Doubt About Tax—A committee of the Automobile Club of Maryland, Baltimore, Md., was appointed to confer with Mayor Preston and the judges of the Appeal Tax Court to learn whether the proposed municipal tax on motor cars would apply to pleasure vehicles operating on the streets of Baltimore and whether the Mayor and City Council would have the power to impose such a tax without first being authorized by the Legislature.

Government Losing Money—Service Director Kinnear, of Columbus, O., is authority for the statement that the municipal government is losing money every day because of the few city automobiles used. He advocated the purchase of a larger number of cars in order to save the time of high-salaried employees. While it is said that some people laugh at the idea of the city buying automobiles, it is a plain business proposition and a matter of economy.

Automobile Incorporations

AUTOMOBILES AND PARTS

Austin, Tex.—The Oakland Motor Company of Jersey City; capital, $10,000; to engage in the automobile business.

Boston, Mass.—Ultra Motor Car Company; capital, $100,000; to deal in automobiles. Incorporators: R. H. Randall, Elisha A. Bagg, C. A. Parker.

Canal Dover, O.—S. Toomey Company; capital, $50,000; to manufacture and deal in automobiles. Incorporators: R. I. Toomey, T. Williams, J. S. Brister.

Chicago, Ill.—Guaranty Auto Company; capital, $50,000; to manufacture automobile parts. Incorporators: J. T. Shea, E. J. Crimski, C. B. Kittenhofer.

Columbus, O.—Columbus Auto Parts Company; capital, $25,000; to manufacture automobiles. Incorporators: R. E. Klages, C. J. Krag, C. K. Klages, J. D. Stoddart, W. D. McKinney

Columbus, O.—Kelly-Springfield Motor Truck Company; capital, $2,500,000; to manufacture motor trucks. Incorporators: E. S. Kelly, J. S. Crowell.

Des Moines, Ia.—Van Vliet-Bradt Motors Company; capital, $10,000; to deal in automobiles. Incorporators: W. E. Moyer, W. J. Bradt, C. G. Van Vliet.

Detroit, Mich.—Oostdyke Gear Shifting Company; capital, $100,000; to manufacture a gear shifting device which does away with shifting levers on the car.

Haverhill, Mass.—Rambler Motor Car Company; capital, $10,000; to sell automobiles. Incorporators: G. A. Burnham, J. P. Molloy, C. S. Goodwin, F. P. Kimball.

Holden, Mass.—J. W. McIntosh Company; to engage in the automobile business. Incorporators: J. W. McIntosh, B. M. Sickels, H. Sickels.

Houston, Tex.—Cole Motor Car Company; capital, $12,500; to deal in automobiles. Incorporators: J. J. Settgast, Fr., A. J. Binz, T. H. Buelow, D. F. Burks.

Louisville, Ky.—Southern Motors Company; capital, $100,000; to deal in motor cars. Incorporators: A. T. Hert, R. A. Whitehead, R. L. McCormick.

Waite Sales Manager—G. S. Waite has taken the position of sales manager of the W. A. Paterson Company, Flint, Mich.

Muzzy Garage Manager—W. W. Muzzy is the new manager of the High-Seventh Garage, located at High street and Seventh avenue, Columbus, O.

Lawrence a Ford Manager—The Ford Motor Company of Canada, Walkerville, Ont., announces the engagement of A. N. Lawrence as sales manager.

Establish Tire Branch—The United States Tire Company, Washington, D. C., will establish a branch at 1303 H street, N. W., about November 1, with E. H. Johansen as manager.

Morrison Gets Promotion—Harry S. Morrison, formerly a salesman for the Whitney-Barney Company, of Boston, Mass., has been promoted to be general sales manager of the company.

Butler District Manager—W. T. Butler has been appointed by the Stewart Motor Corporation, Buffalo, N. Y., manager for the district comprising northern Pennsylvania and New York State.

Lights on Standing Cars—Hereafter all automobiles left standing in the streets at night throughout Connecticut must have lights lit, the attorney-general having rendered an opinion to that effect.

Club Rewards Twenty—The Louisville, Ky., Automobile Club has paid a total of twenty rewards this summer to persons who assisted in the conviction of offenders who threw glass into the streets.

Car for Inspector—In order to facilitate the enforcement of the sanitary regulations Shreveport, La., has purchased an automobile which will carry an officer throughout the city each day on inspection trips.

Depasse Takes R. C. H. Agency—After being chief selling agent for the Ford Company for about five years, Henri Depasse has taken up the complete selling agency for the R. C. H. car in Paris, France.

Open Washington Agency—The Washington, D. C., branch of the Foss-Hughes Company, agent for the Pierce-Arrow, was opened recently at 1220 Connecticut avenue, N. W., with F. N. Prendergast as manager.

Clement Production Manager—C. M. Clement has become production manager of the Metal Products Company, Detroit, Mich., having resigned as factory manager of the Weston-Mott Company, of Flint, Mich.

To Hold Sociability—The Louisville, Ky., Automobile Club will conduct a sociability run on November 9. The intention is to make a trip to Lexington. Awards will be made to the car making the run nearest to a secret time.

Buy U. S. Motors Branch—Frederick J. Linz and L. W. Sanborn, two of the pioneer automobile men of San Francisco, Cal., have purchased the entire assets and capital stock of the United States Motor San Francisco Company.

In this building in Detroit, Mich., the Studebaker Corporation has organized a model garage, salesroom and repair shop which is used for the purpose of educating its dealers and representatives all over the country

Packard Service Building—The new building being constructed by the Packard Motor Car Company in Buffalo, N. Y., will provide for a salesroom, general offices and a service station with facilities for inspection and overhauling.

Packard Moves in Paris—Business having increased in favorable proportions, R. N. Goode, European manager of the Packard Motor Car Company, Paris, France, has moved from Boulevard Pereire to a handsome store in the Rue Newton.

Dennett Handles Trucks—George Dennett has been appointed manager of the truck department of the newly formed Pope-Hartford agency in Boston, Mass. He was with the Dodge Company handling trucks and fire wagons for some years.

Sociability to York—The Lancaster Motor Club, Lancaster, Pa., will hold a sociability run to York, Pa., on Saturday, October 26, and will be the guests of the York Motor Club at the races being held there that day and at the York club's new home along the Wrightsville pike.

Association In Maine—The Somerset, Me., Automobile Association, the first one formed in that county, has just been organized in the Pine Tree state, making its headquarters at Skowhegan. It will work in conjunction with the Maine State Association for the benefit of good roads.

New Dallas Motordrome—The new $40,000 motordrome at Dallas, Tex., was officially opened recently. Racing programs are being given each night. This motordrome is said to be the largest in the world. The track is an 18-foot saucer, .25 mile in length. Seats are provided for 10,000 people.

Takes Three Cars Per Week—The D. F. Poyer Company, manufacturing the Menominee commercial car, Menominee, Mich., has contracted with the Stoddard-Dayton Automobile Company, of Portland, Ore., to be Pacific coast distributor. The Portland company takes three cars per week on a 1 year's contract.

Chauffeurs Fight Speedometers—A proposal on the part of taxicab owners in New Orleans, La., to equip their cars with recording speedometers has met with decided opposition on the part of the chauffeurs. No reason is given for the stand taken, but it is thought an attempt to install the device would result in a strike.

Good Roads Day—The germ of good highways is penetrating all over America, the latest example being up in New Brunswick when the motorists in that region got together and observed October 12 as Good Roads Day. Members of motor clubs went out over the most important roads there putting up signs and making repairs where a little work of that kind was needed.

Preaches in Automobile—His own chauffeur, and in cases of necessity his own organist, Archdeacon J. H. Dodshon, of the southern diocese of Ohio, Episcopal church, has been performing his duties through the mining region of southern Ohio with his automobile, equipped with a portable organ. The novelty of a large touring car bearing an organ entering a little mining village that never boasted a church has been productive of much good and the Columbus man's coming always draws an interested audience.

Automobile Incorporations

GARAGES AND ACCESSORIES

ACTON, MASS.—Davis-King Company; capital, $20,000; to deal in automobile accessories. Incorporators: A. W. Davis, H. E. Mead, B. A. King.

AMHERST, MASS.—H. E. Page; capital, $12,000; to conduct a garage business. Incorporator: Dr. Henry E. Page.

BOSTON, MASS.—Walpole Tire and Rubber Company; capital, $4,500,000; to manufacture automobile tires. Incorporators: E. W. Tinkham, A. T. Baldwin, F. J. Gleason, E. C. Green, E. W. Furbush, L. O. Duclos, J. C. Blanchard, Jr.

CHICAGO, ILL.—Triangle Tire Company; capital, $50,000; to manufacture automobile accessories. Incorporators: L. A. Cohen, C. Aaron, F. M. Stahl.

COLUMBUS, O.—J. C. Sherwood Rubber Company; to handle the tire business. Incorporators: J. C. Sherwood, R. C. Crippen.

CLEVELAND, O.—The Ideal Tool & Specialty Company; capital, $15,000; to manufacture automobile accessories. Incorporators: J. C. McLoland, G. E. Penty, G. P. Moulton, J. A. Hocker, C. Fuller.

DAYTON, O.—McVey Manufacturing Company; capital, $60,000; to manufacture automobile accessories: Incorporators: J. L. McVey, C. Fraine, A. N. Burkhart, M. Galloway. R. J. McCar.

DETROIT, MICH.—The Wolverine Castings Company; capital, $100,000; to manufacture motor castings.

PORTLAND, ORE.—Motor Truck Owners' Protective Association; capital, none; to secure legislation favorable to their interest and fight unfavorable legislation. Incorporators: K. Poorman, W. M. Miller, C. L. Hamawalt, J. F. Guerin, P. W. Yett, F. P. Field, W. E. Moon, A. F. Roberts, J. J. Bryan, W. Eden, W. C. Smith, O. J. Cornell, H. F. Moon.

TACOMA, WASH.—Automobile Equipment Company; capital, $5,000; to deal in accessories.

WINNIPEG, CAN.—Canadian Motor Company, limited; capital, $500,000; to carry on a garage business. Incorporators: E. S. Sherwood.

CHANGES OF NAME AND CAPITAL

BOSTON, MASS.—American Marine Equipment Company, change of name to American Motor Equipment Company.

CLEVELAND, O.—The Auto Owners Company, change of name to the Sixth City Tire Repair Company.

Hartford's New Bumper

Comprising Four Highly Elastic Springs in Frictional Contact and Attached To Chassis Without Bolts

As a trade running-mate to its Truffault-Hartford shock-absorber, the Hartford Suspension Company, of Jersey City, N. J., has decided to add to its line a kindred article, this being a bumper. The latter not only combines the friction idea with the application of springs, but a new element designed to warrant great strength is introduced in the use of concrete as a filler for the hollow steel bumper bar used in the equipment.

The simple, fundamental feature of the Hartford bumper lies in the use of four springs which are in frictional engagement with each other and the ends of which bear directly upon the chassis frame, being attached to the same without the use of bolts which pierce the members and so arranged that none but tensile and compressive strains are set up in the material, thereby avoiding all tendency to shearing.

The four-spring idea is carried out in all types of the bumper, of which there are three; these are designed for use on overslung, underslung and Ford cars. The bumpers of these types vary in the shape of the springs and the consequent manner of securing the same to the chassis, while the concrete-filled bumper bar is common to all models. Reference to Figs. 5, 6 and 7 shows the difference in spring design and attachment of the three types, Fig. 7 showing the principal representative of the line, which is constructed for use on ordinary type of frame, the overslung, so to speak.

Construction of Spring Bumper

In Figs. 3 and 4 the details of construction of this type of bumper are illustrated, showing the four bent leaf-springs S1, S2, S3 and S4, which when the spring is assembled are held together by a bolt B and its nut N. In the assembly the bolt passes through the hole H of the arched cap or cover C which is so dimensioned that the flat end of the longest, or clamp, spring S4 projects slightly under the plane of the lower edge of the cover. As Fig. 4 shows, S4 is so shaped that if its shorter end contacts with S3, its longer or clamp-shaped end diverges from S3. The purpose of this feature of the design will be seen at once. The spring ends arranged above the clamped end of S4 are held together by means of U-bolt U which seats in a yoke Y. A central stud C1 formed in the lower side of the yoke fits into a hole bored in the spring S1 near its end. The lower cross-piece connecting the ends of the U-bolt bears in the inverted angle formed in the clamped end of S4. As the nuts on the end of U are drawn tight, as in Fig. 3, S4 is pressed against S3 and its natural shape keeping it under tension counteracts the compression caused by the tightening of the bolts. While S4 is held tightly in this way and the springs are so brought together that they cannot be moved relatively to each other except by overcoming friction between them, the clamped end of S4 is drawn tightly around the bumper bar which fits into it. To secure the spring to the chassis, in the manner shown in Fig. 7, the U-bolt or clamp U1 is used which fits into a slot S5 of the cover C. When the nuts on the ends of U1 are tightened to press the cross-piece above them against the chassis members, the end P and the point Q of the spring S4 bear down fast upon chassis, and the more they are compressed the more do the central portions of the four springs, shown along the line C2, press against the top of the arched cover C. This makes an almost rigid system of the shorter ends of the four springs, while the longer ends are capable of considerable inward bending—toward their middle angle—accompanied by friction which absorbs a fair part of the impact of a shock taken by the bar.

When such a one takes place a double action is set up by the bumper: the impact transmitted from the bar to the two spring assemblies is partly absorbed by bending the longer spring ends toward the shorter and partly by being transmitted to the strong chassis members from the arched, covered section of the spring system. The slightest impact on the bumper causes the end of S4 to grip the surface of the chassis, the spring being made of steel harder than the pressed metal of the frame. Continued and increased shock compresses the short spring ends toward their arched centers, whereby a straight upward pull is set up in the U-bolt U1. While the grip of S4 on the frame prevents the springs from slipping, it also provides a fulcrum for the longer ends to bend about, and as they do this, the friction between their surfaces as well as the change of their shape absorbs the impact. The diameter of the holes through which the bolt B passes is slightly larger than that of the bolt, so that a slight displacement of the springs relative to each other is allowed for.

How the Springs Are Shaped

As the shape of the springs is obviously of great importance, it may not be without interest to consider the process through which they are formed. The springs are made of flat plates, are cut in various lengths and each is bored with a hole near each end; so that when the ends which later form the short ones are lined up, the holes punched near them are in alignment and the springs may be held together by a pin. The holes near the other ends do not fall upon each other, but after the first-mentioned ends are pinned together, the four flat springs are heated to redness and bent, in a special tool, to form the middle angle, whereby the holes which are to accommodate the bolt B are brought above one another. The pin is then removed and the short ends are bent to the degree shown in the illustrations, as well as the long ends of S4 which is given its clamped shape. After shaping the springs are tempered and assembled with the cover, bolts and nuts, which are made of cold-rolled machine steel; this work is followed by dipping the assembled sets into black japan, which is then baked on.

The underslung type of bumper equipment differs from the first-described type only in the shape of the springs which grip

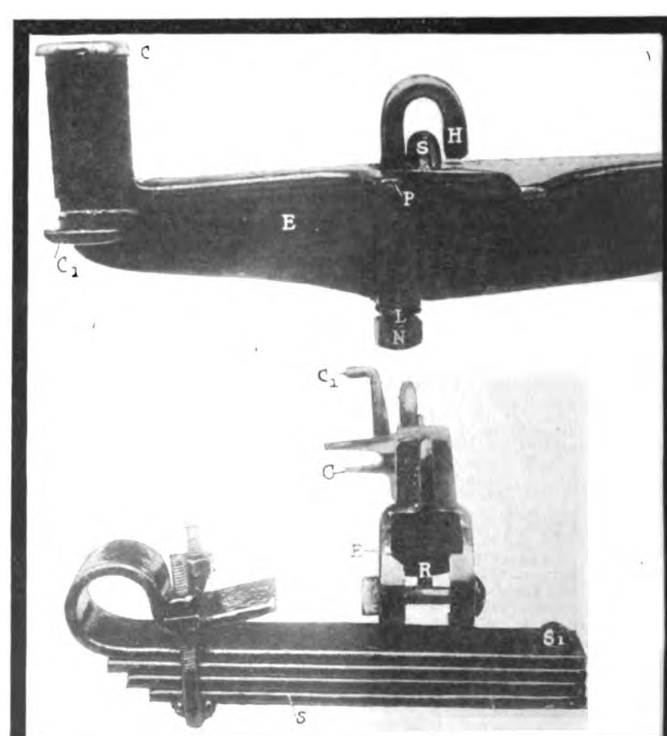


Fig. 1—Details of extension for attaching bumper to Fords
Fig. 2—Springs and extension of Ford type of spring bumper

the under surface of the chassis frame members. As a result of the different requirements the springs in this design are shaped as a flat arch. instead of with a middle, angular bend. The spring ends are formed substantially in the same manner as in the overslung equipment, and the action is the same in both models. The springs when receiving a shock press the lower end of the clamp spring against the chassis member, whereby a fulcrum is provided as before. Instead of bending around a middle angle, however, the springs are pressed around the front end of the chassis member. The springs are tempered to withstand a very heavy shock without distortion; but if the latter is occasioned in consequence of an exceptionally severe collision, the springs may be easily restored to their original shape and strength. A set of springs used with a bumper of a 1,250-pound car which ran into a tree when traveling at 15 miles an hour, showed a comparatively slight distortion, which was the only effect of the accident, neither car nor its passengers or equipment being hurt. As for the concrete-filled bumper bar, it is claimed to be capable of withstanding any practical shock.

Description of the Ford Type

Coming to the third type of bumper, which serves for Ford cars, the manner of meeting the special requirements of such service is shown in Fig. 5. illustrating the method of attaching the springs by extension members to the side members of the frame, while the details of the construction are seen in Figs. 1 and 2. The extension members E. Fig. 5. are used due to the design of the Ford frame which only extends as far in front as the radiator; by this expedient the bumper bar is placed far enough ahead of the radiator and lamps to protect them, at the same time leaving ample clearance for cranking. The general shape of the extension member E, shown in Fig. 5. makes it desirable to use four straight springs, instead of bent ones. with the Ford design, and to make this possible an ingenious method of securing the springs to the extensions has been evolved.

Figs. 1 and 2 illustrate the same. The latter illustration shows the flat springs, one of which is clamped at its end to take in the bumper bar in the same fashion as the other types of the equipment. The other end of the clamped spring is shaped with a projection having the form of a truncated cone; **this end of the spring set fits into the open end E_1 of the extension E.** In Fig. 2 both extension and springs are shown with the lower side turned up. When assembled on the car, however, the spring set is so inserted into the end E_1 of the extension that

Fig. 3—Springs which fasten to chassis and hold the bar
Fig. 4—Details of bumper springs, arched cover and bolts

the lower surface S of the shortest spring bears against the lug R formed on the extension, which prevents the springs from bending back too far upon being exposed to an impact. Lateral tightness of the spring set in the extension is insured by the expedient of drawing the nut M a good way into its bolt which passes through the two jaws of the end E_1. Displacement in the direction opposite to that of a head-on shock is averted by the fitting of the stud S_1 into a suitably formed depression in E_1. The securing of the extensions to the cars is also obtained in an original fashion and without the use of bolts through the chassis frame. A grip on the frame is insured by the end of E opposite E_1, which end is formed with channel jaws C, C_1, C gripping the upper and C_1 the lower flange of the chassis frame. In order to permit of the channeled end of the extension E gripping the chassis frame, the apron extending from the mudguard to the frame is punched with a suitable tool. This end, however, is not directly fixed to the frame, the point of attachment being at A, where the extension is fitted with a hook-bolt H adapted to be drawn tight against the stud S by a nut N and its lock-washer L. In installing the bumper the hook-bolt is placed over the bracket extending from the frame and supporting the lamps, so that when the ends E_1 are placed as far outward as possible the extension E is fulcrumed by the hook-bolt and the channeled end is pressed against the chassis frame. The part P formed on E lies against the front of the radiator support and helps to keep the extension permanently in alignment with the chassis.

Overslung and underslung types are made in three sizes, while the Ford equipment come in one size only. Black japan finish is standard for all parts except the bumper bar, which is optional in brass or nickel.

Mertz Spring Release; Standard Tire-Tube Ball Check; Edelmann Hose Connection; Marvel Casing and Tube Vulcanizer; Exhaust-Operated Vacuum Cleaner; Westinghouse Portable Electric Vulcanizer

Mertz Valve Spring Release

A PRACTICAL, neat valve spring release, made by H. B. Mertz, 1408 Rutherford avenue, Pittsburgh, Pa., is shown in Fig. 1. While the construction is evidently simple, the device is made strong enough to compress any automobile-valve spring. It consists of a vertical bar B to whose lower end an arm carrying the fork F is secured, while slidably arranged on it is the arm A; the end of the latter is formed as a nut N working on the worm W which is fitted with a handle H. The point of the worm W fits into the central depression of the valve head. In order to keep the fork centered on the valve stem, F is provided with an adjustable gauge G which, once set, always keeps the stem in central alignment with the axis of the fork. The operation of the device is very simple, consisting in removing the valve cover and applying the fork between the retaining washer R and the pin P which keeps it from coming off the stem. At the same time the end of the worm W is set into the depression of the valve head and if the handle H of the worm is turned clockwise the retaining washer and spring are pressed upward, permitting of driving the pin P out of the valve stem, so that the valve may be lifted out of its seat.

The arm A being slidable on B and capable of coming off its upper end, it is possible to use the spring release also where this would seem impossible due to the interference of the manifold with direct application of the device. In such cases, the arm A is simply slid off the upper end of the vertical bar; after this the bar is placed back of the manifold and A is put back on it. This makes the tool adaptable for practically any type of valve.

Potter Standard Tire Valve

Taking advantage of the field for improvement in tire valves, the Standard Engineering Works, Woonsocket, R. I., offers now a design which is claimed to be a step in the forward direction and which while keeping the air tightly locked in the tube permits of easy inflation without a continued expenditure of hard work in keeping the valve open. As Fig. 3 shows, the valve is of the ball check type, and it is claimed for this design that it allows of pumping up a 36 by 4.5-inch tire within 2 minutes with one hand. This end is obtained by the expedient of using an opening area about ten times that ordinarily present in tire valves, whereby not only the pump pressure on the valve ball is increased, but the total friction between the inflating air and the valve passage is considerably diminished. In connection with this valve, the company brings out an automatic valve connection, the Standard, Fig. 2. It is of an extremely neat design and worked out very nicely, its construction being such that the valve connection may be put in place in 2 seconds and removed in 1 second.

Marvel Roadside Vulcanizer

Tire upkeep proves such a large item to the average automobilist that one cannot too often attempt to impress upon him the desirability of owning and operating a vulcanizer, even if it only be a small one, so that he may at least handle his smaller tire repairs. Among the many products which have of late appeared in the market to fill this want, the Marvel, Fig. 5, is distinguished by its applicability to both casings and tubes. Furthermore, the vulcanizer is so small it may be easily carried along with the other tools, and its simple construction makes it ready for work at a moment's notice. In short, the device con-

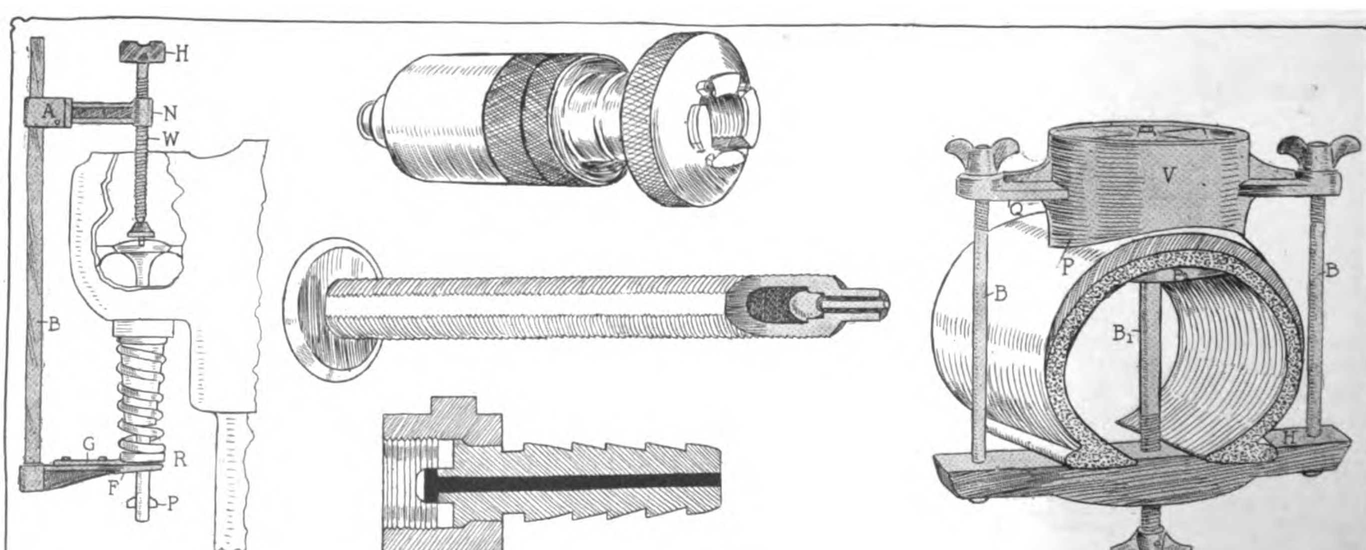

Fig. 1—Mertz spring release. Fig. 2—Potter tire valve connection. Fig. 3—Potter valve. Fig. 4—Edelmann pump connection. Fig. 5—Marvel vulcanizer

sists of two vulcanizing plates P and P1, the first of which is curved concavely and the second convexly. These plates are held in relation by the use of a holding plate H to which P is fixed by two bolts B, while the plate P1 is attached through the bolt B1. Bolts B are screw-threaded near their upper ends and work in threads in the plate Q which is integral with the vulcanizing heater V, while a thread on B1 works through plate H. The heater V is a small kettle into which gasoline is poured which when ignited supplies to plate P the heat necessary to cure the rubber applied to the tire being repaired. It stands to reason that the vulcanizer is just as easily applicable to tubes as to casings, as the curved surfaces of plates P and P1 do not interfere with the repairing of the tubes. This vulcanizer is made by the National Auto Specialty Manufacturing Company, Inc., Tama, Ia.

Edelmann Economy Pump Connection

E. Edelmann & Company, 229 West Illinois street, Chicago, have added another small accessory to their line, this being the Economy pump connection No. 45, Fig. 4. The latter is somewhat similar in design to the No. 46 connection, but it is a cheaper product, being made of but two parts, the nut taking in the pipe and hose carrier which is of serrated longitudinal section, as shown by the illustration. The connection is designed for .3125-inch hose and .25-inch pipe thread. This pump connection is being handled in the Metropolitan district by Asch & Company, 1777 Broadway, New York City, dealers in automobile accessories and specialties.

Auto Vacuum Cleaner

A vacuum cleaner for keeping the automobile free from dust without any hard work is an accessory which has many attractions, and realizing this situation the Auto Vacuum Cleaner Company, 253 West Twenty-third street, New York, has begun the construction of a suitable outfit, shown in Figs. 7 and 8. The suction, which represents the effective force in vacuum cleaning, is in this device obtained by utilizing the pressure of the exhaust gases of the engine, and efficient use is made of it through the application of a suction nozzle inserted in the line between the engine and the muffler, where the pressure in the waste gases is strongest. The manner of installation is clearly seen in Fig. 7, and Fig. 8 illustrates the details of the construction. The passage M is interposed in the exhaust line; it is designed as a T and the middle piece contains a throttle-valve by the use of which the lower T-piece may be cut off from the exhaust line. The piece T is fitted with the part N containing the nozzle, the capacity of which is regulated by an adjusting screw S. By means of the fitting F the dust-conducting tubing is attached to the pipe P; its other end carries the brush-nozzle B or the upholstering tool U. When the engine is running and the throttle V open, the air is sucked out of the tubing, being followed by new air through the brush-nozzle or the tool U, which at the same time carries along the dust being taken off the car body surface.

Westinghouse Electric Vulcanizer

Electric vulcanizers of the portable type are equally applicable in garage work as on high-class automobiles, and the latest type of this tool has been announced by the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa. This vulcanizer comprises a heating plate with a curved surface for casing repairs and a flat one for the vulcanizing of tubes, a fifteen-step rheostat and thermometer for regulating the temperature produced in the heating plate and attachment straps, current being drawn from any 100-125-volt circuit by a standard plug. A flexible connecting cord, 15 feet in length, is included in the equipment. The heat is produced in a metal ribbon which is embedded in mica and hermetically sealed in the heater plate, thereby being shielded from contact with air. The vulcanizer normally consumed from 150 to 175 watts for the repairing of a 36 by 4-inch casing, or about 1.5 amperes on a 110-volt circuit.

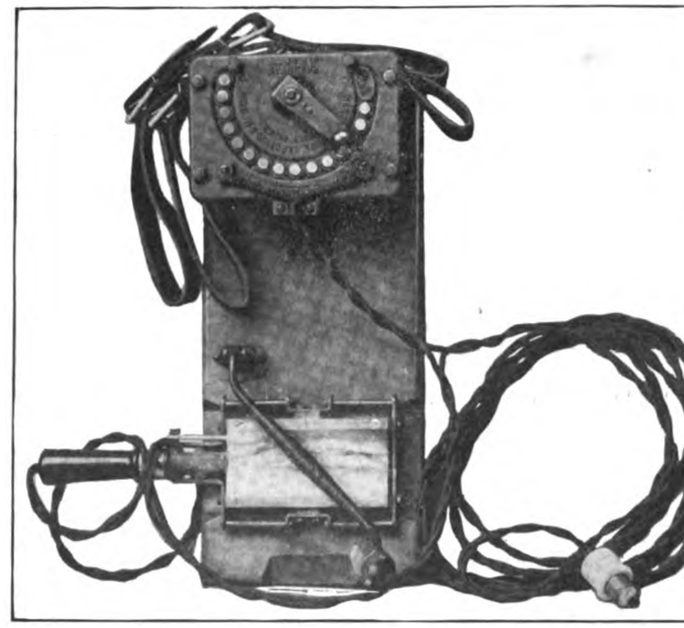

Fig. 6—Westinghouse electric portable vulcanizer for car and garage

About 20 minutes are required to complete the repair. One of the principal points in the operation of the vulcanizer is to keep the temperature at 275 degrees before starting the repair and to keep it there until the work is done. The rheostat with its thermometer permits of easy control of this factor.

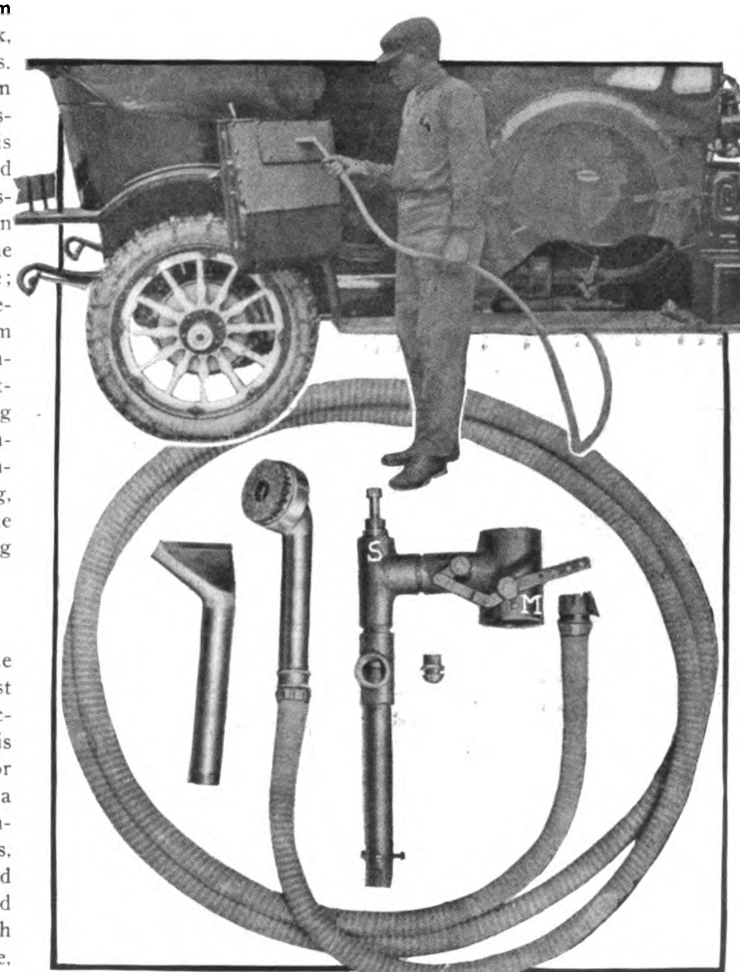

Fig. 7—Vacuum cleaner operated by the exhaust. Fig. 8—Parts of cleaner

AUTOMOBILE Top Construction—Utilizing links so made that the mechanism may be operated quickly and with ease.

The top described in this patent, Fig. 1, comprises two main forward and rearward bows, F and R respectively, which are spaced when the top is open. The lower end of R is attached to the end of a bar, B, whose other end is so pivoted at the car body that the bar points rearwardly. The front bow F is fitted at its lower end with means M for attaching it to the body, and with means M1 for securing it to the rear bow R when the top is closed. Braces B1 and B2 keep the extremities of the top material under tension, while its middle section is taut between the upper end of F and R. To close the top, B is turned through an angle of 180 degrees and B2 is dropped along the path shown by the dotted line; after this the top may be folded back and F be attached to R by engaging M1.

No. 1,041,571—to Clarence L. Bair, San Francisco, Cal. Granted October 15, 1912; filed September 20, 1910.

Wheel-Hub and Shock-Absorber—Springs surrounding bolts which bear against bosses on the axle serve as shock absorbers.

Fig. 2 shows the subject matter of this patent. A pair of spaced bosses B carried by the axle end extend into the annular depression A of a circular plate P. A central depression C opens in the opposite direction, relative to A, and from its center extends a stub axle. A pair of bolts B connect the opposite sides of the annular depression and pass through the bosses, being surrounded by springs S which are interposed between A and one side of each boss. A hub mounted on the stub axle enters C, which is surrounded by a circular extension of the hub. The hub supports a tread surface and the plane of the tread is in line with the centers of the bolts.

No. 1,041,097—to Charles L. Kennedy, Winnipeg, Can. Granted October 15, 1912; filed March 27, 1912.

Driving Gear for Electric Cars—Comprising a suspension for the motor and a worm drive between its shaft and axle.

This patent has reference to a drive for electric vehicles, illustrated in Fig. 3. A suspension S is mounted on an axis parallel to the vehicle axle, so as to be able to rock on the body. The motor M is mounted transversely to this axis; a bearing is mounted to rock on the axle A and is attached to the motor casing, and a shaft S is journaled in the bearing. This shaft has a driving connection with the motor and the axle. The above-mentioned suspension is ring-shaped and is fitted with oppositely arranged trunnions. A groove in the motor casing receives the suspension, and bearings depending from the body support the trunnions.

No. 1,041,450—to William Henry Douglas, Belleville, N. Y. Granted October 15, 1912; filed May 18, 1910.

Two-Cycle Combustion Motor—In which a valve box containing three chambers regulates the distribution of fuel.

The patent refers to a two-cycle construction, Fig. 4, comprising cylinders C, the lower ends of which are connected to an air compression chamber A. Each cylinder is water-jacketed at W, the water being charged into the jacket at a point near the bottom of the cylinder casting. A valve box communicating with the chamber A through the passage P regulates the mixture of fuel and air as well as the admission of the mixture to the cylinder. The box is divided into three chambers—V1, V2 and V3. The central chamber, V1, communicates with A. The upper chamber, V3, communicates with the lower one, V1, which in turn communicates with the combustion chamber when the piston is near its outer dead center. Fuel is fed to V2, and a valve operated by compressed air simultaneously admits air to V3 and fuel to V2.

No. 1,041,154—to Leon Palous, Berlin, Germany. Granted October 15, 1912; filed December 26, 1911.

Pneumatic Tire Construction—Comprising a triple rim, through whose use tread and tube are kept separate.

The tire construction referred to in this patent consists of three rims, an inflatable tube and a solid tread. An inner rim, R1, is concentric with the wheel, and a floating rim, R2, to which a rim, R3, is concentrically fastened, surrounds it, being held in place by the inflated air chamber A. An expansible security band S is held by radial bolts B to the intermediate rim R2, which is kept concentric with R3 by two annular clamping plates C. Bolts pass transversely through the plates C to hold them in place. A tread band T is mounted permanently on the outer rim R3.

No. 1,041,350—to Eugene Richard Riedinger, London, Eng. Granted October 15, 1912; filed July 2, 1912.

Making Tire Cores—Process for the manufacture of a filler for automobile tires.

This patent refers to the making of a tire, consisting in shaping a mixture of crude rubber, sulphur and a gas generator in ring form, wrapping it tightly with tape so that it may fit the core mold. The ring is then placed in the mold and vulcanized; in this way a core of sponge rubber is produced in the tight-fitting envelope.

No. 1,041,377—to Ira F. Trautman, New York City. Granted October 15, 1912; filed October 25, 1911.

VOL. XXVII NEW YORK—THURSDAY, OCTOBER 31, 1912—CHICAGO NO. 18

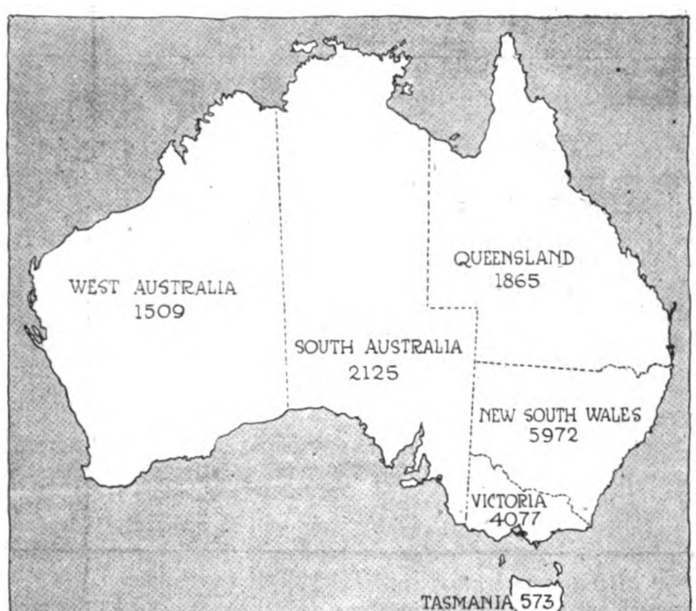
The AUTOMOBILE

Progress of the Automobile Industry in Australian States

Although Comparatively a New Continent and as Yet Largely Undeveloped, Australia Has 16,000 Cars

American Automobiles Already in the Lead and Rapidly Coming Into Greater Favor—American Cars Average 20-25 Horsepower While European Are Only 12-15

TO supplement the statistical information on the automobile industry of the United States and elsewhere already published, THE AUTOMOBILE has obtained figures showing its progress in Australia. Here is a vast continent, 2,974,581 square miles in area, with a population of 4,275,000 and furnishing great opportunities for the automobile exporter who can convincingly demonstrate the value of his wares.



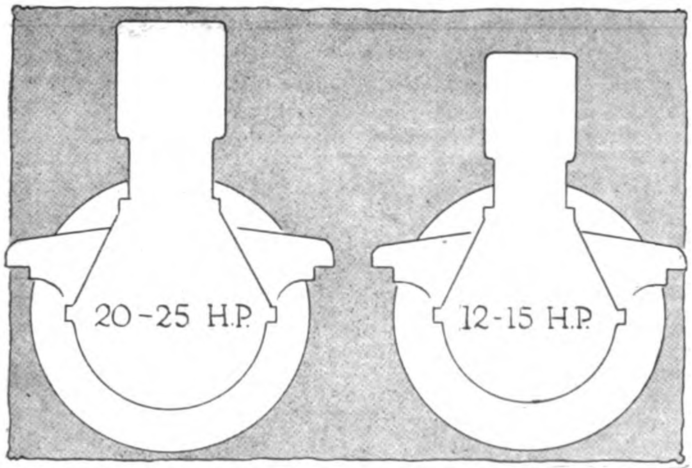
Map of Australia, showing distribution of automobiles in the various states

Many makers, chiefly European, realized the possibilities presented by this territory a few years ago and, having started early, are today reaping deserved benefits. The American manufacturer was too busy at that period with his own domestic trade to afford time for much export development. But with the growth of immense factories and standardized output these conditions are rapidly changing and at the present day the agencies of the various American automobiles established in Australia are doing an excellent business. An American car, in fact, heads the list of sales in all five divisions, or states, the Ford having a total of 900 in use throughout the continent. Second to this car stands an English product, the Talbot, with 700.

Australia is divided into five states, namely, New South Wales, Victoria, Queensland, South Australia, West Australia and the Island of Tasmania. The number of cars registered in each of these states may be seen on the map at the head of this article, while the table on page 872 gives the actual number of the various makes for each state registered up to May 31, 1912. At this date the total for the entire continent was 16,123 cars. This figure includes about 300 commercial vehicles, besides the taxicabs plying for hire in Melbourne. The taxicabs of New South Wales, amounting to about 200, chiefly Napiers, are not included, their registration being separate, whereas in Melbourne the licensed vehicle is registered in the same class as the pleasure car.

Special conditions prevail in Australia and it is possible that these may have caused some hesitation on the part of the exporter, but in this respect the American has the advantage over the European maker, owing to his experience and knowledge of requirements in the West and Canada, where the special needs are more or less closely allied to those obtaining in Australia. The establishment of agencies and provision for the supply of spare parts in wide territory are more familiar and experience has demonstrated their great importance.

A comparison between Canada and Australia is interesting The former has a population of 7,000,000 and has registered 22,000 automobiles, roughly speaking, three automobiles to every thousand of the population. Australia, with a population of just over 4,000,000, has a total of over 16,000 automobiles, which works out on a scale of nearly four cars to each thousand of population.



In Australia the American car averages 20-25 horsepower and the European car 12-15

Comparing the conditions in Australia on the mere basis of cars per population brings out the fact that in West Australia, where there is a car to every 182 people, the ratio between the number of machines and inhabitants is practically the same as in Texas, while the minimum ratio, one car to each 332 inhabitants in Tasmania, ranges between the respective registration figures up to July 1, 1912 for the states of Tennessee and Oklahoma.

An interesting difference between American and Australian statistics is brought out by the ratio of pleasure and commercial vehicles. In the United States there were, on July 1, 1912, some 860,000 cars including 31,600 commercials; while Australia has 300 truck among her 16,123 cars, or one truck to every fifty-four pleasure cars, while in the United States there is a truck to every twenty-seven pleasure vehicles. If, however, the taxicabs used in New South Wales are included among the trucks, the ratio for Australia is one truck to thirty pleasure cars, in other words, very close to that of the States.

The number of automobiles per capita in all the Australian states is shown in the table appearing on page 873. The highest number of cars for every 1,000 inhabitants, that is 5.5, obtains in West Australia, while three cars for every 1,000 of the population holds for both Victoria and Tasmania, the rest of the states ranging between these two limits. The ratios between automobiles and the areas upon which they are distributed are as follows. There is one automobile to every 21 square miles in Tasmania, to every 46 in Victoria, to every 358 in Queensland, to every 425 in South Australia, 520 in New South Wales and to every 646 square miles in West Australia. The maximum ratio for cars per capita goes hand in hand with the minimum ratio of cars per area. This however, is accounted for by the difference in the size of the territories and in the density of their population, rather than by the difference of topographical conditions. Western and South Australia are to a great extent favorable ground, so far as the formation of the same is concerned, while the two smaller states are mountainous. The high ratio of cars per capita is South and Western Australia also seem to indicate that these states are excellent selling ground for automobiles.

The peculiar character of the Australian continent is, if anything, favorable for the introduction of automobiles. Think of a space of almost 3,000,000 square miles, with a coast line 8,800 miles in length, which has only 2,345 miles of navigable rivers. Consider further that what mountainous territory there is in Australia extends parallel with the coast, while the interior of the country is practically one great plateau, excepting one group of mountains in the center of the continent and surrounded by a sandy desert 500,000 square miles in area. Leaving these arid stretches of land out of consideration, there are surfaces many hundreds of miles in size on which settlement has just about begun. In these places, as road building progresses, the automobile has a chance of sharing the business with railroads that are to come. It might even be hinted that nothing but good roads are lacking to make this land a splendid territory for automobiles.

The fact that Australia has a dry climate almost throughout calls for as little use of wood as possible, and for a prolific application of metal in wheels, body, etc. At the same time this end should be realized without undue increase of weight.

Coming to the question of prosperity of this territory, it should be remembered that the agricultural, pastural and timber industries of the five states yield about $3,500,000,000 a year. This leaves fisheries, mining and fuel production, which also are increasing every year. Then, taking all this in consideration, there is a population approximately equal to that of New York City, including one-twentieth who are aborigines, and who uses one-third the number of cars used today in the American Metropolis. This alone should suffice to illustrate the excellent possibilities of an export field which has "just been scratched." But in addition to all this comes a huge and ever increasing commerce, and as the buying public is practically concentrated along the coasts the conditions which permitted of introducing 16,000 cars within a very few years must of necessity be very favorable to the automobile industry.

As is stated in another portion of this article, Australian conditions resemble somewhat those existing in Canada and in the West. This permits of drawing the conclusion that cars should be just high-powered enough to give pleasure to the average driving owner, while excessive power would be a sheer waste of investment and upkeep, due to the prohibitive stand taken by authorities against speeding. Where speed regulations do not exist, the possibilities for speeding are generally absent as well.

LEADING MAKES OF CARS IN AUSTRALIA

Simplicity, strength and accessibilty are three points which cannot fail to attract the Australian purchaser. Cars going to that far territory should be trouble-proof if not fool-proof, for their care will in many cases depend upon men other than mechanics and in a locality remote from such men skilled in the art of handling automobiles.

It will be noticed in the tables that the sales in Australia lie in the direction of the small car. The large, expensively-equipped car is not seen in great numbers. Whether this can be attributed solely to demand cannot be definitely stated, but the more active salesmanship in the small car field may be a factor of more importance than would at first be supposed. The average horsepower of the American car is considerably in excess of that supplied in the cars exported by European manufacturers, the figures being respectively 20-25 and 12-15 horsepower.

Looking over the accompanying table which shows the various cars and their relative numbers as represented in the several Australian states, reveals the interesting fact that the Ford product is fully 200 cars ahead of any other make. While it might not seem reasonable to draw general conclusions from this specific instance, its importance must nevertheless not be overlooked. In addition to the delivery of a fair amount of power, this make of automobile has three points in its favor which admittedly are of great significance in Australian automobiling: These advantages are: (1) light weight and proportionately high power; (2) ample ground clearance; (3) low price, and actual cheapness, that is, good value in proportion to the retail price.

There is hardly any need to argue on the importance of the first point. Light weight means direct economy on tires as well as gasoline. In a country where all tires are imported as ready products, over distances of thousands of miles, the prices of these products are necessarily high, and conditions relating to gasoline are somewhat akin, although Borneo represents a near point of supply. Thus the light weight is in direct proportion to the upkeep of the car, and it goes without saying that in a young country, such as Australia is, when one looks at the commercial side of the matter, money is one of the most precious commodities.

As to ample ground clearance, this appears to be a necessary provision in a car lest trouble is to be courted deliberately. Good roads, though they make progress, are but in their infancy in Oceania, and sufficient clearance is doubly significant on this account as well as because of the necessity of getting down under the car for inspection and repair work.

The point of cheapness has been touched upon before, and its importance is borne out by the table showing the distribution of various products in the various territories. The fact that Renault cars rank second after Fords in number is probably due to the early introduction of this product and the energetic pushing of its business once a momentum had been obtained. Otherwise the difference between the numbers of this

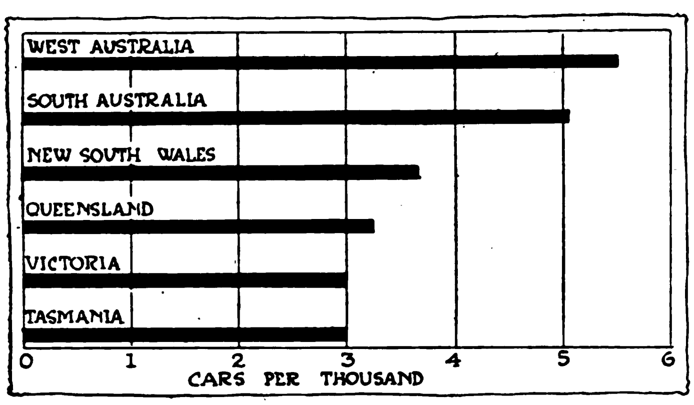

Chart showing relative numbers of automobiles to each thousand of the population in the Australian states

make and, for instance, that of Fiat cars, could not be explained.

Speaking of the advantages of American construction, the accessibility of parts, especially the engine, contrasts favorably with that in the average British design, and, while the amplitude of the power output seems to satisfy male buyers, the weaker sex takes great delight in using our machines on account of the easy riding given by the well-tempered springs. Flat, long springs are looked upon as the most suitable pattern for Australia. To elaborate on the benefit of complete equipment is, of course, unnecessary in these columns. Australians appreciate comfort fully as much as we do.

But, on the other hand, several points in which British cars are superior to ours should be kept in mind. Perhaps the most important among these is the question of wheels. Wooden wheels are short-lived in the dry climate of the interior country and therefore advisable only for use near the coasts. Wire wheels, while they are free from this defect, clog up easily where the cars operate in so-called black soil. The logical solution would be the introduction of a metal wheel different from the wire design, which latter does not permit of protecting the spokes against the soil. Next to this disadvantage comes the alleged weakness of the average rear axle on cheap cars. Australian users claiming frequently that after using the car a short time this member proves not strong enough to stand up under the severe strains which have their cause in the peculiar topography of the country.

In both advertising and methods of salesmanship there is still a good deal to be learned in the Australian automobile field. Sydney, New South Wales, can show some fine and costly garages and salesrooms, but, for the most part, both there and in Melbourne, Victoria, another main center of distribution, the garages are adaptions of old buildings, often quite unsuitable for the purpose. The lighting is generally inadequate and, as a result, it is common practice to run the prospective buyer out into a neighboring park in order to obtain the necessary light for inspection purposes. In Melbourne there is the further disadvantage that the agencies are not centered in any one part of the city, but are scattered. This is a condition of things which will doubtless improve as the sales advance.

The Australian dealer does not seem to make enough use of the capabilities of a car as selling points, but generally refers the buyer to some user who is getting satisfaction in the use of a similar car. This is a perfectly sound line of selling argument, but it need not be the only one.

A serious handicap under which the dealer in Australia labors is the illegality of speed contests. Public interest is therefore difficult to attract, except through the ordinary channels of advertisement. Such tests as the Glidden Tour or club reliability tours are unknown. Now and then there is a hill-climb or a fuel consumption test, but, from the dealer's point of view, these are of little use, for the contests are open only to members of the automobile clubs, which are run on rather conservative lines. Members of the trade, for instance, are not allowed to compete except under the loss of points by penalty as they are considered as professional drivers.

Another fact brought out by the table showing the comparative number of cars of different makes in use in Australia would seem to be the importance of the personal equation as represented by the personal energy of the salesman or agent. No other cause could be given for the difference in number of Ford cars and other low-priced American automobiles. Leaving other things out of consideration, the establishment of an Australian trade for American cars becomes a question of selecting a capable, hustling importer in that territory. There is no more potent means of inducing an agent to make good sales than to insure to him a fair portion of the selling profit. Thanks to our manufacturing conditions, it is easy for the majority of makers to sell their product at a very fair profit to themselves and to the agent, and still sell somewhat below the figure set by the selling representatives of the various European makes of cars. It is due to this fact that some Australian agents who handle two or three European or British makes, as well as a cheap American car, make more money out of the latter than out of all the others combined.

Furthermore, territories are often too extensive to be covered by one man, and in order to do efficient work the importer has to appoint agents or sub-agents which form the connecting link between him and the ultimate purchaser. For this reason, relatively liberal commissions for importer are indispensable if an American manufacturer seeks to introduce his product in Australia.

TABLE SHOWING AREA, POPULATION, NUMBER OF AUTOMOBILES AND RATIO OF CARS TO POPULATION IN AUSTRALIA

State	Area in Square Miles	Population	Automobiles Registered	Population per Automobile	Automobiles per 1000

United States Motor Company Financed by Order of the Court

While Receivers Recommend Scrapping Plants Except Maxwell-Briscoe, Flanders Investigates Property Pending Merger

Court Grants Receivers Permission to Issue $1,500,000 in Certificates to Finance Maxwell Company's 1913 Schedule and Sets Discussion of Decree of Sale of U. S. Motors for November 11

STATUS OF U. S. MOTOR COMPANY

Court orders deposits returned to dealers; provides for settlement of claims that arose between extension and receivership, in all $133,000.

Receivers recommend that all plants be closed down except Maxwell trio and ask permission to issue $1,500,000 of receivers' certificates to finance manufacturing schedule of 1913.

Certificates are a lien on all property but must be applied first to other assets than those of the Maxwell plants.

Application for a general demurrer to the jurisdiction of the court is filed on behalf of Frederick D. Bond, acting for some minority stockholders.

Walter E. Flanders and the United States Motor Company are making examinations of each others' properties in contemplation of a merger when the court tangle is settled.

Court orders decree of sale to be prepared as to form and provides for discussion of the decree November 11.

ROBERTS Walker and W. E. S. Strong, receivers of the United States Motor Company, presented their report to Judge Charles M. Hough, of the United States District Court on Monday, recommending that manufacturing of automobiles be abandoned in all the plants of the company except the three belonging to the Maxwell-Briscoe Motor Company and that the court should give permission for the issuance of a maximum sum of $1,500,000 of receivers' certificates to finance the beginning of the Maxwell 1913 activities.

Not a word was said officially concerning any reorganization and as far as surface indications go, all parties in interest contemplate proceeding toward a sale as the culmination of the present suit in equity which was instituted by the Brown & Sharpe Manufacturing Company.

Mr. Walker read the receivers' report, which was very voluminous, covering forty pages of closely written manuscript. The report described in detail the physical and financial condition of all the properties of the United States Motor Company as outlined in the accompanying balance sheet.

The recommendations of the receivers, so far as finance is concerned, were included in the following list:

To provide for the liquidation of selling companies and the full payment of the local creditors of such selling companies and of the dealers who dealt with such selling companies, where deemed advisable by the receivers.

The indebtedness to local creditors of the selling companies referred to amount to about $140,000 after setting off certain credits. The amount owing to dealers who did business with the selling companies is in the neighborhood of $120,000 net. In all, permission to pay $260,000 net was asked by the receivers on account of the selling companies. It was indicated that such a move would be good business for the embarrassed company because of the valuable assets that would be added to the estate after settlement of the scattered debts of the selling companies; that it would serve to continue the good will, an intangible but valuable element in the situation and that in case of continuance of the business it would make a favorable sale easier than if the usual outlet for manufactured product was eliminated.

The second recommendation was for payment in full to the dealers who made deposits with the United States Motor Company.

It was shown that the company held about $63,000 of such deposits and that just prior to the receivership a virtual trust fund was deposited by the company in the Central Trust Company to provide for the protection of the dealers. The court was asked to construe this fund as a trust fund for the benefit of the dealers. It was also shown that there were certain credits of the company that should be charged against this fund, making the total net amount due the dealers about $29,000. This would leave a credit of about $33,000 for the estate.

The third recommendation was for payment in such manner as may be ordered by this court to creditors who shipped goods or furnished materials or services to the company just prior to the receivership.

In this regard it was shown that claims for about $100,000 had accrued between the time certain materials were shipped to the company or services rendered the company and the appointment of the receivers.

Under the working agreement of the creditors as outlined in their letter of June 18, it was provided that all current indebtednesses of the company should be paid in cash upon delivery. The amount covered by the class of claims included in the recommendation represents materials and services contracted for under the creditors' agreement, that fell due after the recivers took possession. They could not be paid by the receivers without permission of the court.

The fourth recommendation was for continuance of the business. The receivers reported that the Alden-Sampson and Brush companies were closed down except for sufficient activity to maintain the supply of spare parts likely to be required by the cars in service. The Columbia is completing its manufacturing schedule and the receivers recommend that the plant be closed down as soon as the few remaining cars are finished, except that a certain amount of work should be done in the manufacture of spare parts for automobiles in service. The Courier Car Company was pronounced moribund and it was recommended that it remain so for the present. The Dayton Motor Car Company was reported to be finishing its manufacturing schedule for 1912 and it was recommended that the plant be closed down as soon as the present work is ended except for the making of spare parts and repair supplies. As far as the three Maxwell factories are concerned, the receivers recommend that they be closed down also, by or before December 15 unless provision can be made to finance the 1913 campaign.

In this particular it was shown that the United States Motor Company had on hand about $500,000 and sufficient quick assets, over and above the amounts asked in the first three recommendations, to make up about $800,000. That sum with $1,500,000 to be raised by the issuance of receivers' certificates at par, based upon all the assets of the corporation, would in the opinion of the receivers be sufficient to make a good start on manufacturing for 1913 and enough to carry the operations of the company for 3 months.

It was pointed out that the element of time is the vital one in the situation and that even with the utmost celerity it will be necessary to proceed at high pressure in order to retrieve the fortunes of the company.

James N. Rosenberg, attorney for the receivers, explained with much clarity to the court that unless a manufacturing schedule was framed and material progress made at once, the effort would prove futile. He said that it was imperatively necessary that there be a volume of cars ready for market in April and May and a fair supply in March and a few in February. This he said would be impossible to accomplish unless work was begun practically instanter.

The alternative, he pointed out, was that the plants must be closed down and scrapped along with the rest of the properties.

The fifth recommendation was that the court should give such directions as it saw fit respecting the sale of any of the properties or assets.

Objection was made by Judge Bisbee on behalf of the Maxwell-Briscoe creditors to the fourth recommendation as outlined by the receivers. Judge Bisbee stated that the Maxwell company was the only solvent concern of the U. S. Motors and that at a sale as scrap, the property would realize enough to pay its debts. He stated that it would work a substantial injustice to his clients in case the recommendation for the issuance of receivers' certificates should be approved, if the operation so financed developed into a failure. He said that the Maxwell creditors could be paid off at forced sale and that there was an element of chance unjustified involved in case of continuance, where the only solvent company would have to bear the brunt of the risk.

Judge Hough rather leaned toward Judge Bisbee's presentation and for a time it seemed as if a period would be placed to the affairs of U. S. Motors.

After recess Judge Hough took up the question and settled the matter by approving the recommendation of the receivers, but ordering that the lien of the receivers' certificates should be first borne by other companies than the Maxwell and that if, in case of liquidation under the certificates, the properties of the Maxwell company should be applied only to the payment of any balance that might remain after all the other assets had been used to satisfy the liquidation.

While the recommendations of the receivers were approved broadly by the court, the whole tense situation is still under high pressure. Under the order the manufacturing schedule of the Maxwell company will be commenced and in case of a sale the company would have a colorable claim to being a going concern and not scrap. But there are still two hurdles to take before the difficulties can be smoothed away. One, if course, is as to the adoption of the widely heralded scheme of reorganization and the other is to surmount the difficulties outlined in the application made by Judge Van Etter of Ulster County, E. Metzger, Kingston and George A. Knobloch for permission to file a demurrer to the whole proceeding. This action was taken on behalf of Frederick D. Bond, who declares he represents certain minority stock interests.

According to Mr. Bond, one ground taken by the demurrer is that the court has no jurisdiction of the action. He states that the complainant in this case is a corporation having a legal residence in Rhode Island and that the defendant is a New Jersey corporation. The equity suit is in New York and the demurrer holds that it should have been started either in New Jersey or Rhode Island under the federal equity procedure.

A number of additional grounds are also covered in the pleading.

If the court allows Bond to intervene with his demurrer it is conceivable that a considerable delay might take place. In case the application is denied, the right of appeal on the law point might drag in the courts for a long time, even going as far as the Supreme Court of the United States on the constitutional question involved.

At headquarters of the United States Motor Company it was stated that Walter E. Flanders recently had made an inspection and appraisal of the properties of the company and that representatives of the United States Motor Company were at present engaged in examining the Flanders plant in Detroit looking toward a consolidation as soon as the legal tangle in the United States District Court was unraveled.

Deposits of stock and claims under the proposed plan of reorganization is continuing and a tentative limit has been set for such deposits on November 9. It is said that the amount deposited already represents a material amount more than a majority.

Final action on the reorganization will be impossible until some time after November 11, but with such a large proportion of the securities and obligation on deposit it is hoped that it can be consummated without undue loss of time. The action of the court in decreeing to progress with the Maxwell program met with the hearty approval of the attorneys of the creditors.

The balance sheet, showing the aggregate assets and liabilities of the company, as compiled by the receivers will be found in full on page 904.

Judge Hough's opinion as to the recommendations of the receivers was delivered from the bench and was as follows:

The Court: Now with respect to the first application of the receivers, which is as follows:

The liquidation of selling companies and the full payment of the local creditors of such selling companies and of the dealers who dealt with such selling companies where deemed advisable by the receivers.

No general authority to the receivers to deal with all the selling companies will be given now or at any time. In my opinion, circumstances may arise in respect to any selling company, as the word is used in this litigation rendering it advisable for the receivers to liquidate themselves, to act as their own local courts, so they can pay their own local creditors in full, and the receivers are advised to prepare a separate petition as to each and any selling company which they wish to liquidate in the manner suggested.

The second proposition is with regard to payment in full of dealers who made deposits with the United States Motor Co.

In my judgment it has been sufficiently shown that there was an effort on the part of the motor companies shortly before the appointment of these receivers to create a trust fund for the securing of the said dealers who had so made deposits. Entirely irrespective of any question that might arise about deposits made so soon before the appointment of the receivers, it is in my judgment evidently advantageous from a business standpoint, that the claims of those dealers be settled, by offsetting deposits against amounts due, with the net result that there will become available, as I am informed if I correctly understand the receivers, the net sum of $33,000 approximately out of $62,000 now on deposit which is not now available to them in any case. They are authorized and directed to settle this matter in this way.

As to the third proposition regarding a payment to creditors who shipped goods or furnished materials or services in the interval between the creditors' committee circular of June, 1912, and the appointment of the receivers herein on September 12. As to those creditors it is directed that where the receivers are satisfied that any particular goods were not only furnished, but delivered to and used in a certain factory during the period specified, that certain goods and materials may be paid for and charged against that particular factory.

As to the future continuance of the business. It is directed that the receivers have authority for a future continuance of the business along the lines indicated by them in their report. They are authorized to apply for receiver's certificates to an amount not exceeding in the aggregate the $1,500,000 mentioned by them, and in such amounts as they may deem advisable, showing their reasons therefor from time to time, and that upon the issuance of such certificates, and in the order authorizing their issue, it shall be provided that the lien thereof, or payment thereof, shall be made in the first instance on properties other than those of the Maxwell-Briscoe Company, to the end that only in the event of all the other property in the hands of the receivers being insufficient to pay the receiver's certificates shall the property of the Maxwell-Briscoe Company be touched.

As to the sale of the property. It is believed that this property ought to be sold as soon as reasonably can be. The receivers in conjunction with the solicitors for the complainant are hereby directed to draft a decree of sale, concerning the form of which I give more specific directions at this time. That they do this as speedily as possible, not pausing to obtain the formal legal descriptions by metes and bounds of the real property, if any be affected, but drafting such a document as shall so show the scheme of sale proposed. That they serve notice of that proposed form of decree upon the attorneys who have appeared here today, as well as upon any who may be on the formal record on the docket of this court, and that for the purpose of discussing that form of decree an adjourned day of this meeting may be fixed. I would think that two weeks from today would be ample time for that purpose.

Mosler Loses Action

Court Holds That Canfield Patent on Chambered Spark-Plugs is Valid But Not Infringed by Defendants

Laches of Previous Owners of Patent Weigh Against Present Assignor—Case Will Probably Be Appealed at Once

JUDGE Hand, of the United States District Court, has rendered an opinion in the suit instituted by A. R. Mosler & Company against the Auto Supply Company for alleged infringement of the Canfield patent 612,701, covering a type of spark-plug which has a recess around the electrode. The opinion sustains the patent within certain narrow limitations but holds that the defendant company is not guilty of infringement.

The reasoning adopted by the court is based upon the fact that Canfield, a pioneer in the automobile industry, really devised a patentable element when he produced spark-plugs of the kind covered by the terms of the patent. Canfield, however, disposed of his patent in 1902 and later it was assigned to the Torbenson Company and afterward to the Association Patents Company, subsidiary of the old A. L. A. M. There it remained from 1906 to 1909, when Mosler purchased it.

The ruling that the patent was not infringed is based upon the fact that under the construction of the court, Mosler himself manufactured a type of spark-plug that came within the claims of the patent, long before he acquired any interest in the patent.

The words of the court are as follows:

"The suit is really against the (six) manufacturers, but whether against them or not, defendant and others have been notoriously selling these goods to a large extent for a number of years.

"Here then we have a situation where nothing was done by the patentee or his assignees for 11 years, while others risked their money in putting on the market an improved and very important device, in an industry which has developed by leaps and bounds and which has revolutionized travel for pleasure and utility. While the public has been getting the benefit of the use of the devices and the competition between the manufacturers, the assignees of this patent have sat supinely by, not even bringing one suit against any one of the many open alleged infringers.

"Then comes along an ex-infringer, on its own theory, who has bought the rights under this and another patent and asks a court of equity to fill its treasury with license fees and damage money.

"It is no excuse that complainant obtained its title only in 1909. Its claim is affected by the laches and want of equity of its assignors.

"The court will go a long distance to protect the inventor who is ahead of his times and who, unable to interest capital, finds that some one has stolen the fruits of his genius. But that is not this case.

"The patent is sustained within the limits herein dictated and it is held that there is no infringement. The bill is dismissed with costs."

Boston Electric Show a Success

BOSTON, MASS., Oct. 28—Boston's big electric show closed Saturday after 4 weeks of remarkable success, during which it is estimated that there were 500,000 in attendance. And of all the exhibitors who were pleased at the amount of business done none was more so than the men who handle the electric vehicles in Boston. Those dealers who had commercial vehicles alone found that there were innumerable places in New England where business men could utilize trucks. This was brought home to them through the co-operation of the men at the heads of the various electric light plants in the cities and towns of the New England states.

The Edison Company of Boston, the real power behind the show, had made arrangements so that the managers of the electric plants in the New England districts were allowed to give complimentary invitations to business men who used electricity or were possible users of it. With the railroads co-operating so that special excursions were run from all sections it brought to Boston to the show thousands of people each week. So out of all these visitors there were many who were anxious to get a line on what was new.

That electric motor cars would be shown was expected by some, but the greater number were surprised to find the big commercial vehicles right on the main floor. To many of these visitors motor trucks were associated with gasoline in their minds because of the fact that they had not seen any other vehicles in their territory except those operated by gasoline. So they made inquiries and examined the trucks. The dealers did the rest, for they showed how easy it was to get current from the lighting companies.

The Electric Vehicle Club has arranged now to meet every week at a luncheon at some hotel or club, and once a month have a meeting at night.

Creditors Take Charge of R. C. H.

DETROIT, MICH., Oct. 30—The condition of the business of the R. C. H. Corporation was fully disclosed to the stockholders and merchandise and money creditors at a meeting at the Pontchartrain hotel, this city, October 25.

The meeting was largely attended, the creditors present representing an indebtedness of the corporation of $1,600,000. Plans for the refinancing of the company were discussed at length and an agreement was drawn up between the creditors and the R. C. H. Corporation whereby the latter's affairs will in the future be in the hands of a creditor's committee of nine, the former directorate consisting of three.

Sixty per cent. of the capital stock is to be under the direct control of three men chosen from this committee of nine under the terms of the agreement. It was pointed out that this was done in order to protect the concern in the event of the death of the Hupp Brothers, owners of a large proportion of the stock. This agreement is to be submitted to the stockholders and creditors for their formal ratification the latter part of this week.

November 8 when the directors of the R. C. H. Corporation meet, it is expected that the entire plan will be finally adopted. The six directors who have been placed on the directorate become practically debenture holders, but it is expected that all obligations will be cleared away within the next 18 months.

The condition of the concern's affairs may best be explained by the fact that it has grown too rapidly for its capitalization. At the present time the corporation's books shows assets over liabilities of $576,000, according to the auditing of MacPherson, Weiss & Company, certified public accountants. Domestic and foreign contracts for some 16,000 cars are in hand.

The production at present is normal, the concern having 417 cars in stock at Detroit and its branches. Materials for about 1,000 more cars are at the factory. During September, 617 cars were shipped while thus far this month 342 have left the shops. By the adoption of this plan the output of the plant will not be curtailed in anyway, and at the same time the corporation's financial position will be made secure. Although the members of the new directorate have not yet signed the agreement, all are favorable to it. It is understood that the following nine will compose the committee: John Kelsey, Kelsey Wheel Company; J. F. Hartz, C. F. Hall Lamp Company; H. S. Firestone, Firestone Tire & Rubber Company; J. H. Clark, attorney; C. A. McCutcheon, American Gear Company; F. M. Randall, C. H. Fuller Company; J. H. Sieberting, Goodyear Tire & Rubber Company; C. P. Sieder, Sieder Manufacturing Company, and R. C. Hupp.

Truck Space Allotted

Practically All Ground Floor Space for Chicago Commercial Vehicle Show Divided Among 65 Makers

American-La France to Reorganize—Milwaukee Dealers Elect Officers—Denver Wants Place on Transcontinental Highway

NEW YORK, Oct. 26—Sixty-five commercial motor vehicle makers have been allotted space in the Chicago show to be held in the Coliseum, Coliseum Annex and First Regiment Armory. All of the ground floor space in these buildings has been absorbed excepting two of the least desirable, and there is a waiting list of six for these.

Last winter the show opened with eighty-two exhibitors of complete vehicles and chassis, but at the October drawing the allotments were smaller and only three or four companies went into the Armory, which, however, filled up later.

Those concerns on the waiting list are: Mogul Motor Truck Company, Chicago; Mercury Manufacturing Company, Chicago; H. J. Koehler Sporting Goods Company, New York; Ideal Automobile Company, Ft. Wayne, Ind.; Kentucky Wagon Manufacturing Company, Louisville, Ky.; Ware Motor Vehicle Company, St. Paul, Minn.

American-La France Seeks Capital

ELMIRA, N. Y., Oct. 26—In order to provide the concern with $600,000 additional cash capital, the American-La France Fire Engine Company, of Elmira, N. Y., is considering complete reorganization. The plan proposed by the fiscal agents of the engine company provides that the present bondholders will receive 100 per cent. in 7 per cent. preferred stock of the new concern with a bonus of 33.3 per cent. in new common stock. The preferred stockholders are to receive 50 per cent. in the new preferred stock and 33.3 of common, while the present holders of common stock will receive 30 per cent. in new common. With the $600,000 new preferred stock to be sold at par there will be a bonus of 100 per cent. of new common, this being offered to present stockholders on a basis of four shares of preferred to every 19 shares of the old preferred and two shares of new preferred to each 10 shares of the common.

M. A. D. A. Elects Officers for Year

MILWAUKEE, WIS., Oct. 28—Isaac G. Hickman, president of the Hickman-Lauson-Diener Company, state agent for the Ford, was re-elected president of the Milwaukee Automobile Dealers' Association at the annual meeting held on October 23. Emil Estberg, representing the Pope-Hartford and Waverly electric, was re-elected vice-president. George P. Hewitt, proprietor of the Wisconsin Auto Sales Company, Cutting, National, Westcott, Herreshoff, Little and Chevrolet agent, was elected treasurer, succeeding August A. Jonas. A. E. Raffauf, of the American Automobile Company, Pierce-Arrow agent, was re-elected secretary. The executive board consists of Messrs. Hickman, Estberg, Hewitt, Raffauf and Alton J. March, of the Curtis Auto Company, Reo representative.

Although the association wound up the fiscal year of 1910-1911 with a comfortable surplus in the treasury, reports at the last annual meeting showed a huge deficit, due to the promotion of the Vanderbilt cup races at Milwaukee this year. The association has twenty-two active members, consisting of the principal dealers in Milwaukee county.

Denver Seeks Place on Through Route

DENVER, COLO., Oct. 28—As a vital step in a persistent campaign being carried on by the Denver Chamber of Commerce, the Denver Motor Club, the Colorado State Highway Commission and other organizations, to have this city placed upon a great transcontinental highway, a trip to mark out the Denver-Salt Lake City section of the projected Midland Transcontinental Route was started this week by Charles M. Kittredge, Jr., assistant secretary of the Chamber of Commerce, and A. L. Westgard, official map-maker for the American Automobile association, New York City. Kittredge is acting as official representative of both the Chamber of Commerce and the Motor Club.

Punctureless Tire Plant Planned

DETROIT, MICH., Oct. 28—A new rubber company with capital close to $1,000,000 is reported to be planned by interests in this city and in Cleveland. It is proposed to manufacture tires which will be non-puncturable and blow-out proof, and which are the patented invention of Arthur Elliott, of Cleveland. Three patents have been issued to Mr. Elliott covering a lap-lock base, straight side walls and steel band inner liner for the tire shoe. It is understood that several rubber men are interested in the venture which is contemplating the building of a factory either in this city or in Cleveland. Negotiations are being carried on here by Charles Ritter, while the Cleveland representatives are the Standard Sales Company.

To Make New Carbureter and Clutch

DETROIT, MICH., Oct. 28—The Sprung Carbureter & Clutch Company has been incorporated to manufacture the patented devices of Edmund Sprung, which consist of a carbureter and a clutch. The former is a three-jet type, the throttle lever connecting with a sleeve which goes over the jets and which uncovers more of them as the throttle is opened. The incorporators are: Edmund Sprung, Wm. Healy, and J. S. Kennary.

Recent Legal and Trade Developments

Court Denies Injunction Against Connecticut Shock Absorber Company But Imposes a Bond for $20,000

Government General Supply Committee Opens Bids for Furnishing Federal Departments

THE United States District Court at Trenton, N. J., has denied the motion recently made by the Hartford Suspension Company for a temporary injunction against the Connecticut Shock Absorber Company in the suit of the Hartford company against Ellis, an accessory dealer of Newark, N. J., charging infringement of the Truffault patents. The court, however, imposed a bond of $20,000 upon the Connecticut company, despite the fact that the order dismissed the motion for an injuncton. The Connecticut company asked leave to intervene and defend the action and the court granted the motion.

The procedure with regard to the reason for asking a bond where the motion for injunction was nominally denied attracted a large amount of interest not only in the industry but among the legal fraternity as well.

Bids for U. S. Truck Business

WASHINGTON, D. C., Oct. 29—*Special Telegram*—The General Supply Committee of the Federal government today opened bids for furnishing various government departments with motor trucks. While only six trucks will be purchased under this opening, it is intended to use the figures submitted as a basis for further purchases. The amounts of the various bids will not be made public for several days.

Streator Assets Show Margin

CHICAGO, Oct. 28—No definite policy as to the future has been outlined as yet by the Streator Motor Car Company, of Streator, Ill., maker of the Halladay, which last week was placed in charge of a receiver, the Central Trust Company. The plant is being operated by the receiver and it is expected that by the end of the week the officers of the company will be in a position to issue a statement as to their plans. It is stated that whereas the company's liabilities are in the neighborhood of $225,000, that its assets will total $400,000.

N. A. A. M. to Meet in Detroit

DETROIT, MICH., Oct. 28—The National Association of Automobile Manufacturers has given out the complete program of its first mid-year meeting which takes place in this city November 13-15. The first day will be devoted to business meetings of the board of directors of the N. A. A. M. and of the Automobile Board of Trade. On the following 2 days, papers by a number of prominent figures in the industry will be read, as follows:

November 14—Morning: "The National Association—What Has Been Accomplished and What Can Be Accomplished," S. A. Miles; "Multiplicity of Models," G. W. Bennett; "Some Selling Problems," Hugh Chalmers; "Yearly Models," C. C. Hanch.

Afternoon—"Relation of the Volume of Motor Carriage Business to the Volume of Commercial Car Business," David Beecroft; "The Commercial Car," S. D. Waldon; "Why All Manufacturers Should Use the Standard Warranty," Walter C. White; "Traffic," J. S. Marvin; "Injudicious Methods of Selling Commercial Vehicles," M. L. Pulcher.

November 15—Morning: "Good Roads," R. D. Chapin; "Territory and Discounts," E. R. Benson; "Labor Conditions," H. M. Leland.

On the evening of November 14, a banquet will be tendered to the visitors by the Detroit members of the Association at the Pontchartrain Hotel.

The N. A. A. M. now has 101 members, having added seven at the last meeting. The new members include the following: T. J. Toner, Flanders Manufacturing Company; P. D. Schenck, Speedwell Motor Car Company; Frederick A. Brand, Broc Electric Vehicle Company; U. D. Grannis, Borland Grannis Company; Carl J. Metzger, Argo Electric Vehicle Company; V. De Palmer, Michigan Buggy Company and A. H. McFarlan, McFarlan Carriage Company.

Swinehart St. Louis Company Ready

ST. LOUIS, Oct. 26—Articles of incorporation were filed recently by the St. Louis Tire and Rubber Company, with a capital stock of $150,000 fully paid. The company is to use a building in University City, which was formerly used by one of the E. G. Lewis companies. Harry C. Barker, one of the directors of the new company, stated that the company expects to be turning out all kinds of automobile tires in about 6 weeks.

The concern will be managed by J. A. Swinehart, formerly of Akron, O. The contracts with him and the patents are placed

Automobile Securities Quotations

Stock prices declined throughout the list of automobile and accessory securities during the past week. There were only three issues that advanced and they were tire stocks. Goodyear continued its remarkable strength making new high records almost every day of the week in anticipation of a wonderfully good annual report and the possibility of a juicy melon to the stockholders. Firestone also advanced smartly and the quotations of the Miller company were pegged up. Trading in the listed securities on the New York Stock Exchange was small in volume and generally at lower figures. American Locomotive, Goodrich, General Motors and Studebaker were all off from a fraction to a point or more on account of European liquidation consequent upon the Balkan uneasiness. The list follows:

in the capital stock at $59,100 while the balance is subscribed in cash. Swinehart, the largest individual stockholder, has 900 shares of stock and the other six who have been named directors each have 100 shares. They are: Harry C. Barker, C. M. Skinner, A. C. Einstein, W. H. Glasgow, Roy F. Britton and C. C. Collins.

Contracts will be let in a few days for the erection of an addition to the present building 30 x 100 feet in which will be placed the heavier machinery. All the machinery necessary for the operation of the plant has been received and the work of installation will start immediately.

Crude Rubber Declines 2 Cents

Crude rubber worked lower during the past week with purchases confined to the minimum of requirements and offerings checked in view of the known character of the demand and the hope that extensive buying will be forced in the more or less distant future. The level for up-river fine declined to $1.05 with pale crêpe at $1.02 1-2. This is a decline of 5 cents a pound for up-river since mid-September and 15 cents a pound for pale crêpe. The basic reason is to be found in the increasing shipments of plantation rubber. The trade would not be surprised at some immediate strength in the market but the prevailing opinion is that lower levels are to be expected because of the larger supply becoming available. Receipts at Para are estimated at 2,316 tons for September, which is well in excess of last year and about what the trade expected.

Market Changes of the Week

The most important features of the week's market was the decrease of lead cottonseed oil, and rubber, and the increase of Bessemer Steel, Open-Hearth steel, and scrap rubber. Lead dropped on Friday to $5.00 per hundred pounds, and remained at that figure to the close of the week, with a loss of $.07 1-2. Cottonseed oil dropped $.31 due to the inactiveness of trade, closing $5.67 a barrel. Bessemer steel and Open-Hearth steel experienced a $.50 gain in price, due to the large contracts by the steel companies for those products, Bessemer closing at $28.00 a ton, and Open-Hearth at $29.00. The rubber markets were weaker, due to quiet trading. Here in New York consumers either held aloof from the market or limited their purchases to comparatively small quanities for early use. Jobbing sales were reported on the basis of $1.04 for up-river Para, a decrease of $.02 from Wednesday's price.

Rise in Oil May Be Reflected in Steel

Tremendous Consumption of Petroleum Products by Automobiles, Etc., May Affect Cost of Steel Processes

Price of Fuel Oil Used in Steel Mills Has Advanced 50 Per Cent. Within the Year

CHICAGO, ILL., Oct. 28—According to Standard Oil reports, the motor car is responsible for a revolution in the steel manufacturing processes now in vogue. This may result in higher prices for steel and crucible steel castings. The cause is laid to the immense consumption of the higher grade products of petroleum principally by motor cars, and by motor boats, ocean vessels and locomotives. Fuel oil, which is the residue left after the distillation of gasoline, benzine, naptha and kerosene, is at present used in enormous quantities. The Inland Steel Company uses 2,000,000 gallons of the oil per month, the International Harvester Company, 120,000 barrels per year, and the Illinois Steel Company, which formerly was a heavy consumer of this fuel, foreseeing the result of the steadily increasing prices, has been changing to other methods, and now uses very little.

Fuel oil is used extensively in the manufacture of glass, brick and tile, and in forging, annealing and founding of steel. It is preferred for the latter uses because of the absence of sulphur fumes in burning, which must be constantly guarded against in the use of other fuels. These fumes have a very injurious effect on steel, making it more brittle.

The changes necessary, according to estimates made by G. H. Jones, vice-president of the Inland Steel Company, will cost that company from $400,000 to $500,000, the cost to the industry therefore, in the aggregate, will probably run into the millions of dollars, which can only be met with by an increase in the price of steel, in all the forms affected.

The Standard Oil Company has given formal notice to the principle consumers that the Whiting refineries can no longer supply the fuel oil that they have in the past. This is taken to mean, by some, that the Standard Oil Company has discovered a process of refining by which a higher percentage of the crude oil can be turned into the better grades, and hence more profitable, kinds of oils and distillates. At present the price of fuel oil has advanced 50 per cent. within a year, which fact would eventually force steel manufacturers to abandon its use in favor of producer gas, without the edict of Rockefeller's minions.

The price of western fuel oil at present is about 2 1-2 cents per gallon, while Pennsylvania prices are prohibitive. It is said that California oils would cost from 10 to 12 cents per gallon in Chicago.

Cotton Makes the Cars Go

NEW ORLEANS, Oct. 28—Sales during October have exceeded any single month in the history of the industry in this city and tributary territory. A large cotton crop is the basis of the general prosperity which the South is enjoying. The growth of the trucking business within a radius of 100 miles of the city is proving a great source of wealth and is having a direct influence on the motor car industry, as many of the owners of truck farms live in the city and have to make frequent trips to and from the properties.

Some Elements to Be Considered in the Choice of Inlet and Exhaust Valve Sizes Discussed by Von Löw—Also the Equal Distribution of Gas Mixture to Cylinders—Fischer's Motor and Change-Gear—Wheel for Heavy Loads

INLET and Exhaust Valve Dimensions—The successes accomplished here and there in raising poppet valve motors to the same maximum power which is obtained with the best sleeveless motors of the same cylinder dimensions, or even above it, have led to renewed investigations of the proportion in valve dimensions which should be expected to fill the cylinder as completely as possible with the explosive mixture, it being understood that all the advantage of the sleeve-valve construction in the matter of power depends upon a superiority at this point. A study by Freiherr von Löw on this subject is rendered in substance in the following:

The views of constructors vary widely on valve diameters and gas velocities, as will appear from the appended table giving certain data of three representative German cars:

		Benz 1910	Adler 1910	Horch 1908
1	Rear wheel diameter	0.8 m.	0.8 m.	0.8 m.
2	Rear wheel circumference	2.5 m.	2.5 m.	2.5 m.
3	Rear wheel revolutions per kilometer	400	400	400
4	Bevel gear, numbers of teeth	25 + 62	19 + 55	13 + 42
5	Bevel gear, ratio	1 + 2.48	1 + 2.89	1 + 3.23
6	Revolutions of motor shaft at 60 kilometers per hour vehicle speed, direct gear	996	1156	1292
7	*V-max.* = highest average speed on level 8 kilometer stretch	134 km./hr.	125 km./hr.	89 km./hr.
8	*t-max.* = r.p.m. at *V-max*	2217	2412	1913
9	*h* = piston stroke	175 mm.	150 mm.	120 mm.
10	$v = \frac{h\pi}{60} \times$ *t-max.* = highest piston speed	20.1 m/sec.	18.8 m/sec.	11.9 m/sec.
11	*d* = diameter of bore	115 mm.	105 mm.	85 mm.
12	$F = \frac{d^2\pi}{4}$ = piston area	104 cm.²	87 cm.²	57 cm.²
13	*q* = area of inlet valve	44 cm.²	16 cm.²	12 cm.²
14	Area of exhaust valve	21 cm.²	16 cm.²	9 cm.²
15	Gas current velocity in inlet valve = $\frac{F}{q} \times v$	45 m/sec.	102 m/sec.	57 m/sec.
16	Current velocity in exhaust valve	92 m/sec.	102m/sec.	76 m/sec.

[The exhaust velocity, it will be noticed, is given without reference to the expansion of the gases which takes place in the exhaust valve.—Ed.]

As this table shows, Adler makes the inlet and exhaust valve diameters alike and reaches a gas velocity of 102 meters per second at a vehicle speed of 125 kilometers per hour. In the Benz car the inlet valve area is about twice as great as that of the exhaust valve and the inlet gas velocity is 45 meters per second with a vehicle speed of 134 kilometers. And in the case of Horch the inlet and exhaust valve areas are as 4 to 3, while the inlet velocity is 57 meters per second at 89 kilometers per hour.

The most favorable proportion between the two diameters can probably only be determined by systematic tests, but certain things which are to be considered in the choice of the diameter may be deduced by mere reasoning with the aid of charts. In Fig. 1 *aa* represents atmospheric pressure and *vv* a complete vacuum, while the pressure variation during the larger portion of the exhaust stroke is shown in line 1-2. At the point 2—when the piston has reached dead center at the end of the exhaust stroke—atmospheric pressure has not yet been reached; the gases in the combustion chamber retain a tension represented in line 2-3 owing to strangulation in the exhaust valve. When now the piston begins its new stroke these gases will first expand and atmospheric pressure will only be reached at point 4, and here, then, begins the real induction stroke. The line 3-4 represents the volumetric loss of explosive mixture at the beginning of the induction stroke. (Even if the inlet valve is opened as early as at the dead center, so that the tension 2-3 can expand into the induction pipe, this will make no difference, for the expansion of the exhaust gas into the induction pipe will push the fresh mixture back and the latter will not reach the cylinder till the piston is at point 4, and the expedient of leaving the exhaust valve open after the dead center is considered later.)

It is now to be examined what the effect will be of the same degree of strangulation at the end of the induction stroke. Under this condition the shortcoming in reaching atmospheric pressure, represented in line 5-6, must be equal in tension value to the pressure represented in line 2-3. The induction valve is supposed to be closed at dead center, and now the compression stroke begins from point 5. As the compression curve at this point rises much more slowly than the expansion curve falls from 2, the considerable volumetric loss represented in line 6-7 is suffered at this point, and it is noticed that this loss is about six times as great as the loss 3-4 sustained at the beginning of the induction stroke. [The proportion in the losses is about the same as between the volume of the combustion chamber and the total cylinder volume—usually 1 to 6.—Ed.]

It is hereby shown that with equal strangulation of the gas in the two valves the volumetric shortcoming in explosive mix-

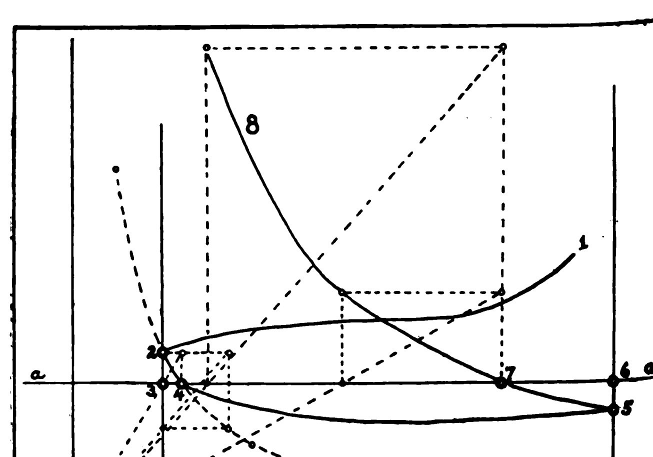

Fig. 1—Diagram showing exhaust (1—2), induction (4—5) and compression (5—7—8) curves; valves opening and closing at dead centers and being of equal diameters and lift

ture caused by the strangulation in the induction valve is decidedly larger than the loss caused by strangulation in the exhaust valve. And as these losses may be reduced, to be sure, by deferred closing of the valves, but never can be quite obviated, it seems that it should be correct to make the inlet valve larger than the exhaust valve, in accordance with the design of Benz and Horch in the above table. It is also notable that among racers those which may be considered the most important have been won with motors having the induction valves larger than the exhaust valves. [It probably does not escape the reader that, in addition to valve diameters, the valve lift and the current-energy may also play a part in determining the degree of strangulation to which the flow of gas is subject.—Ed.] On the other hand, it must be said that the leaders in the matter of enlarged inlet valves—Daimler and Horch—have lately gone back somewhat on this design; for the Daimler company now builds aviation motors mostly with valves of the same size and Horch has in his new Audi cars made the diameters equal. Lehmbeck and Isendahl in their book *Design and Calculation of Automobile Motors* recommend even to make the exhaust valve diameters twice as great as the inlet valve diameters, evidently with a view to the increase in the volume of gas caused by the explosion.

EFFECTS OF GAS CURRENT INERTIA

As already referred to, the cylinders can be filled more completely by deferring the closing of valves. This effect depends in the case of high-speed motors mainly on the expansive energy and momentum of the moved gases. But the opinions of engineers vary as much on this subject—how much the valve closure should be retarded—as they do on valve diameters. An interesting table in the book by Lehmbeck and Isendahl (opposite to page 70 in the second edition) shows that in twenty-eight motors the retardation of closure varies from 0 to 49 degrees after dead center for the inlet valve and from 0 to 22 degrees for the exhaust valve. In the case of multi-cylinder motors it may even be justifiable on account of current-momentum at high gas velocities to arrange the opening and closing of the valves differently for the different cylinders, because the customary inlet manifold for four-cylinder motors, on the plan indicated in Fig. 2, does not render an equable distribution of the gas charge to the cylinders possible. An equable distribution may perhaps only be effected by an arrangement of the manifold as shown in Fig. 3.

On the plan of Fig. 2, cylinder 1 must set the gas in the left portion of the manifold in motion, but cylinder 2 finds it already in motion and therefore gets more gas if the valve regimen is the same. The cylinder marked 3 is the next one to act, and the gas now stops moving in the left portion of the manifold and begins to move in the right portion where cylinder 4 gets more gas than cylinder 3. Whether this "more-or-less" element is a matter of practical importance may easily be decided by experiment, for example, by first cutting out the spark from the inner cylinder of a pair and afterwards from the outer cylinder. The suctions remain unchanged by this proceeding while it should be shown plainly, with a dynamometer, to what extent the power varies. A manifold on the plan of Fig. 3 gives no rise to stoppages in the currents. Cylinder 1 draws the larger part of its charge from the left branch leading from the carbureter V, but, as cylinder 4 was in action just before it, there will also be a current toward it of the surplus gas remaining in the pipe which leads to 1 from 4. When cylinder 1 ceases to draw, the gases set in motion by it move farther to cylinder 2 and, when this ceases to draw, they move farther to cylinder 3, both 2 and 3, however, also drawing directly from the carbureter, and when the valve of 3 is closed, the current moves on to cylinder 4, and so on. Through the uninterrupted flow of the gases losses otherwise caused by current-momentum are thus avoided.—From *Zeitschrift d. M. M. Vereins*, September 15.

SMALL Swiss Car with Valveless Motor—Among the vehicles which depart from the customary type the Martin Fischer car, which is made at Zurich, Switzerland, has attracted attention by a workmanship which is declared most admirable in conjunction with design features which appear at first glance preposterous. The different gear speeds are obtained for example, by taking a pinion mounted on the rear end of a short driving shaft, which is coupled to the clutch shaft by means of a universal joint, to any one of three internal gears of different diameters, all of which are formed in a disk of hollow conical formation, and this disk connects by a universal joint (with a transmission brake) with a driving shaft of the ordinary type, so as to take the power farther to the rear axle. The smallest of the internal gears, which of course is in the center of the disk, is of the same dimensions as the pinion, which therefore simply fits into it, the two parts forming a positive clutch giving a direct drive without any gear transmission whatever. In order to bring one of the other gears into action, shifting forks of the usual kind are made to displace, longitudinally, a bearing-block in which the rear portion of the short driving shaft rotates, and this movement in conjunction with a cam-plate brings the pinion on the end of the shaft into mesh with one of the internal gears. The construction is evidently intended for a vehicle which may be driven practically all the time on the high gear, as continued driving on any of the other gears involves a considerable angular deflection of the short driving shaft and consequently much wear of the universal joint. The clutch in this vehicle is an open multiple plate clutch composed of alternate fiber and brass or bronze disks and is operated without lubrication. The gear-box, containing the universal joint and the short driving shaft

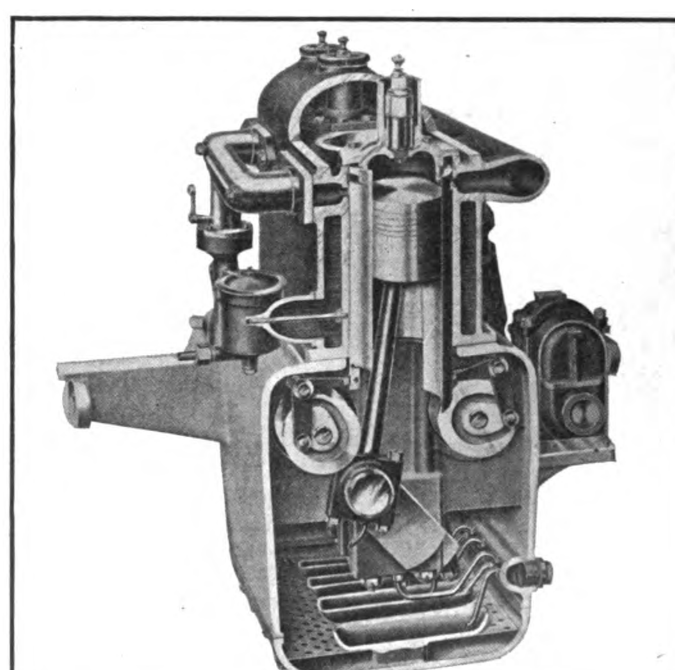

Fig. 4—Section through the Martin Fischer valveless motor

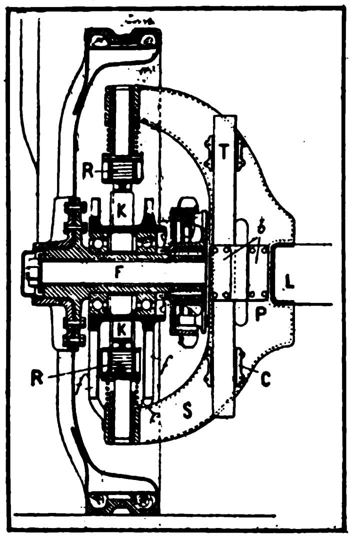

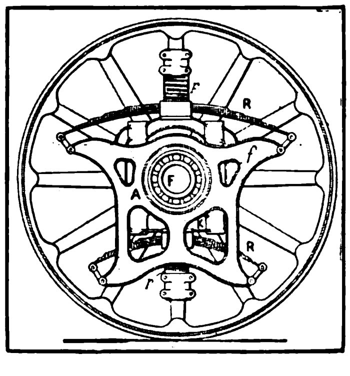

Figs. 5 and 6—Section and partial side view of the Heilmann truck driving wheel as made for vehicles with chain drive. The spring suspension is in the wheel plane and axles are dispensed with

with bearing-block, cam-plate and locking provisions, is located immediately behind the clutch, suspended at three points.

The motor used in this car is shown in Fig. 4. The cylinder bore may be conceived as a cylinder with two opposite bay windows of crescent-shaped cross-section. In these enlargements of the bore two valve bodies of the same section are ensconced, so as to leave an exactly cylindrical bore for the piston, as usual, and they are arranged to be moved up and down by the means plainly shown in the illustration, one operating the inlet and the other the exhaust of gases by means of ports at their upper ends. They enclose each only about one-fourth of the piston surface, so that one-half of the cylinder wall has the same chance for being properly cooled as in a poppet valve motor, and with a view to the same purpose of safeguarding the cooling—which has proved the most difficult feature to bring into permanent working order in sleeve-valve motors in general—an elastic ring above the combustion chamber assists the piston rings in pressing the two valve segments tightly against the built-out portions of the cylinder wall, at the same time securing the compression. The enlarged surface in contact with the cooling water also helps to bring about the desired thermic condition. Manufacture of the valve segments is facilitated by producing them in one piece and afterwards splitting this into two perfectly symmetrical halves. This motor has been operated successfully but no data are at hand with regard to its efficiency.—From *Auto-Technik*, September 13.

HEILMANN'S Truck Wheel—A wheel intended for use on trucks of heavy load capacity has, after several years of experiments, been so far perfected as to attract favorable notice from the technical committee of the Automobile Club of France. It is designed by a Mr. Heilmann, well known as a prolific inventor and especially as the designer of an electric locomotive. Its construction is shown in Figs. 5, 6 and 7. The objects of the construction are to dispense with the use of axles, to bring the load directly in line with the wheel plane, to permit the lowering of vehicle body and load and the increase of wheel sizes, and to reduce the swaying of the vehicle body and the load, not only by lowering the center of gravity but especially by increasing the width between springs and to improve the spring suspension.

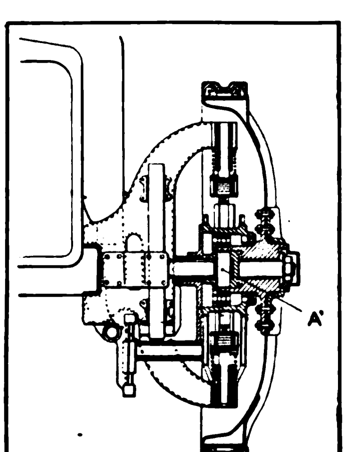

Fig. 7—Heilmann front truck wheel

The spindle F receives the hub of the wheel and is integral with the sliding pieces T which have a vertical movement in the guides C upon the heavy U-shaped bracket S, the latter being securely riveted to the vehicle frame L. Guide plates P in friction contact with bronze bands *b* assist in maintaining alignment and transmitting traction effort to the chassis. The springs are placed between the wheel hub and the ends of the bracket. Special precautions are taken to insure that the spring action shall always act accurately in the plane of the wheel. To this end, there is mounted upon the wheel hub proper, which has a long parallel, bearing upon the spindle, another hub revolving upon a double row of ball-bearings. This second hub comprises a middle portion A carrying two stems which are guided vertically in the frame K and are located in the central plane of the wheel. On each side pressed steel horns *f* support the ends of leaf springs R. The frame K serves to join the two spring clips and is continued above and below in the form of rods which are clamped in the arms of bracket S. Intermediate portions of them serve as guides for helical springs which are stiffer than the leaf springs.

The front wheel requires a somewhat different construction which may be figured out by an analysis of Fig. 6 showing a divided spindle and a pivot pin A upon which the outer portion of the spindle may turn, while the shaft portions of frame K are also journaled in the ends of the bracket S. The construction seems to be too complicated to enlist serious interest in its details but at least shows to what lengths a capable mechanical mind finds it necessary to go in order to find a supposedly acceptable substitute for current construction in the matter of the running-gear for automobiles.—From *Bulletin Officiel*, September.

ELECTRIC Smelting Ovens—The Sweedish *Elektrometal* company has patented the method illustrated in Fig. 8 foı smelting iron and steel. The free polepieces from each phase of a two-phase alternating current are connected each with one of the two electrodes, or groups of electrodes, which hang down into the furnace and from which the current, with formation of an arc, goes into the melt; and the other set of polepieces of both phases is connected with the conductive furnace lining. The oven is mounted upon the iron plates 10 which at the same time can act as conductor for the resulting current of the phases. If the lining consists of magnesite, dolomite or silicious substance which is not sufficiently conductive when cold, a layer 11 of graphite, which is not thermo-conductive but is electro-conductive at any temperature, must be placed on top of the iron plates. But if tar or pitch is used as a binder in the lining this is unnecessary. The electrodes 12 which are connected with the free terminals of the phases are adjustable and pass through a cooling-box in the masonry. This construction is said to admit of de-sulphurizing and de-phosphorizing of the melt.

The design of an electric resistance oven intended to obviate the great radiation of heat occurring in the

Welding Copper by Flame

An Italian Engineer Relates Experiments with Copper and Its Alloys under Oxy-Acetylene Flame

Paper read by Dr. E. Carnevali, Royal Polytechnic School, Turin, Italy, before the Institute of Metals, London, England, September, 1912.

I HAVE undertaken the study of the oxy-acetylene welding of various metals, iron excepted, largely used in modern industry, particularly copper and its principal alloys and aluminum. In this study I have tried to reproduce as closely as possible the conditions which can be obtained in practice.

I propose to divide this group of researches on the oxy-acetylene autogenous welding of metals largely used in practice, other than iron, into two groups, as follows:

First Group: Oxy-acetylene autogenous welding of copper and its principal alloys.

Second Group: Oxy-acetylene autogenous welding of aluminum.

Copper—A first series of experiments was carried out with pure copper, containing 99.9 per cent. of the metal, the welding metal being copper wire of equal purity, supplemented in certain cases by a small quantity of phosphorus, in order to obviate possible oxidation of the metal during the process of welding.

The samples were cut off round wire-drawn rods, measuring 35 millimeters (1.25 inch) in diameter; each sample was sawn half through, and the edges were thrust apart in the form of a V at an angle of about 45 degrees. After welding, some of the samples were cooled in air, while others were subjected to various thermic and dynamic processes; and, being thus prepared for mechanical experimentation, were so treated as to undergo a notable diminution of their original diameter in order to ascertain the success of the welding operation, care being always taken that the weld should be in the center of the sample. Before and after the mechanical tests, from each sample a portion was taken from the zone of welding, and a portion from the immediate neighboring zone, for purposes of microscopic examination. In Tables 1 and 2 a summary is given of the experiments and observations made in this first series of researches. A microscopic study of the samples was directed to the zone of welding, including the structure of the portion added for the weld, also the original structure of the metal and its structure in the intermediate stage. This research exhibits clearly the change induced by the process of welding in the mechanical properties of the metal, as also the profound alteration of its structure.

The microscopic examinations showed the great development which the copper crystals underwent, a development due to the high temperature attained by the fused metals in the process of welding. The suboxide formed during the process and dissolved within the metal. On the contrary, where the metal used for the weld consisted of phosphorized copper, the suboxide was practically eliminated; but coincidentally with that elimination a very slight modification in the mechanical properties of the metal was noted. This proved that the small quantities of suboxide disseminated in the zone of welding had but little effect in the way of changing the properties of the metal. The difference of structure between the original metal and the metal added in welding could be detected by the eye. After a torsional test to try the merit of the weld, the metal was not deformed by the strain to which it was subjected and the rupture under test did not take place in the fused and welded zone, but in the neighboring zone, following the margin of the weld circles in the original metal that had not undergone fusion.

A more minute investigation, while showing continuity between the welding material and the original metal also reveals in this intermediate zone the pressence of innumerable tiny vesicular cavities, imparting to it a peculiar loose granulation, apparently due to the presence of oxides.

In every case of rupture in the welded sample when tested the rupture took place along the margin of the chamfer. The explanation of this apparently curious fact is easy enough, if we consider under what conditions the welding of copper takes place. The great thermal conductivity of copper, for one thing, is well known; this conductivity, indeed, is so great as to make the process of welding big masses extremely difficult, if not impossible. We know also how easily that metal absorbs gases at high temperatures. In the oxy-acetylene process of welding the tongue of the flame is rich in hydrogen and in carbon monoxide, products of combustion which are easily absorbed by the metal during the heating up that precedes fusion.

When the internal surface of the parts which are to be welded begins to melt, then the metal used for the weld is applied thereto, its fusion taking place with extreme rapidity, the period of heating being very brief, as the metal used consists of fine-drawn wire. Cooling and solidification also ensue quickly; while from the mass of metal which heated up more slowly, that is, from the original surface of the chamfer, the gases absorbed in great quantity during the period of heating which preceded the actual welding are eliminated coincidentally with the fall of temperature.

But the elimination of these gases is not complete, as the main mass of the added welding material is at this time quite solidified, and so their occlusion determines the formation of small vacuoles along the original surfaces of the welded parts, that is, along the surfaces of chamfer. These surfaces, pitted with vacuoles and considerably oxidized (despite the precautions observed during the process of welding), constitute a plane of weakness when the metal is subjected to strains and stresses, and it is consequently along them that fracture takes place.

The inevitable existence in the zone of welding of a weak surface of low resisting power being admitted, it will be easily understood how, when carrying out mechanical processes on the weld, as, for example, by hammering, which are intended to assimilate the structure of the welded portion to the original structure of the metal, we obtain a very low efficiency factor, if not one equivalent to zero. This will be noted on referring to the data set forth in Table 2, and for this reason I have not thought it opportune to insist on these mechanical processes in the course of the various series of experiments.

Of greater efficacy, on the other hand, are thermal processes, such as reheating for about half an hour to 750 degrees or 800 degrees Centigrade, to which several samples were subjected after welding, as may be gathered from the results set forth in Tables 1 and 2. A favorable effect on the mechanical properties of the welded metal might be expected from this treatment.

TABLE 1—SHOCK TESTS WITH THE CHARPY APPARATUS ON PRISMATIC RODS, 10x10x60 MILLIMETRES, WITH SEMICIRCULAR NOTCH HALF-WAY DOWN, 2 MILLIMETRES DEEP (DISTANCE OF SUPPORTS, 40 MILLIMETRES)

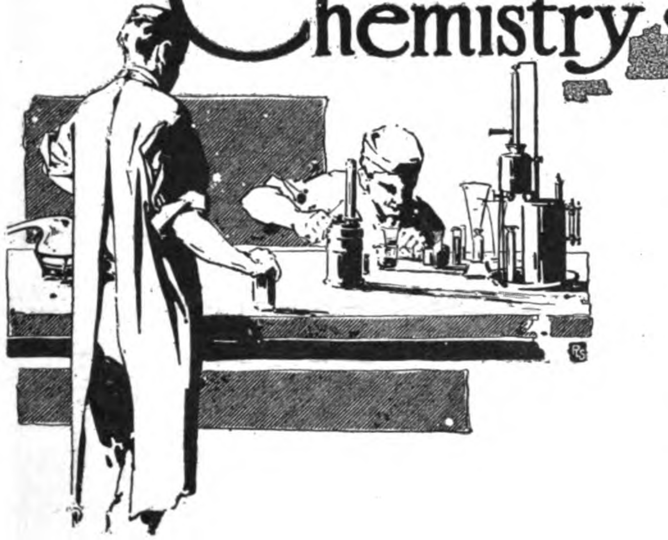
The Chemistry of Cylinder Oils



Facts Based on Chemical Analysis of Cylinder Oils by W. Jones Obtained In Many American Cities and Towns

Part I

This is the first of a series of articles on cylinder oils, which will appear from week to week. Discussions are invited and the columns of THE AUTOMOBILE are open to pertinent criticisms.

By W. Jones

WHAT is a good cylinder oil? What are the standards of measurement by which a good oil for an automobile cylinder can be determined? In every field of science we have units of measurement, or standards by which values are gauged. In the financial world 6 per cent. is the present standard of money value per annum. If you pay 12 per cent. it is usury, and you cannot get it at 1 per cent.

In dealing with oils for automobile cylinder lubrication what are the standards for measurement? Salesmen speak of viscosity, of flash point, of fire point, of specific gravity, of carbon test and of acid test. What is the particular value of each in determining the merit of any oil, and in what proportions should each of these characteristics figure in the makeup of a satisfactory oil?

In this and the following articles of this series an effort will be made to analyze oils as applied to the cylinders of gasoline engines. The facts stated are deductions from chemical analyses and tests with oil. This first article is largely elementary and introductory, and many of the questions which will be suggested in the reader's mind will be discussed in succeeding articles. It is aimed to draw attention to the behavior of various oils under high temperatures and pressures so far as loss in viscosity and carbonization are concerned.

The requirements of the automobile, for a cylinder oil to give satisfactory results, are such as to make the selection of oil for this purpose a much more important matter than for any other kind of motor.

This is due to the motor being an internal combustion type, which produces very high temperatures in the cylinder. These high temperatures produce certain effects from the oil in the cylinder that we do not get in any other piece of machinery.

Our great trouble with this motor is the carbonization of the oil at the high temperature, which is of course a necessary evil.

However, all oils do not act alike in this respect. Some oils give much more trouble in regard to this carbon deposit than others, and it is with a view to determine a specification which would represent an oil that would give the best satisfaction and yet be possible to obtain in the market, at a price that would not be prohibitive. Such an oil should not only lubricate, but should give little trouble from the carbon deposit in the cylinder. An oil of this character would be represented by the following specifications:

Specific gravity should be between	0.8600 and 0.8800
Specific viscosity at 212 should be not over	1.200
Carbonization should be between	0.3% and 0.5%
Flash point	350°F. to 400°F.
Fire point	400°F. to 450°F.
The acidity should not be over	0.003%

The oil should show no action on metallic iron, after 48 hours immersion, and heating to 400° Fahrenheit.

In starting this work it appeared to be the best plan to begin with the deposited carbon in the cylinder. We therefore obtained a fairly good-sized sample of this troublesome substance for analysis, which we found to consist of:

Carbon	86.34%
Metallic Oxides (Iron with a small amount of Copper)	3.96 "
Oil	9.70 "

We would expect to have this deposit fairly saturated with oil, which was the case, but we were a little surprised to find such a large amount of oxide, which simply means one of two things, either the oil carried enough acid to corrode the metal of the cylinder, and thus produce the oxide, or that it was produced by the abrasion due to the presence of the solid carbon. In either case, it would seem that the wear on the cylinder and piston would be rather heavy. The causes for this wear will be taken up later on, when we come to consider the individual oils.

It being impossible from the observed results to tell what, if any, special kinds of oils were producing these results, or if any special oil would carbonize more than another. We decided to make tests on those oils which were in general use, or which were recommended by the automobile manufacturers. We therefore sent a circular letter to all the large builders, asking what oil they recommended or were using for their machines. To this a large number of replies have been received, and it has been a surprise to see what a wide variation has been recommended as the most suitable, ranging from the very lightest Russian oil to the heaviest American oils.

It does not seem possible that there can be enough difference in the construction of the engines to call for any such difference in the oil required, and while there may be a vast difference in the handling or management of the engine, even this could hardly call for any such difference in the oil.

We have obtained samples of the oils recommended, and representing oils in general use. These samples have been subjected to the usual tests for oils of this class, such as gravity, viscosity at two temperatures, flash and fire points, and also for carbon, or what might be called carbonizable carbon; that is, carbon produced from the oil, not exactly as it is produced in the cylinder, which would, of course, be quite impossible in a laboratory test, but in such a way as to represent the results produced in the cylinder. We experimented in many ways to get these results, and finally found that we got the best and most concordant results by taking a weighed amount of the oil in a well-covered platinum crucible and raising the temperature high enough to drive off all the oil, but not hot enough for ignition, and finally increasing the heat to a full red, to burn off any carbon which may have collected on the outside of the crucible.

The viscosities are reported as specific viscosities, taking water as unity. That is, dividing the number of seconds it takes a given amount of oil to pass through a certain sized aperture by the number of seconds it takes the same amount of water to pass the same aperture. The other tests were made in the usual way.

In looking over the tests as tabulated we have a fairly wide variety of oils. In gravity we see a variation of from 0.8651 to 0.9103, in oils showing a much wider variation in the viscosity, which is from 1.7647 in No. 1867, to 18.6071 in No. 1896/e. This last, however, is a special oil for use in motor cycles. It has been included in this list for the extremely high viscosity, which we think may be of interest as we go further into the subject of viscosity.

It may be further observed that **the highest gravity does not by any means give us the highest viscosity,** neither does **the lowest gravity give the lowest viscosity. These figures do not appear to have any relation to each other in the least.**

It may also be noticed that the higher the viscosity is at the temperature of 80 degrees Fahr. the quicker it falls, so that upon reaching the temperature of 212 degrees Fahr. we find a very much wider variation for the high viscosity than for the low.*

In looking over the amounts of carbon produced from these oils we find that they follow more nearly the viscosity, although it does not do so in all cases, for we find that in No. 1890/a, where we have a viscosity of 5.7657, there is 0.80 per cent. carbon, while in No. 1894/b there is a viscosity of 4.4643, nearly one-fourth less, and a carbon product of 1.70 per cent., or over double. It is therefore quite impossible to foresee from the gravity or viscosity just how the oil is going to act in regard to the carbon deposit.

The most important determination seems to be the percentage of carbon deposited, and it would seem to decide the value of the oil so far as this carbon deposit in the cylinder is concerned, and without stating the names of the different samples we will say that oil No. 1867, at the top of the list, is an oil which has been more highly spoken of than any of the others. This would tend to show that the figures for the carbon, which, while we do not think they represent accurately the amount of carbon that would be produced in the cylinders, still show the relative proportion which might be expected from the different oils.

There is one other case which we would like to call attention to, that is, No. 1894/a and 1894/b are supposed to be the same oil. They were both received under the same brand, only one was obtained in New York and the other in Detroit.

*To explain: No. 1867 has a viscosity at 80 Fahr. of 1.7647 and at 212 degrees Fahr. of 1.428, a drop of .6219. Compare this with No. 1896 D, which is an automobile oil. At 80 degrees Fahr. its viscosity is 6.3214, at 212 degrees Fahr. it is 1.4285, a drop of 4.8929 or practically eight times that of No. 1867.

Use of Castor Oil

Pharmaceutic castor oil, the colorless product used for medicinal purposes, is the only vegetable oil that is recommended for purposes of lubrication. When a motor is in a delicate state, or, if it is desired to make a long, high-speed run, it is not out of place to dose with castor oil, removing all traces of other lubricating oils before resorting to the castor oil treatment. Castor oil is efficacious when it is desired to operate at high piston speeds, say, 2,000 feet per minute. It will be remembered that 1,000 feet per minute of piston travel is regarded as the normal rate of piston speed.

It would be imprudent to use castor oil in a motor without making sure that it is pure. A simple test is to place a sample of the oil, with five times its volume of 90 per cent. alcohol, in a graduate, and at a temperature of 62 degrees Fahrenheit, corresponding to about 17 degrees centigrade, observe the result; if the solution remains clear and brilliant, no substantial adulterant is present. If the solution riles up, it is not pure. This is the Finkener test for the quality of castor oil. If the oil is not colorless to begin with, it is not worth while to test it at all.

The best grades of castor oil are cold pressed from the castor bean. Chemical processes of extracting the oil are prone to leave substantial traces of free acids of refining. In the process of extracting the oil from the bean, in addition to getting all of the oil out of the same, removing the albuminoids, is needed.

Oil Tests—In the movement which is now under way to remove from the automobile the last vestiges of offensiveness in the street traffic, systematic investigation of lubricating oils has been taken up with so much more vim as the same line of research promises to remove also the last uncertainty in the control of the thermic functions of the internal combustion motor. The most important work looking to the avoidance of nauseous odors in the exhaust gases of the automobile has been done by the Royal Prussian Bureau for the Testing of Materials and showed that, by first removing those components of the oil which are soluble in acetone, odorous exhaust was obviated. Another important step was the construction of the Ossag oil-testing machine by means of which the physical properties may be determined. It has been introduced in England under the name of the Sternol machine and has already been used in an extensive series of tests.

TABLE A—ANALYSES OF AUTOMOBILE CYLINDER OILS—BY W. JONES

No.	Specific Gravity	Specific Viscosity at 80°F.	Specific Viscosity at 212°F.	Carbon	Flash Point, °F.	Fire Point, °F.
1867	0.8684	1.7647	1.1428	0.30%	325	358

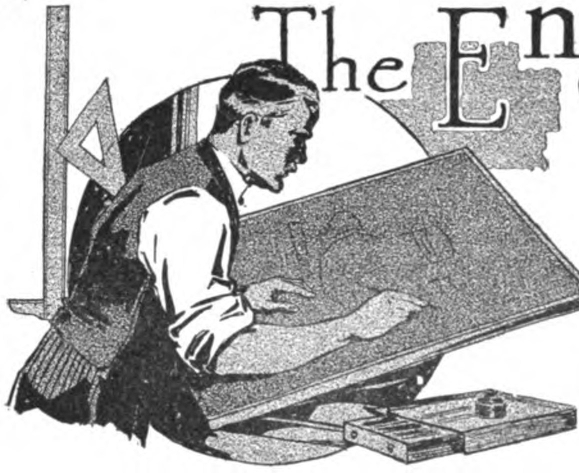
1935	0.8777	3.5714	1.2500	0.78	438	486
1936	0.8738	3.5714	1.2500	0.53	442	494

In articles to appear later we will analyze and enlarge upon these analyses.



The Engineers' Forum

Discusses Contet's Formula for Counter-Springs—Analysis of Problem

Forrest R. Jones, Knoxville, Tenn., Sets Forth His Views on Them

KNOXVILLE, TENN.—Editor THE AUTOMOBILE:—Relative to the abstract and discussion in THE AUTOMOBILE of September 26, of Mr. Contet's article on Countersprings:

While teaching in different universities several years ago, the formula of which Mr. Contet has given a development was used whenever occasion called for it. My development is thought to be somewhat simpler and possibly more readily understood.

A specific numerical example of a compound spring made up of two simple springs which are exactly alike may serve to primarily give a clear conception of the action of such compound springs.

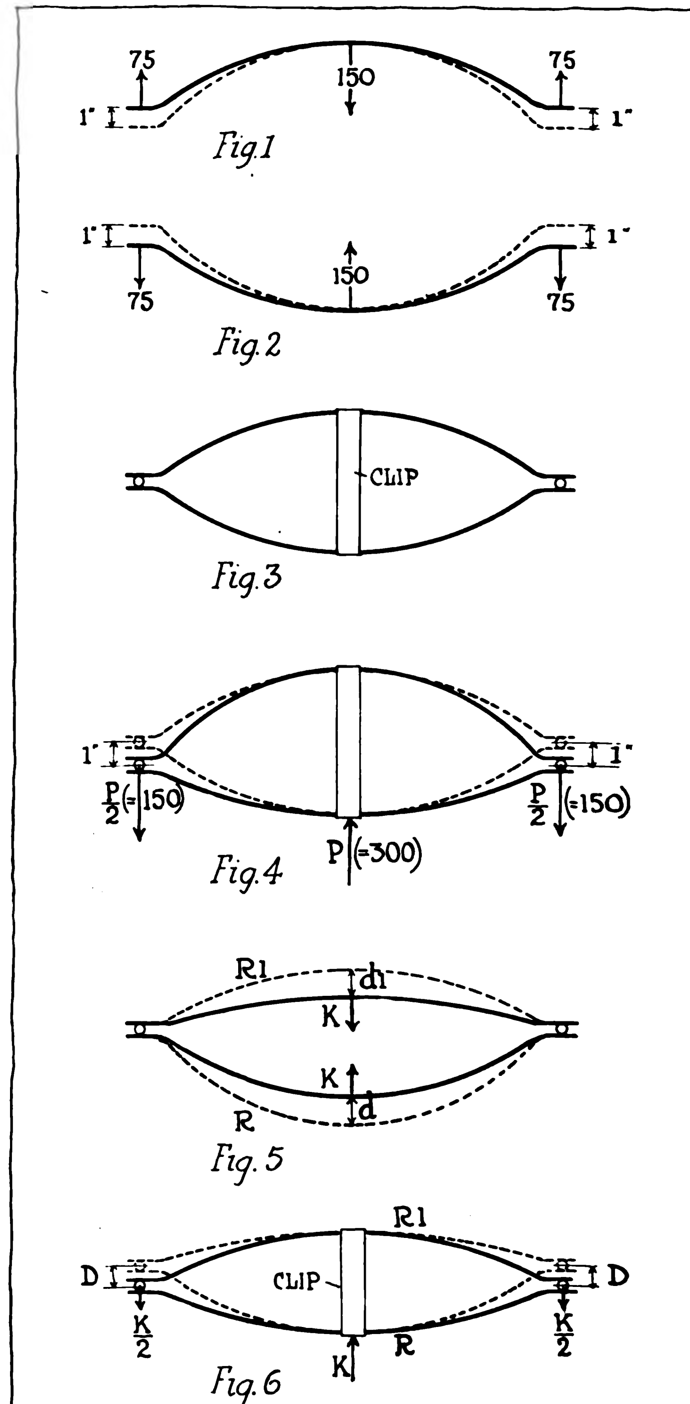
In Fig. 1 a simple spring is shown acted upon by a force of 150 pounds at its middle, and by the corresponding forces of 75 pounds each at the ends of the spring. The solid curved line shows the form of the spring while stressed by these forces, and the broken line shows the form which the spring takes when unstressed. The ends of the spring are deflected 1 inch from the unstressed position by the applied forces.

In Fig. 2 another simple spring exactly like the first one when turned upside down is shown similarly with forces of the same magnitude as before, but applied in opposite direction.

In Fig. 3 the two springs of the preceding figures are shown placed together while still deflected by the forces and with a clip over them to hold them in their deflected, or stressed positions. A small roller is shown between the springs at each end. These rollers are added merely as a convenient aid in the description of the action of the compound spring formed by placing the two simple ones together. The tension in the clip is 150 pounds, and each half of the spring is deflected 1 inch from its unstressed position. The pressure between each roller and the corresponding end of each spring is 75 pounds.

In Fig. 4 the compound spring of Fig. 3 is shown by solid lines in the form it takes when a force P, which may be considered as the pressure of a car axle against the spring, acts upward against the middle of the lower half of the compound spring, and the corresponding forces, each having the value P/2, act downward on the rollers between the ends of the component simple springs. The two forces, each equal to P/2 and together equal to P, may be considered as the load that is applied to the compound spring. The broken lines represent the form of the compound spring before the load is applied, which form is the same as in Fig. 3.

The deflection of the loaded compound spring in Fig. 4 is 1 inch from its unloaded position. The movement of the compound spring while being thus deflected increases the deflection of the lower half, but allows the upper half to recoil to its unstressed form corresponding to that of the broken line in Fig. 1. In order to deflect the lower spring 1 inch, the pressure of each roller against the corresponding end of the lower simple spring must be increased by the amount of 75 pounds (since the flexibility of the simple springs is such that 75 pounds at each end cause a deflection of 1 inch). Before applying the load to the



Figs. 1, 2, 3, 4, 5 and 6

compound spring the downward pressure of the upper simple spring against each of the two rollers was 75 pounds, but after the deflection of 1 inch there is no pressure of the upper simple spring against the rollers. Therefore 75 pounds of each force

P/2 are required to keep the pressure of each roller against the corresponding end of the lower simple spring the same in amount after deflection of the compound spring as it was before applying the load.

In order to obtain the required increase of 75 pounds pressure of each roller against the corresponding end of the lower simple spring, the force P/2 must be 75 + 75 = 150 pounds. The corresponding value of the upward force P, at the middle of the compound spring, is of course 300 pounds, which is the amount of the load applied to the compound spring to deflect it 1 inch. The deflection of the compound spring for a load of 150 pounds is 1-2 inch, since the deflection is proportional to the load, for a load not greater than 300 pounds.

The flexibility of the compound spring composed of the two like simple springs is therefore only one-half as great as that of one of the simple springs when the load is applied as shown.

If the two simple springs were used as an elliptic spring, the clip then not being used, the deflection for a load of 150 pounds applied at the middle of the upper simple spring would be 2 inches, in which case the flexibility is four times as great as when one of the simple springs is used as a counterspring and the load applied as in Fig. 4.

If two simple springs like that of Fig. 1 or Fig. 2 are placed side by side so that the load is divided equally between them, then a load of 300 pounds will deflect them 1 inch from their unstressed position, and a load of 150 pounds will deflect then 1-2 inch. When used in this manner the two simple springs together have a flexibility equal to that of, and are twice as strong as the compound spring with the load applied, Fig. 4.

Now taking up the more general case as discussed in THE AUTOMOBILE:

In Fig. 5 two simple springs, R and R_1, are shown as elliptics, with rollers between their ends for convenience of discussion, as before. The solid lines show the positions of the two simple springs when each is subjected to a force K as shown, and the broken lines represent the positions which the springs take when no bending forces are applied to them.

In Fig. 6 the broken lines have the same form as the full lines in Fig. 5. These two broken lines, Fig. 6, represent the positions of the two simple springs, R and R_1, when bound together by a clip which holds the simple springs bent to the respective amounts, d and d_1, and when no load is applied to the compound spring. The solid lines in Fig. 6 represent the position of the compound spring when deflected by a load K, half of which is applied to each of the rollers.

In order to deflect the lower simple spring R to the amount D from the broken-line position of Fig. 6, the sum K/2 + K/2 = K of the pressures of both rollers against the lower spring must be increased by the amount $\frac{D}{d} \times K$. The accompanying recoil of the upper simple spring R_1 to the same amount D corresponds to a decrease of the sum K of the pressures of the ends of the upper spring against the rollers to the amount $\frac{D}{d_1} \times K$.

The required increase, $\frac{D}{d} \times K$, of the total pressure against the ends of the lower spring R is equal to the difference between the applied load K and the decrease $\frac{D}{d_1} \times K$ of the sum of the pressures of the upper spring R_1 against the rollers.

Accordingly,

$$\frac{D}{d} \times K = K - \frac{D}{d_1} \times K$$

whence,

$$\frac{D}{d} = 1 - \frac{D}{d_1}$$

$$\frac{D}{d} + \frac{D}{d_1} = 1$$

$$\frac{Dd + Dd_1}{dd_1} = 1$$

$$D\frac{d + d_1}{dd_1} = 1$$

$$D = \frac{dd_1}{d + d_1}$$

or,

$$D = d\frac{d_1}{d + d_1}$$

The value of the last fraction is less than unity, since the numerator d_1 is smaller than the denominator $d + d_1$. Therefore, the value of D is always less than that of d.

If the applied load is taken as 100 kilograms, and the corresponding respective deflections as Y, y and y_1, as is done by Mr. Contet, then the equation corresponding to the first one of the last group is:

$$\frac{Y}{y} \times 100 = 100 - \frac{Y}{y_1} \times 100$$

which reduces to the form

$$Y = y\frac{y_1}{y + y_1}$$

The last equation is the same as that obtained by Mr. Contet. —FORREST R. JONES.

Note—Mr. Jones assumes that the load K produces the deflection D in the compound spring RR_1; next he reasons that to produce this deflection in the lower spring R alone the load must be $\frac{D}{d} \times K$; next, that the pressure or load required for producing the deflection D in the compound spring is smaller than that required for producing it in the lower spring alone; less by $\frac{D}{d_1} \times K$; and so far he is in full accordance with the data. This last and correct assumption, however, means just exactly the opposite of his final result; for, if the load required for producing a given deflection (D) is smaller for the compound spring RR_1 than for the simple spring R, then the former is the more flexible of the two. And the final result of both Mr. Contet and of Mr. Jones is that the compound spring is less flexible, that D is smaller than d.

The error lies in the application of the mathematics. Up to the point of formulating the equation

$$\frac{D}{d} \times K = K_1 - (\frac{D}{d_1} \times K)$$

there is question of numerical values for the deflections only, but the moment Mr. Jones says: "Accordingly" followed by the above equation, this condition of the inquiry is changed. The object is now to determine a deflection operating in a certain direction, namely, from the load toward the ground. In this deflection of the compound spring, toward the ground, the tension of spring R and that of spring R_1 are both involved, but these forces work in oposite directions. If the load applied to overcome the tension of spring R is considered positive then the load required to overcome the tension of spring R_1 must be considered negative. As the equation is formally correct, however, one can work with it so long as one remembers that d_1 is in reality a negative quantity in so far as it is used for determining the deflection D of the whole compound spring. The final equation

$$D = d\frac{d_1}{d + d_1}$$

can therefore be accepted if it is understood that the value of d_1 is negative. Now, with d_1 negative, the final conclusion of Mr. Jones as well as of Mr. Contet falls to the ground. The value of the last fraction is NOT less than unity, and D is NOT smaller than d. In other words, the flexibility of the compound spring is greater than that of the simple spring R, which was also the first assumption of Mr. Jones, although by putting it into equations he afterwards made it contradict itself.

The error in Mr. Jones's reasoning is exactly of the same nature as that which was pointed out in Mr. Contet's develop-

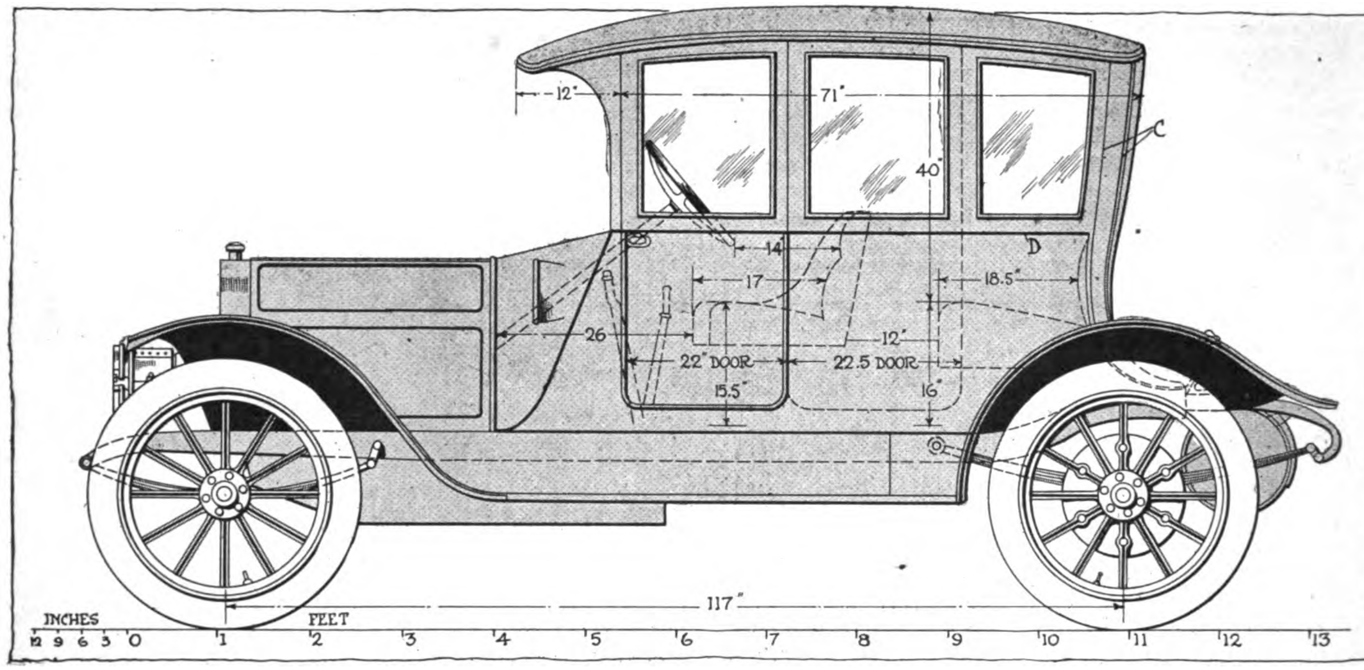

Fig. 1—Side view to scale of coupé design adapted to Hudson 37 chassis

Four-Passenger Hudson Coupé Design

Body Designer Utilizes Hudson 37 Chassis and Makes Few Changes—Drawings and Plans Drawn To Scale

By George J. Mercer

IN continuation of the plan mentioned in the last issue of THE AUTOMOBILE, the accompanying illustrations show another design of a closed body suitable for use on a medium-powered car. This design is totally different from the one preceding; it is made to carry four passengers, including the driver. There are two seats, and each seat is comfortable for two people, and the doors for entrance are offset, that is, not in line across the body; the one on the left side is forward and is used for entrance to the front seats and that on the right side is toward the rear and is used for entrance to the rear seats, the width of the door openings is, respectively, 22 and 22 1-2 inches and is so indicated on Fig. 1.

Allowance for the individual tastes and requirements of the customer is becoming every day a more important part of the duties of the automobile salesman. Close competition in the trade caused by the advance upward of the standard of the popular-priced car has made it possible for the public to become more dictatorial and the desires of the customers are acceded to as far as the selling profits of the business will permit.

The buyer who is able to purchase an article costing from about $2,000 and up is not willing to be treated collectively and this trait in human nature is well understood and provided for by the successful salesman. As a rule, the changes suggested by a customer are made in good faith; it is the critical buyer who forces up the standard and the reform work of the particular person benefits all that come after. Style and appearance count largely in determining a purchase.

This body design is unique in that a straight-line effect is obtained in combination with the arched roof and the ogee sweep of the back line, Fig. 1, the exterior or border lines of this body all show a curve that combines with the curves of the mudguards, yet the straight lines of the belt, the window lines and the cowl hood give the body a severe tone and the rear view, Fig. 4, is made to carry out this same design.

The body is illustrated mounted on a Hudson-37-1912 chassis, 118-inch wheelbase, 36-inch by 4-inch tires, and as the body will weigh when finished ready to mount approximately 650 to 700 pounds, it will come well within a reasonable limit to mount on a standard chassis. The design is made to harmonize with and utilize the standard mud-guards, lamps, tire holders, etc.; the electric lighting system as regularly provided will furnish current for the dome light in the roof and the standard dash lamps can be inserted in the recessed pockets of the cowl hood, Figs. 1 and 2. The extra tires are carried on the right side on the running-board; this is the position provided for on the standard car and by retaining this place the regular equipment for holding the tires can be utilized and the offset body doors permit of this selection. This utilization of the standard parts of the car as far as the harmony of design will permit will help out in the final cost more than the actual saving in money, because a commercially-purchased article will be cheaper than one specially designed.

The change-speed and brake levers on the standard chassis are located, for convenience of operating, inside the standard foredoor body and the body design illustrated is wide enough to allow ample room for these levers and also hand clearance around the steering wheel. The plan view, Fig. 3, will give the thickness of the framing, which will equal the inside of the framing at a point opposite the steering wheel. Measured in this way, the hand clearance is approximately 2 1-2 inches, and, as the wheel is above the framework and opposite the glass, the hand clearance will be even greater, or approximately 3.5 inches.

The body is made to cover the entire length of the frame back of the hood and without having to add the customary box at the rear. The actual body length inside is short for a four-passenger job, yet plenty of room is allowed for all seatings; this is accomplished because the 22-gallon gasoline tank is at the rear of the chassis and outside the body lines and the space under the front seat is utilized for foot room for those seated at the rear. The space allowed between the back of the front seat and the front of the back seat is only 12 inches, Fig. 1, but the maximum entrance from the doorway to the rear seat is obtained by tilting the back of the front seat forward as indicated in Fig. 1, and the full complement for the seating of those occupying the rear seat is the utilization of the space under the front seat for foot space.

It might be added that the location of the doors in the design is not arbitrary, the door on the left side can be placed opposite the right side one, but as it will necessitate lifting up one side of the front seat to pass forward and as there will be two doors, the design will certainly appeal to many customers.

The principal dimensions of the body sizes, doors and seating arrangements are indicated by figures on the drawings, and these proportions are ample for the average person.

Ventilation is by a shutter at the offset part of the body at the front, indicated in Fig. 1, a long, narrow shutter with provision for operating from the inside is placed at each side at the point above mentioned, and the cowl, which is graduated from the hood to the body, is provided with recessed pockets for the electric lamps, and at the top is a glass panel E, Fig. 3; this panel is serviceable to light up under the cowl and permit the reading of indicators on the dash, etc.

Locker space is under the rear seat and at the each side under the cowl at the front. The side windows are made to drop full length and are of 1-4-inch plate glass without wood frames. They shut out the rain when raised by setting over the guard rail on the middle bar. The rear window is stationary. The front glass is made with rain vision and swings outward like the conventional windshield for this style of body.

The construction of the body is reasonably simple, the lower sides, back and door panels, also cowl, are made from 16-gauge aluminum; the panels are shaped and fastened at the rear to the wood corner pillar, and the edges covered with metal molding, as illustrated in Figs. 1 and 4; at the front the side panels terminate as shown in Fig. 1, at this line they turn at right angles to the side surface, with the angle of turn slightly rounded and at the intersection with the cowl the panel is stopped and fastened.

The rear corner pillar is made to form the slight rounded corner, Fig. 3, and no metal is used to cover the wood forming the round. The upper panels are .375-inch whitewood and are glued to the rear pillar and the framework, the lower edges of these wood panels are lapped over the top edges of the aluminum lower panels 1-4 inch and rounded over to give a molding finish. The line of demarkation on the lower finish line of the wood panels on the sides and back is marked D, Figs. 1 and 4. C, which is indicated in like manner on the same two figures, shows the terminating line of the wood panels, back and sides, where they lap over on the corner pillar; these panel edges are made to continue the line of the metal molding up the corner pillar, and the lines C show a molding finish up the whole length of the pillar and the rounded part of the pillar in between these lines show a recessed effect.

The body framing is of good ash and the roof of the regulation laminated whitewood or pine sheathing. The method of framing will be such as general practice dictates. Wood panels have been specified wherever possible, because the design is special and consequently a quicker delivery can be secured if the older-fashioned methods are resorted to. Metal panels undoubtedly give better service as the outer covering on bodies to be used as automobile bodies, but occasionally there are cases where the design and construction are such that equally as good results can be obtained where part of the panels are of wood and part of metal, and it is perfectly safe to guarantee that wood panels as specified will give a good account of themselves.

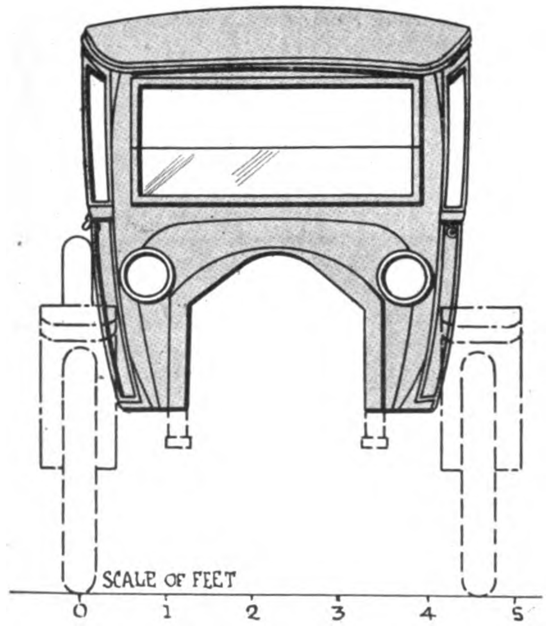

Fig. 2—Front view of Hudson 37 coupé design

The cost of a body made according to the design submitted and with a trimming, interior appointment and color specification in accord with the standard of that furnished by the car makers on their stock bodies, will be approximately $1,300 to the customer, and this should include mounting the body on the chassis. This price is a fair average and will permit the customer to select from samples furnished by the best wholesale houses of broadcloths or other suitable cloths for trimming the interior, laces for binding, carpet for the floor, silk for the curtains, toilet and card cases and a choice of the style of trimming. In regard to this latter it is generally left to the workman to use a style of trimming that will accord with the material selected.

Foreign Constructions Designs and Practices

Shopman Made Practical Steel Tester—Suggested Machine for Quick Work and Reliable Results

German Factory Tests 4,000 Pieces of Steel Every Working Day in Year

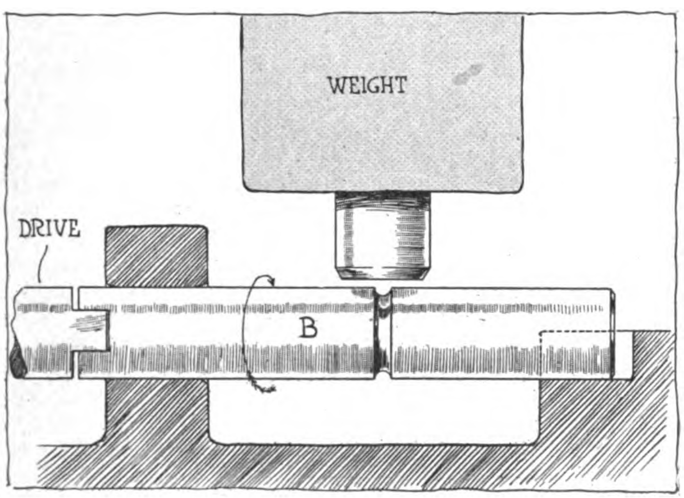

Fig. 1—Method of subjecting automobile steels to shocks to determine ultimate ability of parts in the actual car service

TESTING over 4,000 pieces of steel every working day in the year, and using the shopmen instead of the laboratory to do this testing, may seem a herculean task, but it is what is being done in one of the best European plants and it is being done well, done cheaply and is leading to excellent results.

In the majority of factories the laboratory does all of the testing of steels for use in the company's product. It determines the necessary analysis of the steel, but it has not sufficient capacity to adequately test all of these materials when delivered to the factory; this is the great present weakness of the factory laboratory and the point where there is not sufficient overlapping between laboratory and shop.

Then too many of these materials delivered as per specification at the factory have to be heat-treated after received and it is here that the real difficulties of the shopman begin: More than likely some of the material is unsuited to the actual work to be done. The laboratory merely hopes that heat-treatment will whip the material into shape. Frequently good results come through this process. But there are times when anything but a happy conclusion is reached.

Knowing perfectly well that the laboratory is not to be blamed for the practical happenings of the every-day work, the shopman struggles along under his heavy and swelling burden, or can it be said of him that he has over much time to spend on betterment plans? It may be that the shopman's failing lies in his very ability to struggle along. It might be better for him were he to take a day off occasionally and think it over; to devise means for subduing the situations which are obviously too penny-wise and pound-foolish to be tolerated any longer.

In nine cases out of ten, however, it is more a question of facilities than it is a want of appreciation of the necessity for making tests of materials to use. The shopman can scarcely be expected to have the nimbleness of the laboratory man in the laboratory. What he needs is represented by such facilities as will warn him in time of any danger to the good of his processes that may be lurking in the offing. If the danger is offset by due warning, to ask the laboratory to conduct an investigation is a simple thing to do. The real difficulties of the shop are not completely met by the laboratory. The only pleasant aspect lies in the fact that a good working laboratory reduces the actual number of the shop difficulties which come to the surface from day to day.

Remembering that all great difficulties are mastered by handling their details one at a time, what possible harm would befall the shopman who would conclude definitely to test all of the steel he might use, making a separate test for each condition of heat treatment on each grade of steel used? It might be said, what an enormous undertaking! That is exactly what shopmen did say. All of their failures are readily traced back to this simple statement. **After all it is not such a large undertaking as it looks.** There is one plant wherein an average of over 4,000 determinations are made on steel every working day in the year. The men who make these determinations enjoy every minute of the work. That it pays to make them is a proven fact, indeed, it would not be possible to get on without doing this work. The quality of the product has grown to the point of demanding just this painstaking care in the process.

It has been found that a simple shock-bending test on a test bar of steel, if the process of test is systematically made, develops faults, if they exist in the steel, very promptly. Fig. 1 indicates to a shopman how he can rig up a test of this sort. The test-bar B of the steel to be investigated, is turned down to some convenient size as: Diameter of round section, .47 inch; length between supports (5 diameters) 2.36 inches, and length over all to suit testing machine.

The bar is notched at the middle by a round nose tool to a depth of say 1-8 inch. The important point is to make all test-bars the same size and to have the notch uniform between them. The next step is to provide a falling weight and a means for rotating the test bar so that it will always be rotated an exact number of degrees for each blow struck by the falling weight. In this class of tests it is the custom to rotate the test bar either 90 per cent. or 180 per cent. for each blow struck. The force of the blow must be regulated depending upon the time that can be allowed in making the test. The great question in practice is to adopt a uniform system and to subject all test bars to the same uniform practice. It is not actually necessary to know just what the force of the blow is so long as the same force, under identical conditions, is suffered to play against all test bars used. In the plans of testing it is purposed to so weight the hammer and regulate the diameter and notching of the test bar as to bring about destruction of the test bar within a short time. It would be a small item in point of first cost to rig up a battery of these hammers and provide means for changing speed of blows, and rotation of the test bar would suggest itself to the operator. In the Krupp motors at Essen, where these tests were examined, it was found that the persistance of the steel depended upon its quality. Time and experience with the trip hammer method has enabled the operators there to judge very quickly whether or not a given heat of steel is worth duplicating.

These little testing machines are very noisy. To put up with them it is necessary to place them in a separate room to locate the room as far away from other activities as possible is good practice.

In plants which are fitted out with compressed air equipment, remembering that compressed air hammers are capable of striking blows of some force at a very rapid rate, it is more than likely that preliminary testing work might be done by this equipment. Fig. 2 suggests the idea. The details would depend upon the design and construction of the compressed air tools available in a given case. It is very possible that anyone of a dozen riveting machines now available on the market would readily serve for this class of work. These machines strike a rapid series of sharp blows. It would be a simple matter to give the test bar rotation so that the average travel would be 90 degrees of rotation of bar per blow of the hammer. A properly sized notched test bar would show fatigue very quickly under this treatment.

It is speed of test that the shopman must have. He cannot wait for a week to get results. There would be a certain indefiniteness about the results in an attempt to make a statement, but this point would be submerged in the general accuracy of comparison which is all that practice demands. If a steel comes up to the sample furnished by the laboratory for a given grade of steel, nothing more is required. If it is desired to get finer readings for purposes outside of shop practice, it is time to call upon the laboratory for work to be done. With means for testing, to turn out bars of the several classes of work passing through the plant would necessarily have to be made a routine matter.

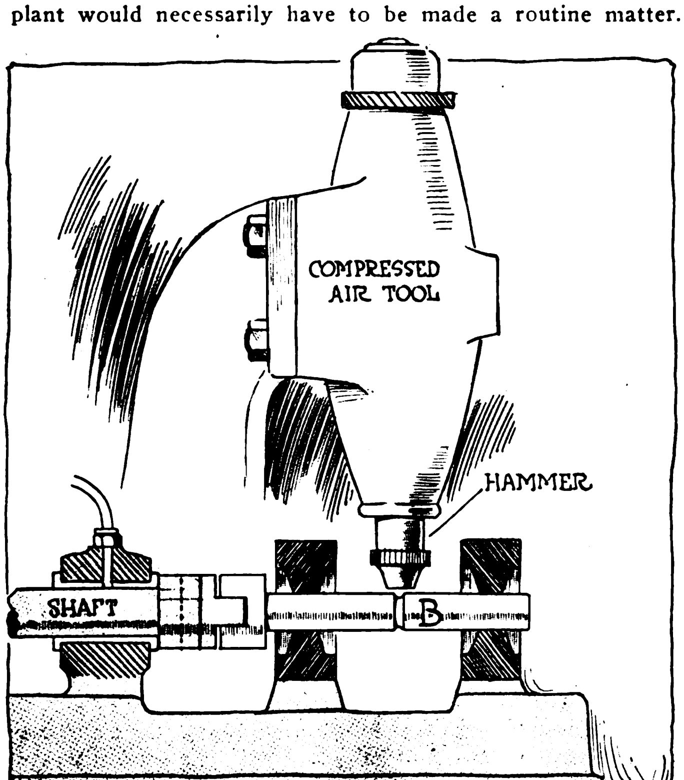

Fig. 2—Compressed air tool for use by workman in shop testing of steel to get reliable and quick results

Harking Back a Decade

What the Motoring Publications of 10 Years Ago Had To Say on Live Matters of the Day

FROM *The Automobile and Motor Review*, October 25, 1902:

The progress made by the automobile since 1895, when the first of the American endurance runs was held, is shown by the percentage of starters that finished in each event of the kind. In 1895 there were two runs; in 1901 there was one and the recent tour of the Automobile Club of America to Boston and return was the fourth. The results are indicated in the following tabulation:

Date	Distance	Starters	Finishers	Per cent.
1895	38	5	1	20
1895	39	7	3	43
1901	394	78	41	53
1902	488	75	68	90

The Chicago Automobile Club gave its twice-postponed race meet at the Harlem race track last week. The attendance was small and the contesting fields very thin. Nevertheless the Peerless Yellow Kid and the Winton Pup in addition to about a dozen locally owned cars performed creditably. The track was so slow that the best time made was just under 1:30 for the mile.

Automobile exports in August reached a total of $71,907, against $56,300 during the same month of 1901. During the first 8 months of the fiscal year the exports were $786,137 against $128,702.

Albert C. Bostwick is demonstrating the first model of the new Pan-American car which is made at Mamaroneck. The motor, body and many if not all of the mechanical parts are imported and the justification for the name lies in the fact that they will be owned by Americans. The car has a motor with four cylinders and is rated at 40-horsepower. The mechanism resembles that of the Mercedes but in appearance the car is more like a Mors.

The effect of the long, novel, orderly and interesting procession during the Automobile Club of America run to Boston upon the average citizen could not fail to be of the best. It is likely that the run has done much for the interests of motoring throughout New England. To the country at large, as informed by the press, the run has given good evidence of the practicability of the automobile in actual road use.—*Editorial.*

The Cleveland Automatic Machine Company, a New Jersey corporation capitalized at $850,000, is preparing for business. A. L. Garford is president and it has been announced that $150,000 of the capital will be used in Ohio. The company was formerly known as the Cleveland Machine Screw Company. Mr. Garford is also president of the Federal Manufacturing Company, of Elyria, O.

The National Association of Automobile Manufacturers has has made preliminary plans for the automobile show will be held in connection with the Louisiana Purchase Exposition at St. Louis in 1904. Manufacturers are invited to send in applications for space as soon as possible. No space charge will be made against exhibitors and a reasonable amount of electric power for lighting the displays of the exhibitors will be furnished free.

The annual automobile show which will be held in Paris next season promises to set a new mark in the growing industry. The show will be much larger than ever before and a number of American manufacturers will be represented. Special efforts are being made by the management in connection with the National Association of Automobile Manufacturers to secure a large American representation. The foreigners, on their part, are planning to show at the St. Louis fair.

What to Do With Your Tires in Winter; Trouble With the Oiling System; Principles of the Claudel Carbureter; Advantages of Air Substitutes; Quick Blowout Explained; Alignment of Drive Mechanism

Winter Care of Tires

EDITOR THE AUTOMOBILE:—I want to jack up my car for the winter; is it necessary to remove the tires?

I would like to offer a suggestion in the way of carrying tire chains. Several times I have noticed that it took me a considerable time to put these chains on because I had not taken sufficient care in putting them away and the links stood up on end at the time and had to be pushed in place before stretching the chain over the tire. If the chains are laid carefully on the ground first and then doubled over, Fig. 7, and placed in a bag it will save a lot of time in trying to put these on in the wet.

Germantown, Pa. FRED MARSHALL.

—It would be better to remove the tires because they can be taken care of more thoroughly. The United States Tire Company gives the following advice for the winter care of tires: In laying up a car the tires should be removed from the rims and washed thoroughly with soap and water. They should then be carefully wrapped in strips of paper or cloth and stored in a dark place which is kept as nearly as possible at a temperature of 50 degrees.

If the tires are to remain on the wheels for a considerable length of time while the car is out of service the wheels should be jacked up and only about 5 pounds of air left in each tire. This keeps the tubes in shape and also preserves their softness and pliability. When the wheels are not jacked up and the car is allowed to stand for any length of time the tires should be kept well inflated and the car moved occasionally so that the tires will not flatten from standing too long on one spot.

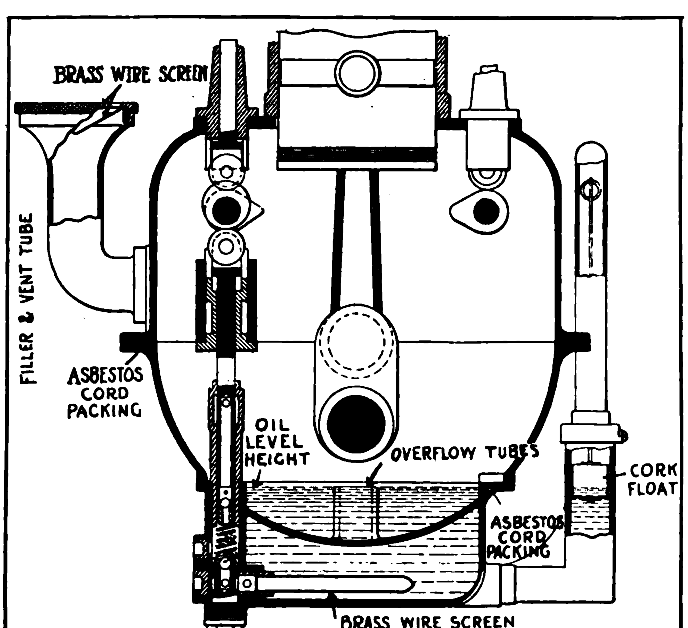

Fig. 1—Section through the Ohio crankcase, showing oiling system

Oiling System on Ohio 1911

Editor THE AUTOMOBILE:—I am running a 1911 Ohio touring car and I am troubled lately by smoke. Would you please tell me if this is due to a defect in the oiling system or what the cause can be. Of late I am also troubled by a large carbon deposit in the two front cylinders. Is this due to the same cause, do you think, or some other?

Saginaw, Mich. OHIO.

—The Ohio motors are lubricated by a system which is contained almost entirely in the crankcase. The oil reservoir, Fig. 1, holds about a gallon of oil, is located in the lower half of the crankcase. The oil may be put into the reservoir in two ways: by pouring it through the breather tube or into the filler pipe which is located on the side of the motor. Within the base of the crankcase and extending vertically there is a plunger pump, driven by means of an eccentric off the camshaft. This pump takes the oil from the base of the reservoir through a strainer tube projecting laterally into the reservoir and forces it up into the upper part of the lower half of the crankcase. This part of the crankcase contains a number of troughs into which the oil is fed by the pump in sufficient quantities to keep them constantly filled to such a height that a proper dip of the connecting-rod into the oil will take place.

There is one of these troughs to each cylinder. As the rapidly revolving connecting-rods are whirled into the oil pools contained in the splash troughs they churn the oil into a vapor which fully envelops the crankcase and lubricates every moving part contained therein. This includes the cylinder walls, connecting-rod bearings, main bearings, camshaft bearings and cams.

After lubricating all the bearings the oil will drain back into the bottom of the crankcase and will pass through the system again, after being strained. A constant level throughout the crankcase is maintained by means of partition walls placed laterally across the crankcase between each pair of cylinders.

Worn piston rings in the two front cylinders is no doubt the cause of your trouble. If you will renew the rings there is no doubt that both the smoking trouble and the carbon will disappear as the oiling system is automatically taken care of and will not change if once adjusted correctly.

Information Wanted on Claudel

Editor THE AUTOMOBILE:—Would you kindly tell me where I can get information and prices of the Claudel carbureter in this country.

Newport, R. I. H. W. BENTLEY.

—The Claudel carbureter is shown in section in Fig. 5. It is of the eccentric float-feed type, so called because the float has not the same axis as the jet. The carbureter is hot water jacketed about the mixing chamber and so arranged that the air is taken both through and around the jet. A tube surrounds the gasoline lead to the spray nozzle and is pierced by holes at the bottom and top. The air passes into the lower holes in the tube and comes out through the upper ones which surround the spray nozzle. Easy starting is obtained with this starter by fitting a shutter into the air channel which permits the suction of the motor to fall upon the jet, thereby securing a very rich mixture for starting purposes.

This carbureter is not handled in this country at the present time, but full information may be had concerning it by addressing the Claudel Carbureter Company, 41 Rue des Arts, Seine, France.

Advantages of Air Substitutes

Editor THE AUTOMOBILE:—Can you furnish me with, or inform me where I can obtain a list of the different varieties of pneumatic tires that have been patented?

2. What are the disadvantages of fillers for tires as a substitute for air, and do you think fillers will ever supersede air?

Chattanooga, Tenn. J. I. LEVENTHAL.

—Any patent attorney will secure this list for you at a very reasonable price. It is a matter of looking up records at the patent office and cannot be secured from them directly. THE AUTOMOBILE has no lists of these patents.

2. The most serious disadvantage under which some of these tires have labored is that the inner filler crumbled to pieces and disintegrated in a very short time. Others could not be left standing for even a short time without the tire having a flat place where it had been left standing. Still others were all very good on asphalt roads, but on other roads developed the same fault as solid rubber tires, that is, too much vibration and bad riding qualities. There are some of these fillers on the market now, however, which are said to overcome all these difficulties. They knead back together if torn apart, will not tend to flatten and are very nearly as resilient as air. THE AUTOMOBILE cannot predict that fillers will ever take the place of pneumatic tires.

Where the Power Goes

Editor THE AUTOMOBILE:—I understand that in an automobile motor that very little power is actually exerted by the road wheels in propelling the vehicle after it once attains a uniform speed on level ground. Take a motor which develops a certain horsepower when turning at the number of revolutions required to propel the vehicle at a given speed. This motor uses up so much fuel; now where does it go? There are a certain number of heat units in each gallon of gasoline. This is converted into useful work to some extent, while most of it is lost because of the inefficiency of the machine. Can THE AUTOMOBILE tell me where the power that is in a gallon of gasoline goes?

Saratoga, N. Y. CHARLES DIXON.

—Your question, which is an interesting one, can be answered graphically to good advantage. In Fig. 2 is represented a gallon jug of gasoline which is fed to the motor. Of this the heat units contained in 35.9 per cent., according to tests which have been made on several different motors, is thrown away in cooling the motor; 35.2 per cent. passes out through the exhaust; 8.1 per cent. is lost through friction in the motor and in heating the incoming charge, etc. The other losses are also indicated in the illustration, which shows that on the average there is only about 6 per cent. of reserve power for the hills and for accelerating.

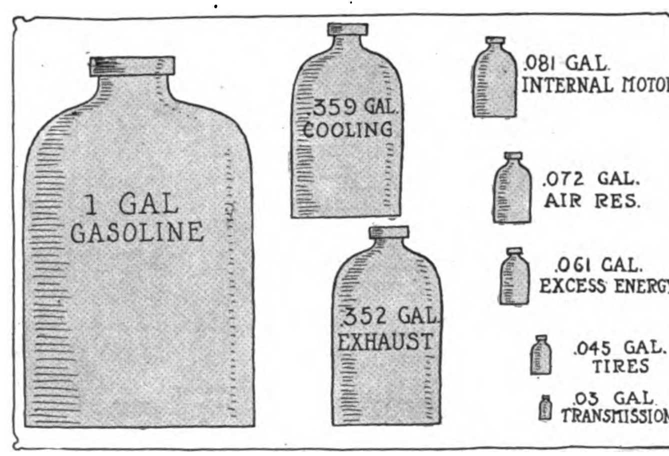

Fig. 2—Graphic representation of the various sources of power loss

Questions Regarding Comfort

Editor THE AUTOMOBILE:—1. Is it not best to run with advanced spark when car is on level road and gas throttle very nearly closed?

2. Is it not best to retard spark when pulling grade if engine begins to pound? Then will you please explain how automatic spark advance can take care of the above opposite conditions, namely, when car does not require much power, spark is advanced, throttle almost closed; next, when car calls for all the power engine has, spark is retarded, throttle is wide open.

3. I am buying new car and want to equip it with anything that will make it more efficient and more economical. The question of shock-absorbers I can't decide. I do not believe in friction absorbers, because when springs are depressed they cannot again come to normal position with friction absorbers. Hydraulic absorbers are not only very expensive, but give considerable trouble in keeping them properly adjusted to give desired results. Is there any known, actual tests that prove beyond doubt that absorbers give a tire more mileage? Which is the

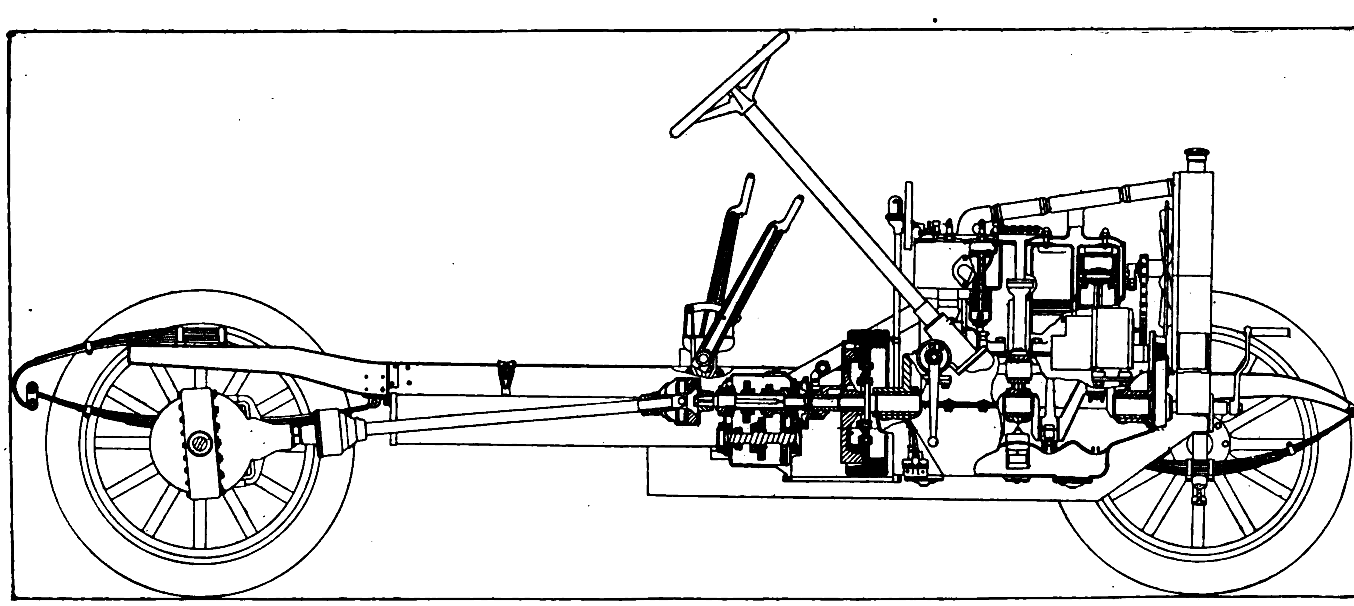

Fig. 3—Section through the driving mechanism of a modern automobile to illustrate features which take care of load changes

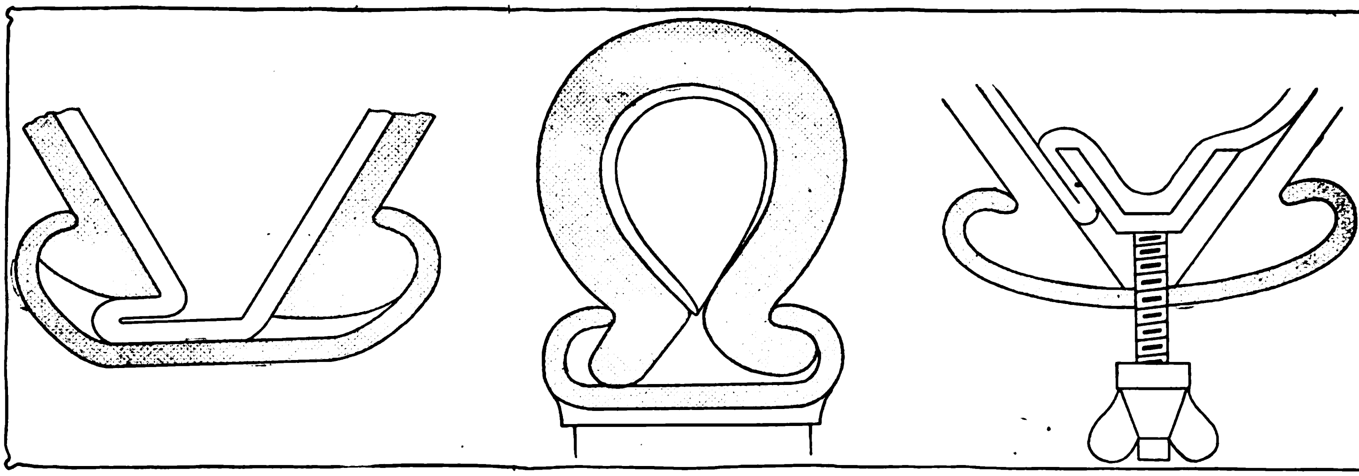

Fig. 4—Showing how the inner tube may be pinched between the bead and the casing, the bead and the security bolt or the two beads

best principle of construction for absorbers, friction or hydraulic?

4. Will you name an equipment for Overland 69 T, equipped with electric starter and lights, that you think covers everything needed for light touring that will aid comfort and pleasure, and for the best possible good of the car and tires, regardless of equipment first cost.

5. Can an electric foot-warmer be operated on a car of the above make, without injury to battery or generator?

6. If foot-warmer can be used, I take it for granted, electric stove, such as toaster, could also be operated from battery when car is standing.

7. I have used an oil heater in car with curtains all down in very cold weather much to the comfort of the passengers. Is this dangerous or not? Danger of oil exploding, I mean.

8. How can you explain that Ford cars generally give more mileage per tire, with their small tires, than most other cars do with much larger tires and in the face of the cry of tire manufacturers to use larger tires. You can put two sets of tires on Ford car for practically the same money you can put one set of 34 by 4 on a car, and if you will get up statistics you will find the two sets of small tires will give one-third to one-half more mileage. You answer, the light car, of course. Then why should not manufacturers strive to lighten up on their cars?

Inman, S. C. G. C. F.

—1. Yes, always run with the spark as far advanced as you can possibly keep it without allowing a knock to occur in the motor.

2. It is necessary to retard the spark or the motor will knock. It must be remembered that the position of the spark is governed by the speed of the motor. When the throttle is wide open and the motor is on a hill under heavy load it will be turned over slowly. The spark will therefore be automatically retarded; a feature which is just what is required or the motor will knock. When the motor is speeded up the spark is automatically advanced, generally by some centrifugal device, and the correct condition for high speed is obtained. A skilled operator can get better results with a hand advance than he can with a fixed spark or one with automatic advance, but the average operator will obtain better results with the automatic.

3. In spite of the many skeptical people the general opinion is that shock-absorbers contribute materially to the easy riding qualities of the car. That this is generally accepted is shown by the fact that the higher priced cars put them on as standard equipment. There have been no actual figures as to tire saving, but the Truffault-Hartford concern estimates it at 10 per cent.

4. The equipment furnished you with your new car besides the addition of tire chains, lap robes, three extra shoes, six extra tubes, blowout patches, warm clothing and a trunk rack will be sufficient. There are endless luxuries which could be added to this and which would no doubt add to your comfort. With this equipment, however, you would not have to struggle.

5. There are no electric heaters of which THE AUTOMOBILE has any record that could be used in connection with the generator or accumulator.

6. Perhaps a heater of this type could be used for this purpose, but the cooking would be very slow work. For a camping trip a small alcohol or oil stove in addition to the regular campfire would be much quicker.

7. An oil heater in good condition will not explode, but there is always a chance.

8. As you have stated, the matter is one of weight. The added comfort of a big, heavy car with its great roominess and luxurious upholstery and heavy motor must be paid for by the greater cost of tire upkeep and first cost. The man who cannot afford all these should be content with a small car.

Tire Blew Out Very Quickly

Editor THE AUTOMOBILE:—I had just made a tire change the other day when the very tire upon which I had been working blew out within 3 minutes after I had fixed it. What could have caused this? I am running an old-fashioned car and am using regular clincher tires.

New Haven, Conn. GEORGE WESTON.

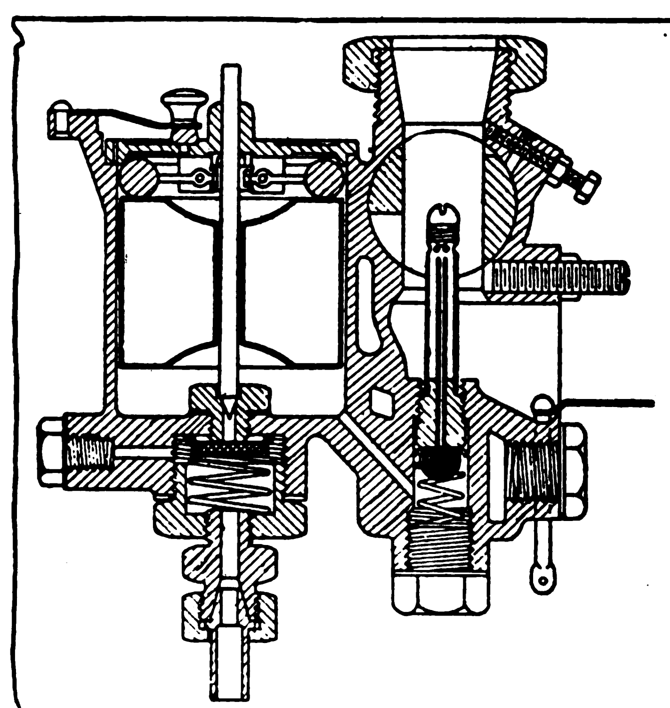

Fig. 5—Sectional view of the Claudel carbureter made in France

—This is no doubt a case of bad assembly. The inner tube became pinched between the tire iron and the rim or perhaps in one of the three ways depicted in Fig. 4. If you will take care in putting the inner tube into the casing the chances are that an accident of this nature will not occur. It is very easy, however, to have a tube blow out through not assembling it properly. When security bolts are used as they were in many of the old-fashioned tires it is easy to see the dangers which surround the inner tube. As shown in the illustration the tube may be pinched between the casing and the rim, the bolt and the casing or occasionally when the tire is underinflated between the two beads of the casing at the top of the tire owing to the tendency of the casing to spring together at the top. In springing the second bead in place after the casing and the tube are on the tire care must be used in not pinching the tube with the tire iron. Many cuts are caused this way and great care is needed in avoiding them, especially if the casing be new and stiff.

Details of Marmon Control

Editor THE AUTOMOBILE:—The spark and throttle of my Marmon car will not stay in place. The factory sent me new gears and advised me to change the springs back of the friction plunger, but after using the car for a short time they became loose. What is the cause?

New London, Conn. PHILIP MORRIS.

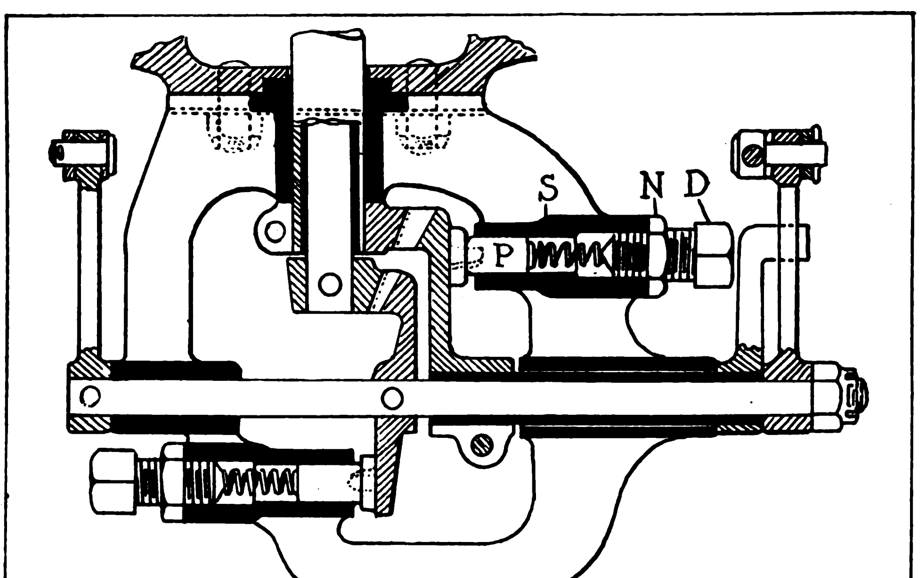

Fig. 6—Control mechanism on the Marmon with a view of the adjustments

—If you have changed the springs back of the friction plungers at the lower end of your steering columns as advised by the factory, perhaps you have not screwed in the studs D, in Fig. 6, to give the springs S the required compression. If you will adjust the springs so that the plungers T press sufficiently hard upon the backs of the gear sectors the friction should be great enough to hold your engine control levers as tightly as desired. It is possible that you have not tightened the locknuts N on the spring adjusting studs. These nuts must be tight in order that the adjustment may be maintained.

Taking Care of Alignment

Editor THE AUTOMOBILE:—What provision is made in the Haynes car for taking care of the change of alignment due to the additional weight of five passengers over the weight of the empty car. That is, if the drive is aligned for an empty car will it make a difference in the arrangement of the parts below the floor of the car if five passengers are carried? I am mentioning the Haynes cars for example as I drive one of these cars now and have owned one of the earlier models for some time. I have heard it stated that a car will have a practically straight-line drive when loaded, while the drive will not be straight when the car is empty. I should like to know what compensating device takes care of this and how it is taken care of automatically.

New York City. CHARLES ATWOOD.

—This cannot be better explained than by a section through the whole car which will show how the drive is transmitted from the motor to the wheels. In Fig. 3 this section is given. It will be noted that the motor sends the power through a clutch into the gearset. From the gearset it is transmitted through a universal joint and then back to the propeller shaft. At the rear end of the propeller shaft there is another universal joint through which the power passes into the rear axle. The rear axle shafts transmit the power to the drive wheels and it is thus that the car is driven. Now when a heavier load is placed in the car it will tend to flatten out the springs at the front and rear. This is especially so in the rear, as most of the passengers will be carried in the tonneau of the car, which is mounted practically over the rear axle. The rear of the car sinks down about the front suspension points as a pivot, although the front suspension itself will be lowered slightly. The frame carrying the motor and the gearset is a part of the main frame which carries the body. Therefore the motor and gearset will be lowered slightly in relation to the rear axle tending to bring the propeller shaft to a more horizontal position. The propeller shaft is permitted to move on account of the universal joint connection it has with the main gearset and rear axle and therefore there is a perfect accommodation for the changes of alignment. It is perfectly true that a motor car will have a more efficient drive when loaded. In fact, many of the four and five-passenger cars are designed to have a straight-line drive when loaded. This form of suspension is common in the modern motor car. It will accommodate not only for changes in the total load, but also for changes in alignment which are caused by the rocking motion of the car when striking spots on the road that cause the springs to come into sudden action.

Carbureter Chokes

Editor THE AUTOMOBILE:—When I am first starting out with my car I notice that it will start to skip if I press down quickly on the accelerator pedal. What is the cause?

C. PETERS.
N. Y. City.

—This does not show that there is anything wrong with the carbureter or the motor. The accelerator pedal should be pressed down gradually, at least until the motor has become warmed up or else the mixture will be too rich and will not be thoroughly vaporized. This, of course, causes the motor to misfire. After the motor has become warmed up, however, this should not occur and you should be able to open the throttle quickly without the motor choking or missing fire.

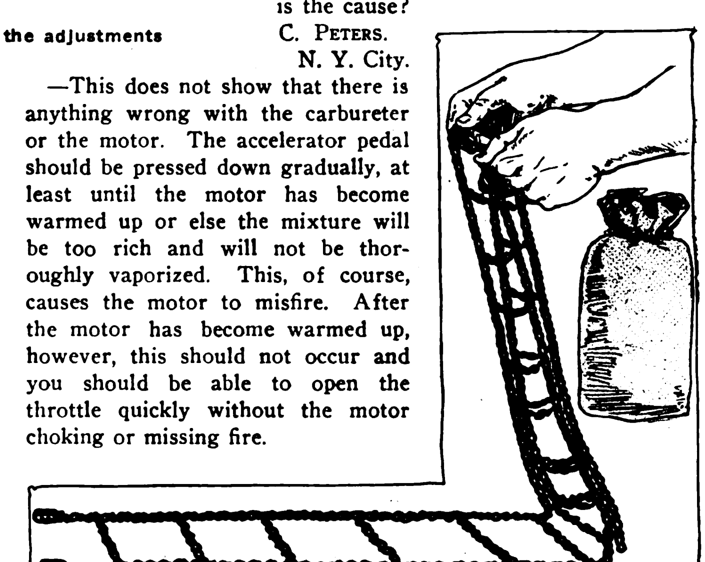

Fig. 7—How to carry tire chains so that they are always in condition

Stearns-Knight Motor Continues Unchanged

Retaining Motor Construction, Stearns Adds Six-Cylinder Model —Bodies Are of Original Design

Fours Are Fitted to Three Different Wheelbases and Sixes to Two—Complete Equipment a Feature

THE Stearns Company, which 1 year ago introduced the Knight type of sleeve-valve motor and entirely discontinued the marketing of poppet-valve types, announces for 1913 that it will build this motor in four and six-cylinder designs, and is continuing its four-cylinder motor without practically any mechanical changes. The six-cylinder model will not be announced for some weeks, but will be characterized by a long-stroke Knight engine and will be built with 134 and 140-inch wheelbases depending on the body type.

The four-cylinder model for next season is very similar in chassis design to this year's model, but fitted with a line of entirely new bodies. The chassis is made in three wheelbase lengths: 116 inches, roadster; 121 inches, five-passenger, and 127 inches, seven-passenger body. Limousine and landaulet are mounted on either 121 or 127-inch size. It is fitted with a motor of twin castings 4.25-inch bore and 5.5-inch stroke, a bore-stroke ratio of 1.29 and a horsepower rating of 28.9. This horsepower figure is claimed to be quite below the actual power generated at running speed.

The characteristic curves for this motor shown by Fig. 4 will bring out this low rating. The motor will develop this horsepower at a speed of 800 revolutions per minute, while its maximum output is seen to be about 64 horsepower at 2,400 revolutions. Naturally its torque, or turning effort, is least at this speed, being 124 pounds. The maximum torque of 181 pounds is at a crankshaft speed of about 1,100 revolutions per minute. In test, the car has required about 160 pounds torque from the motor to start, which means a horsepower somewhere in the neighborhood of 10.

Fig. 4 brings out the interesting fact that the top of the torque curve is at a higher motor speed than is common in most automobile motors. The almost straight horsepower curve is remarkable as the result of consistent valve timing at all running speeds of the motor.

Below is given a table showing the performance of the motor at different crankshaft speeds. These data were obtained on a prony brake test of the four-cylinder Stearns-Knight.

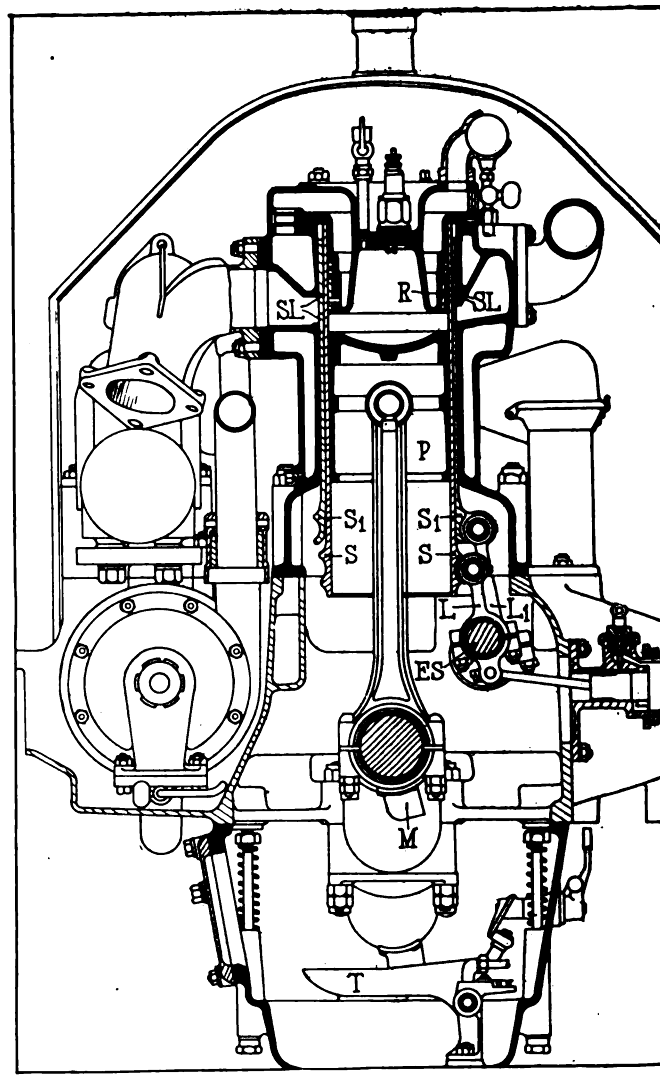

Fig. 2—Cross-sectional view of Stearns-Knight motor, illustrating sleeve construction and design of oiling system

Crank-shaft speed, r.p.m.	Horse-power	Torque pounds	Crank-shaft speed, r.p.m.	Horse-power	Torque pounds
400	14	168	1500	51.2	175.5
500	18	171	1600	53.8	172.5
600	22	174	1700	55.3	168.5
700	26.2	176.5	1800	57.2	164.0
800	30	178	1900	59.0	160.0
900	33.7	179.5	2000	60.3	154.0
1000	37.5	180.5	2100	61.5	147.0
1100	40.5	181.0	2200	62.7	140.0
1200	43.5	180.5	2300	63.7	132.0
1300	47.2	179.0	2400	64.5	124.0
1400	48.8	178.0

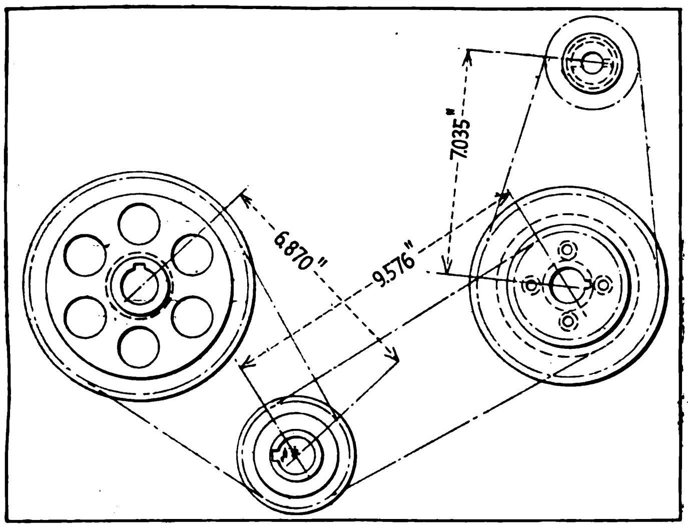

Fig. 3—Schematic view of chain drive used for actuating the sleeve-eccentric and magneto shafts

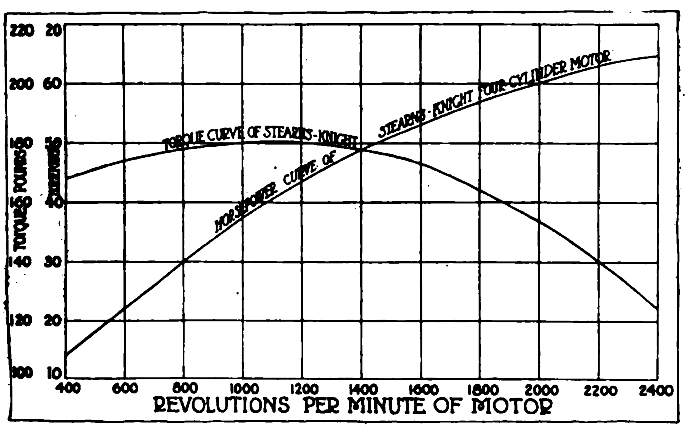

Fig. 4—Horsepower and torque curves of four-cylinder Stearns-Knight motor used in 1913 cars

In making practically no change whatever in this year's power plant, the Stearns people point out that before adopting this type of motor exclusively, their engineers made a number of improvement in it, and the performance since its adoption has been such that no material changes have been found desirable.

In fact, before finally pinning their faith to the sleeve-valve creation of Charles Y. Knight, the Stearns designers worked out extensive improvements in the inventor's conventional type of engine. These improvements were sanctioned by Mr. Knight and later adopted, at least in principle, by the Daimler, Mercedes, Panhard and Minerva concerns abroad. One difficulty which was formerly experienced with the Knight motor was to get it to idle successfully, that is, to pull evenly when running at low speed under no load. After making many tests, the Stearns engineers became convinced that the difficulty lay in the entrance of a slight amount of air through the exhaust port. This port, when not open, was thought to be hermetically sealed, but by means of several delicate tests, it was found that there was a slight amount of leakage between the concentric sleeves, the cylinder wall and the piston. Having thus located the trouble, it was a simple matter to remedy it, although just what method was adopted, the Stearns company refuses to divulge. It is easy to surmise how such leakage could be prevented, however. Clearances might be altered, compression rings changed, or any one of several other means for preventing leakage might be resorted to.

The Stearns concern, before adopting the motor, also worked out a change in the oiling system. The movable troughs into which the ends of the connecting-rods dip were retained as Mr. Knight had designed them, but in addition an auxiliary oiling device connected to the throttle adopted. This device consists of a small oil tank located on the back of the dash, under the hood. When the motor has reached an excessively high speed or the load has become very heavy, this auxiliary lubricator comes into play, feeding through the intake ports. In the early sleeve valve motor, a sort of auxiliary oiler, feeding through the cylinder heads, was used. This, however, gave more or less trouble and had a tendency to smoke. It is claimed for the Stearns system that it entirely eliminates this trouble.

Other changes were made by the Stearns concern, of which only the most meager sort of information is obtainable. The so-called junk-ring or cylinder head ring R, Fig. 2, was redesigned, making it heavier and wider, the system of forcing oil to the crankshaft bearings was changed, the construction of the oil gauge, shown in Fig. 3, was altered, the water manifolding was changed, and so on.

With the construction of the Stearns-Knight motor readers of THE AUTOMOBILE are no doubt familiar, the principle of operation and details of this motor having been exhaustively treated in the technical press within the past year. However, for the benefit of those who are not familiar with the motor, the general features of the Knight construction will be reviewed. The sectional cuts and illustrations herewith will serve to bring out the constructional details clearly. Fig. 2 shows the end section of the motor. There are two concentric sleeves, S and S1, which fit within the cylinder, between it and the piston, P. These sleeves move up and down, being actuated by the small connecting links L and L1, which are connected to the eccentric shaft, ES. In the upper ends of these sleeves S and S1 there are slots cut, which serve as port openings, admitting or exhausting the gas at the proper time. When the exhaust or inlet openings in the two concentric sleeves register with one another

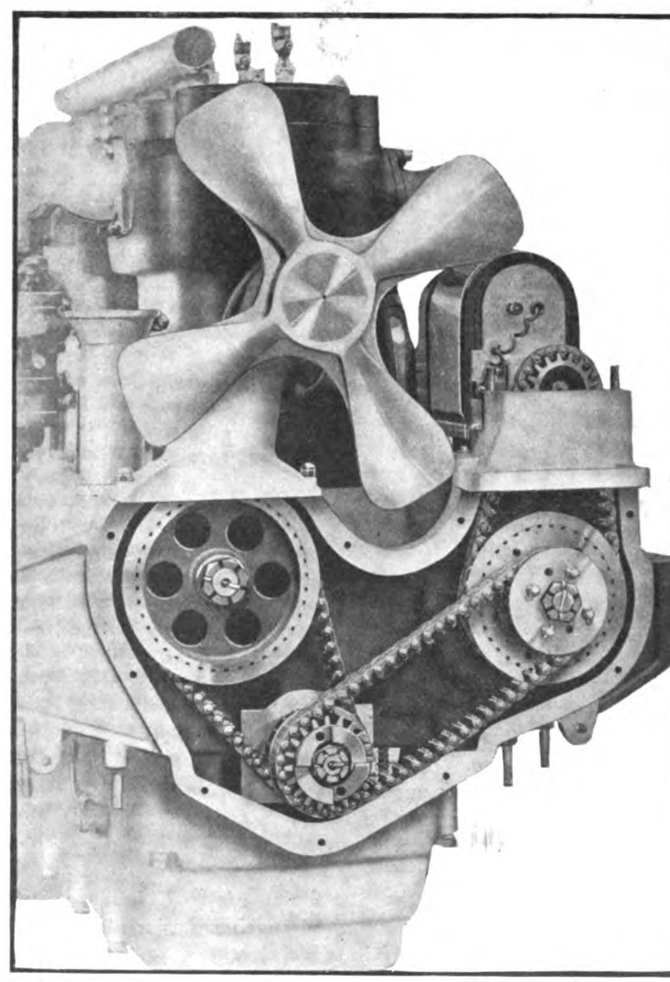

Fig. 5—Front view of Stearns-Knight motor with front plate of timing gear case removed, showing silent chain drive

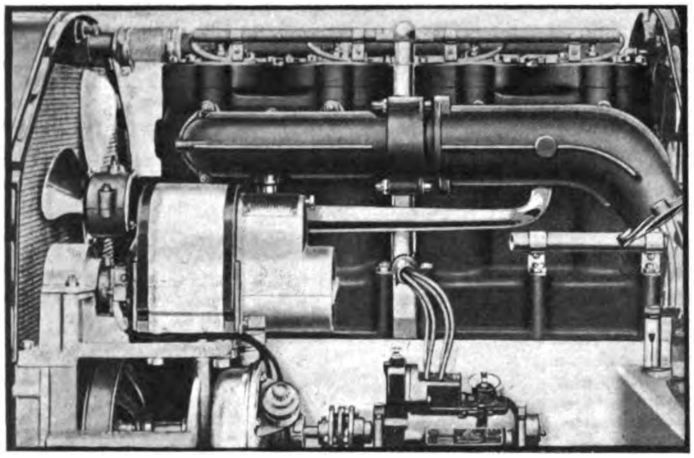

Fig. 6—Left side of the motor, showing the arrangement of Mea magneto and Deaco lighting generator

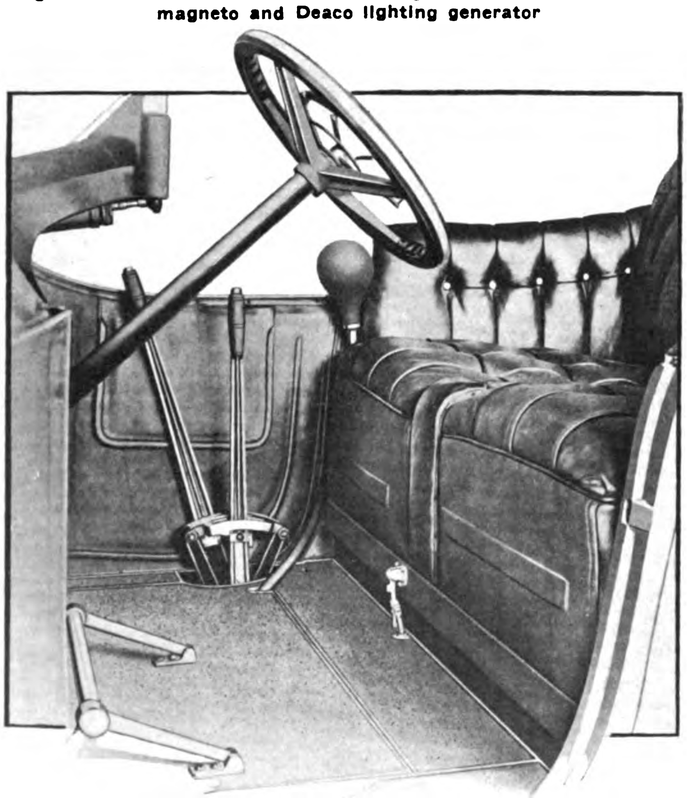

Fig. 7—Driver's seat and control mechanism of 1913 Stearns-Knight, showing provision for operator's comfort

and with the opening in the cylinder wall, there is a path from within the cylinder into the exhaust or inlet manifold, as the case may be. Of course, as soon as the three openings begin to register, there is a partial passage between manifold and cylinder, but the port is not fully open to the gases until all three openings—the two sleeve slots and the cylinder passage—are in exact register. In its motion up or down, the opening or slot in one of the sleeves may be opposite the cylinder opening, but no gas can escape or enter because the passage is barred by the other sleeves. The movement of the sleeves is so timed that only during the exhaust stroke or the suction stroke do the two sleeve ports come together, at the same time being opposite the opening in the cylinder wall.

It will readily be seen that the timing of the Knight motor is a difficult proposition, and required much experimentation and testing during the period of its development.

The movement of the sleeves up and down is very much less than that of the piston, hence the problem of oiling is not a troublesome one. In fact, the stroke of the sleeves is only about

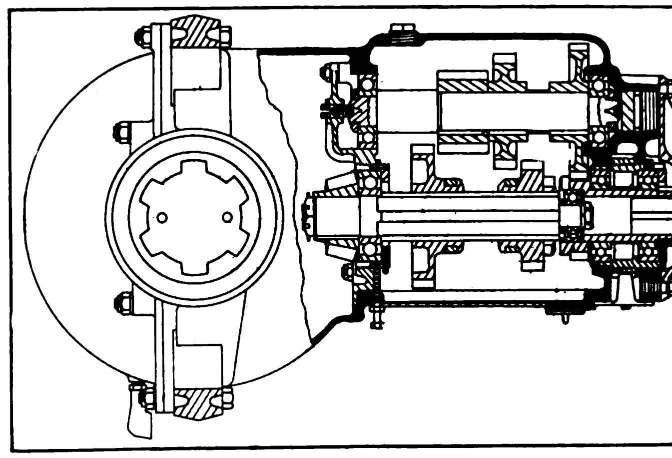

Fig. 8—Sectional view of rear unit of Stearns car, in which the drive is taken directly from the gearbox to the differential

one-tenth that of the piston. That is, while the piston stroke is 5.5 inches, the stroke of either sleeve is only 1.125 inch. For a crankshaft speed of 1,500 revolutions, which means a piston speed of 1,375 feet per minute for a 5.5-inch stroke, the sleeve speed is approximately 140.5 feet per minute, nearly a tenth, as already stated.

The slots in the upper ends of the sleeves are not the same width for both intake and exhaust sides. The lengths are the same, but the width of the exhaust opening is slightly wider, as seen from the following:

	Port length	Port width
Inlet	124 degrees (4.5 inches)	.5 inch
Exhaust	124 degrees (4.5 inches)	.625 inch

The exhaust is made slightly larger than the intake to allow for the complete escape of the exhaust gases and the thorough scavenging of the cylinders.

Silent Chain Drive Throughout

The conventional type of poppet valve motor has its camshafts driven by helical or spur gears, connected with the crankshaft. The Knight motor does not use gears to drive its eccentric shaft, which imparts the sliding motion to the sleeves through the small connecting-rods. This shaft is driven by silent chains, as shown in the illustration. A silent chain also connects the crankshaft with the magneto shaft. The latter in turn drives the electric generator shaft through another silent chain. A diagram of the chain drive and sprockets is given in Fig. 3. The distances between centers of the various sprockets are also noted. They are as follows:

Eccentric to crankshaft	6.87 inches.
Crankshaft to magneto shaft	9.576 inches.
Magneto shaft to generator shaft	7.035 inches.

Each of the three chains has a different width. The chain dimensions are given:

	Width	Thickness	Length
To eccentric shaft	1 inch	.5 inch	29 inches
To magneto shaft	.75 inch	.5 inch	29 inches
To generator shaft	.5 inch	.5 inch	27 inches

The sprockets have diameters as below:

Eccentric shaft	6.424 inches, pitch diameter.
Crankshaft sprocket for eccentric shaft drive	3.222 inches, pitch diameter.
Crankshaft sprocket for magneto shaft drive	3.222 inches, pitch diameter.
Magneto shaft sprocket	3.222 inches, pitch diameter.
Generator drive sprocket on magneto shaft	5.462 inches, pitch diameter.
Generator shaft sprocket	1.406 inches, pitch diameter.

The oiling system of the Stearns-Knight has been briefly touched upon, but special attention should be drawn to the varying-lever oil troughs, T, Fig. 2, one of which is under each of the connecting-rod ends. The scoops M on these rod ends dip into the oil contained in the troughs T and splash it onto the sleeves, bearings, etc. The troughs are connected to the throttle. Opening the throttle raises them so that they will hold more oil, thus feeding more to the bearings, while closing the throttle lowers the troughs so that less oil is available for the connecting-rod ends. A gear pump furnishes oil to the troughs by means of oil leads. Another oil lead goes to the fan, while a fifth passes to the dash sight-feed. The additional lubrication of the sleeves has already been taken up. It will be noticed that they are grooved to aid in the even distribution of the oil over their entire bearing surfaces. The Stearns-Knight utilizes essentially the same oiling system as that of the Daimler-Knight motor of England.

Fig. 6 shows the left side of the motor. The Mea magneto is mounted below the generator, as seen. The generator furnishes current for all lamps, but not for starting. The American Ever-Ready spring starter is used, and is placed at the front of the motor. It consists of a coiled spring of sufficient strength to turn the crankshaft a number of times when released. After the engine is running, the spring is re-wound automatically. The generator is a Vesta and a Stromberg type of carbureter is used. The gasoline tank is carried at the rear and fuel is fed to the carbureter at 2 pounds pressure.

The eccentric shaft and the crankshaft have five main bearings, each as follows:

Eccentric shaft bearings	Diameter, inches	Length, inches
Rear	1.001	2.625
Center	1.250	3
Two intermediate	1.250	2
Front	1.250	2.5625
Overall length of eccentric shaft		32.125

Crankshaft bearings	Diameter, inches	Length, inches
Rear	2.5	5.25
Center	2.5	3
Two intermediate	2.5	2
Front	2.5	2.5625
Overall length of crankshaft		40.2375

The connecting-rod bearings on the eccentric shaft have a length of 1.6875 inch and a diameter of 1 inch. The piston connecting-rod bearings have dimensions of 2.25 by 2.5 inches diameter and length, respectively. The sleeves, cylinder walls and jacket walls all have a thickness of 5-32 inch.

Details of Transmission Set

Passing from the motor to the transmission and rear construction: The gearbox is at the rear axle, bolting to the differential housing, Fig. 9. The clutch is of multiple-disk type, having fabric facings on the plates where they engage with one another. The clutch is located within the flywheel. From this point the power is transmitted through a universal joint, and thence to the propeller shaft, which is inclosed within a substantial torque tube. This latter is hinged in the conventional way at either side of the shaft to a cross-member of the frame by means of two arms, which form a U-shaped construction. At its rear end the torsion tube bolts directly to the gearset housing.

Radius rods run diagonally from the center of the intermediate cross-frame member to either end of the live rear axle, maintaining the correct alignment of the latter. The gearset provides three speeds forward and reverse. It is of the selective type, gear-shifting being effected through the use of an H-gate. Three-quarter elliptic springs are used in the rear, being shackled outside the frame. The front springs are of the half-elliptic class, and sufficient for the requirements, due to the weight distribution of the car over the front and rear axles respectively. The construction of the suspension on this year's Knight cars is such that easy riding is one of the special claims for the product.

The frame is dropped at about the middle, and raised at the rear so as to clear the rear axle. Brakes are internal expanding, two for each drum. One drum is placed within the other concentrically, the same type of cam-operated expanding shoes being used for both.

The standard form of right drive and right control have been retained, despite the rumors to the effect that the Stearns concern had shifted to the left drive on its new fours. It is not known as yet as to whether the drive and control of the new six will be right or left.

A slight change has been made in the steering mechanism, the steering gearcase now extending from below the frame to the floor boards, giving greater rigidity of the entire steering column. Another minor change which is worthy of note is the placing of all wiring for the electric lighting system on the body. This wiring was formerly run along the frame, but it has been removed from the chassis so as to eliminate any danger of short-circuiting, regardless of how slight that possibility is when the wires are properly inclosed in substantial conduits.

It is in the bodies that the greatest Stearns changes have been made. The appearance of the car, even though it is mechanically nearly a counterpart of its predecessor, is different. The straight-line, flush-side body is now used, the door hinges being concealed. The running-boards have been cleared of tool boxes, battery boxes, tires, etc. Upholstery has been made deeper than last year, and the equipment is more complete. The most important items which come under the latter head are the self-starter, silk mohair top, windshield, Warner speedometer, Klaxon horn, electric generator for lighting all lamps, demountable rims, etc. In fact, it is the intention of the company to adhere to the policy which the leading manufacturers have decided upon for the coming year, and make 1913 its equipment year. The metal fittings, lamps, etc., on all cars are finished in nickel plate and black enamel.

Reducing the Weight

AMERICAN makers are retrograding somewhat in the present increase in weight in many of the newer models as compared with older models with practically the same motor sizes. Two years ago the weight-reduction argument was more general than it is to-day. At that time several makers went too far in the reduction rôle, producing cars not adequately robust for heavy road surface, but to-day they are steering in the opposite direction.

There have been many reasons for weight additions within the last year and chiefly on several of the 1913 models. The extra equipment is responsible for many additional pounds. The matter of demountable rims alone in this connection is considerable. On some large cars, by actual weight, the tire inflated on the rim weighs exactly 110 pounds. The owner is not content with five rims, that is one spare for the running board, but carries two extras so that his demountable rim and tire weight is alone 660 pounds. Of this 440 is unsprung weight, the two extras carried on the running board being supported through the springs.

But the causes of extra weight go still further: The starter battery and starter mechanism have added weight, yet it is commendable to see that concerns marketing electric starting apparatus are aiming at reducing the weight as much as possible, some claiming to build a satisfactory device not weighing more than 24 pounds and others announcing that their aim is to still reduce this figure. It is certain that at present the weight question is going to be a factor in determining the exact nature of the electric starting and lighting equipment on certain makes of cars. While weight reduction is commendable when adequate strength is maintained it is to be hoped that efficiency will not be sacrificed for weight reduction.

Foreign makers are devoting much attention on their 1913 models on the reduction of unsprung weight, that is weight carried direct on the road wheels and not supported through the springs. They recognize that unsprung weight is not desirable in any way, shape or form. They recognize that unsprung weight reduces the flexibility of the car on the road; they recognize that unsprung weight means greater tire wear; and they recognize that unsprung weight is harder on those unsprung parts, which, because of the duty they play in the car, cannot be mounted otherwise.

Many means are being used in both pleasure and commercial cars to cut down this unsprung weight: A favorite one is the development of forgings in axle construction and the elimination of steel and malleable iron castings. Engineers are expending much energy on this work. The forging art is being developed to utilize the requisite amount of material, placing it in that part where greatest strength is essential and cutting out those parts where heretofore it has not been necessary. There still remains much room for improvement. Not only has bulk been cut away where not necessary but there has been a perceptible improvement in the quality of material used in the forging and more means made use of for testing more generally these parts before placing them in the machine. Then, too, the laboratory has been busy in going further into the details of heating processes, so that in a word the forging art has been carried to the fifth decimal place.

There is a tendency abroad to follow the DeDion plan of getting away from unsprung weight by the forged stationary rear axle and supporting the differential on the chassis frame, thereby carrying it through the springs. In this way the rear axle weight is cut to the minimum, without any reduction in efficiency. Still further in rear axle design is the use of the higher-grade stampings or pressings for axle housings. These stampings are now being made from alloy steels and the processes are so refined that robust housings for high-powered are being produced which weigh less than 70 pounds.

The use of wire wheels, which is in the eye of the American builder to-day, is growing by leaps and bounds in Continental Europe. A few years ago England was the only exploitation ground and because John Bull brought it out France and Germany would have none of it. Two years ago France took it up and now one of the best engineering houses in France has announced that for 1913 detachable wire wheels will be stock equipment. This company has further announced an average temperature reduction of 33 per cent. in tires on wire wheels, due to the rapid radiation of heat from the tire through the metal wheel rim and its spokes. Added to this is the reduction in rim weight on the wheel and the consequent adding of flexibility to the car when on the road. Here also comes longer wear on tires and brake linings.

Full Equipment Now a Necessity With Car Makers

Nowadays An Automobile Is Judged by Its Equipment Which Also Aids or Hinders The Salesman, C. S. Jameson, of the Willys-Overland Company, Tells Sales Managers' Convention of the Automobile Board of Trade

THE subject of automobile equipment would have admitted of more argument several years ago than it can possibly do today. Custom and demand have settled any question, and beyond any doubt. **Full equipment must be furnished by the manufacturer.**

When the automobile was in its infancy, naturally cars were not equal to those of today in any respect, and the prospective customer had not become motor-wise as he has at this time. Now full equipment is expected and demanded, and why not? Certainly, the prospective purchaser has learned, either by experience or through a friend, that equipment is a necessity, and that he pays whether it be on the car when he buys it or at an additional cost. He further appreciates that if equipment is supplied at the factory, and by the manufacturer, it will mean better material, better workmanship, more effective devices and a more harmonious whole.

He knows that the maker of a car cannot afford to jeopardize his reputation by supplying ineffective devices or material of questionable quality; hence, the fully equipped product has the advantage to start with.

The purchaser of a car at $1,000 should not look for the more expensive equipment, and that which would be out of proportion in comparison with cost or selling price. Still, the evidence is strong that, regardless of what the prospective purchaser may be able to pay, he looks not only for such equipment—which might be termed a necessity—but also for that which represents labor-saving devices and comfort.

Manufacturers of medium—and in many cases lower—priced automobiles have shown a willingness to furnish full equipment, and the builders of the higher-priced cars have, from necessity, been obliged to follow suit.

The greater margin of profit on the latter has permitted of more complete equipment, and occasionally extravagance is shown. The future will see even more attention given to the subject of equipment, which will represent a logical and common-sense reason for the difference in price.

A certain percentage of buyers, at least, will pay high prices for equipment de luxe, as they will pay high prices for luxurious hotel, steamboat, train and other accommodations. However, most buyers are looking for their money's worth, and a wide-awake builder of automobiles will, by ingenuity or through the result of volume production, obtain the desired result, and at the same time keep within his class as to cost and selling price.

It must be conceded that the cost of equipment will be reduced as the demand increases, product becomes larger, and use more general. As the selling price of the automobile advances, the demand is more limited and the purchaser more exacting.

The medium-priced product has reached the stage where full equipment today is required, and the car selling at present for $2,500, or above, must be fully equipped. The manufacturer who fails to realize this should not wonder why his dealers lack enthusiasm, and sales drop off.

The purchaser of an automobile is a progressive, and demands up-to-the-minute ideas that add to his protection and comfort. He must be shielded from the inclemency of the weather. He must be permitted to ride on and on without worry and inconvenience.

The automobile without a top may be compared to a house without a roof. The individual who travels in his residence from one floor to another by simply stepping into an elevator and pressing a button will not accept an old style of equipment, nor the lack of it which requires the cranking of an automobile engine on a hot morning in summer, or a cold one in winter.

The man who has electric lights in his home from cellar to attic will not be subjected to the use of kerosene lamps, with their dirt, oil and smut, and this same party will insist on knowing how far and how fast he is traveling, whether it be by automobile or train.

The demountable rim helps to remove one of the great drawbacks to motoring. It is becoming more and more in demand each minute; **but it remains for some fertile brain to give us an acceptable substitute for the pneumatic tire, something with which the words puncture and blow-out have no connection.** He who can do this will surpass Edison in fame and Rockefeller in wealth.

One of the strongest arguments in favor of full equipment by the manufacturer is presented in the cheaply constructed top, top boot, and similar accessories made to sell to the dealer, or purchaser, of the unequipped car at a price. The question of quality never enters into equipment of this nature; neither does the matter of finish, design nor conformation to the lines of the car receive any consideration. **A car of quality may become a subject of criticism and a discredit to its maker through the ill-fitting, poorly proportioned and cheaply made top and top boot.**

In some instances dealers have purchased tops other than that of the car manufacturers' make, and of inferior design and material, and these have been sold to the customer as the factory article, unquestionably injuring the manufacturer's reputation.

The lack of full equipment has been said to encourage price-cutting. The customer realizes the necessity of equipment, and the lack of it appeals to him as an arbitrary and unreasonable position on the part of the manufacturer. A haggling over cost follows, and oftentimes results in the dealer throwing in the equipment at a loss to himself, and such action represents a cut in price.

The fully equipped car unquestionably gives the salesman advantage over competition in many respects, and without considering extremes or fads, the more equipment the greater the advantage.

Place the salesman in a position where he can utilize his time, his knowledge and his enthusiasm in extolling the merits and construction of the car he sells, and not in making excuses because the manufacturer fails to include a boot with a top, or his fossilized ideas led him to think a self-starter was unnecessary and only a fad, or that the demountable rim rusted, or was no better than the old clincher.

It is said that a man is judged by the company he keeps, the company by the men it employs, and I say an automobile is judged by its equipment.

U. S. Motor Assets and Liabilities

Aggregate Assets of Companies in Receivership

REAL ESTATE, BUILDINGS AND EQUIPMENT—as per the Books	$7,858,266.23		
Deduction—Depreciation as per the Books	1,473,493.24		
	$6,384,772.99		
Value as a going concern—Appraised by Gunn, Richards & Company		$4,999,836.31	
(Auction Value—Appraised by Gunn, Richards & Company, $2,602,000.00.)			
REAL ESTATE INVESTMENTS:—			
Columbus Circle Realty Company—Capital Stock at par—as per the Books	$112,000.00		
Improvements made on premises owned by Columbus Circle Realty Company—per Books	116,311.67		
	$228,311.67		
Building and Improvements appraised by Gunn, Richards & Company at $587,737.00; Estimated Value in the equity based on appraisal	$83,520.00		
New Castle Construction Company—Bonds at par—as per the Books; and Estimated Value, based on appraisal of property by Gunn, Richards & Company	36,000.00		
		119,520.00	
Total Real Estate, Buildings, Machinery and Equipment			$5,119,356.31
FURNITURE AND FIXTURES:—			
Estimated Values, as per Office Employees; Appraiser's Figures not yet received:			
New York Office		$36,000.00	
Factories		40,000.00	
			76,000.00
INVENTORIES—ESTIMATED:—			
At Factories, and on Consignment from Factories, as per actual Inventory July 31, 1912, brought to September 11, 1912, by adding purchases and labor and deducting Sales—as per Books	$5,772,870.52		
Deduction—Reserve for Obsolete Material, etc., estimated by Comptroller of the Company	1,024,831.72		
	$4,748,038.80		
(Of this sum less than $275,000.00 is represented by completed new cars)			
Estimated Value: by Messrs. Anthony, Maxwell, and Jameson (for the Company) on the basis of a going concern for all Factories, all operating, except the "Brush"			4,500,000.00
On the basis of closing down the Brush and Alden-Sampson Factories, $4,100,000.00.			
On the basis of closing down the Brush, Alden-Sampson, Columbia and Dayton Factories, $3,000,000.00.			
ACCOUNTS RECEIVABLE—Not including Inter-Company Accounts—as per Books		$661,257.22	
Deduction—Reserve for Doubtful Accounts—as per Books		73,010.70	
		$588,246.52	
Estimated Value			550,000.00
NOTES RECEIVABLE—In hands of Treasurer—as per the Books		55,406.44	
Estimated Value			34,830.20
CASH IN HAND AND ON DEPOSIT			412,027.80
CASH—Special to provide for Dealers' Deposits (This fund stands to Credit of U. S. Motor Company in Banks as "Special Fund")			62,513.24
PREPAID EXPENSES: Insurance Premiums—Unexpired Proportion—Estimated Value			45,440.21
Total Assets other than Inter-Company Accounts			$10,800,167.76
INTER-COMPANY ACCOUNTS:			
Accounts Receivable—Due from Factories to U. S. Motor Co. and other Inter-Company Accounts—all in Receivership		$4,789,713.56	
Offset by Liabilities in Companies in Receivership—of Equal Amount		4,789,713.56	—0—
Accounts Receivable—Due by Branch Selling Companies on Notes Assigned to Banks with Endorsement		$1,303,838.25	
Unassigned Notes and open account		2,066,844.03	
		$3,370,682.28	
Estimated Value of the Entire Debt, Assigned and Unassigned, $1,954,995.72.			
Estimated Value of the Entire Debt so far as Unassigned			1,198,769.54
Notes Receivable—E. R. Thomas Motor Car Company		$5,000.00	
Estimated Value, problematical			2,000.00
Accounts Receivable—National Motors Company—Estimated Value Par			4,042.23
Accounts Receivable—Providence Engineering Works—as per the Books—Disputed		$180,923.53	
Estimated Value			—0—
Total Assets, other than Securities Owned: Going Concern Value			$12,004,979.53
SECURITIES OWNED IN OTHER CONTROLLED COMPANIES:			
Briscoe Manufacturing Company—Par Value of Capital Stock Owned		$310,000.00	
Estimated Value, over and above amounts due from U. S. Motor Co			367,995.00
Appraisal of Real Estate, Buildings, Machinery, etc., by Gunn, Richards & Co., as a going concern $166,995.00, and Auction Value $121,000.00.			
Providence Engineering Works—Par Value of Capital Stock Owned		$500,000.00	
Estimated Value, problematical			1.00
Appraisal of Real Estate and Buildings by S. A. Nightingale & Company, not including Machinery, to the amount of $91,021.00.			
E. R. Thomas Motor Car Company—Par Value of Capital Stock Owned		$2,400,000.00	
Estimated Value			—0—
Courier Car Company—Par Value of Capital Stock Owned		$500.00	
This Company has no Assets—Estimated Value			—0—
National Motors Company—Par Value of Capital Stock Owned		$849,600.00	
Estimated Value—Based on Equity in Real Estate at Boston (Mass.); New Castle (Ind.); Equity in certain Branch Selling Companies; Cash; Receivables, etc			355,190.07
TOTAL ASSETS, ESTIMATED VALUE			$12,728,165.60

Aggregate Liabilities

REAL ESTATE MORTGAGES		$164,540.90
DEBENTURE BONDS, BOND SCRIP AND INTEREST		6,161,509.87
NOTES OF ONE OR MORE OF THE SUBSIDIARY COMPANIES:—		
Endorsed by the United States Motor Company, and Notes of one or more of the Branch Selling Companies endorsed by the United States Motor Company, with interest		*2,194,258.12
NOTES OF UNITED STATES MOTOR COMPANY:—		
Endorsed by one or more of the Subsidiary Companies		650,820.99
CLAIMS AGAINST UNITED STATES MOTOR COMPANY ONLY:—		
Of this sum, approximately $100,000 is due for goods delivered immediately prior to Receivership		1,961,875.99
CLAIM AGAINST COLUMBIA MOTOR CAR COMPANY, OR UNITED STATES MOTOR COMPANY OR BOTH		91,789.60
NOTES SECURED BY SIGHT DRAFT ON CAR SHIPMENTS		63,691.26
WAGES OF EMPLOYEES AND ACCRUED EXPENSES		74,256.30
DEALERS' DEPOSITS (PARTLY OFFSET BY ACCOUNTS RECEIVABLE)		55,113.24
CONTINGENT LIABILITY ON ENDORSEMENT OF NOTES OF E. R. THOMAS MOTOR CAR COMPANY		†400,000.00
PROVIDENCE ENGINEERING WORKS:—		
Claim made for work performed—Disputed	$138,532.26	—0—
TOTAL LIABILITIES OTHER THAN INTER-COMPANY		$11,817,856.27
INTER-COMPANY ACCOUNTS:—		
Briscoe Manufacturing Company	$313,970.91	
The Capital Stock of this Company is owned entirely by the United States Motor Company, and, as the Briscoe Manufacturing Company is regarded as a solvent Company, this liability is taken at		—0—
EXCESS ASSETS—Estimated Value as shown—Over Liabilities as Shown		910,309.33

*It is estimated that the Branch Selling Houses can pay $756,226.18 on their Notes, after providing for their local indebtedness.

†The Receivers of the E. R. Thomas Motor Car Company estimate that that Company will pay from 25% to 40% to its Creditors.

CAPITAL STOCK (NOT INCLUDED IN THIS STATEMENT) OUTSTANDING—OUTSIDE OWNERSHIP:—		
United States Motor Company, Preferred	$11,499,733.33	
United States Motor Company, Common	12,206,350.00	
Columbia Motor Car Company, Preferred	13,400.00	
Columbia Motor Car Company, Common	118,000.00	
	$23,837,483.33	
TOTAL		$12,728,165.60

Russell Profits Show Increase

TORONTO, Oct. 28—Profits of $180,127 for the year ending July 31 are shown in the annual statement of the Russell Motor Car Company which will be presented at the annual meeting of shareholders October 31. This is an increase of $2,598 over the previous year and is not so large an increase as was expected. After paying dividends on common and preferred stock and deducting underwriting and other expenses connected with the issue of additional preferred stock, a profit and loss balance of $303,133 is carried forward. This compares with $246,068 carried forward last year.

Dixon Company Promotes Long

JERSEY CITY, Oct. 28—At the regular monthly meeting of the board of directors of the Joseph Dixon Crucible Company the following changes in the officers and board of directors were made on account of the death of Vice-president William H. Corbin:

George E. Long, former treasurer, was elected vice-president to succeed Mr. Corbin; J. H. Schermerhorn, former assistant secretary and assistant treasurer, was elected to membership in the board of directors and treasurer of the company; Albert Norris was elected to the office of assistant secretary.

England and Low-Priced American Cars

THE British market only began to feel the importation of the American cheap car about the time of the annual Olympia show, November, 1911, when there was an extraordinary scramble of dealers desirous of taking up agencies for the cheap American car. It was then felt that the British public was at last beginning to feel confidence in low-priced American goods, as previously there had been a good deal of scepticism among the general public with regard to American-made articles, principally caused by the impression left of American bicycles and boots.

Engineers, of course, have long been aware of the excellence of the American machine tools, but the automobile at $1,000 or less was an entirely new proposition,

The Britisher is naturally slow to take up a new thing, particularly such as this, where solidity of construction does not exist, and appearance is so diverse from that which has been his custom.

We will now consider a few figures showing the development of the business in the importation to Great Britain of American automobiles.

AUTOMOBILES AND PARTS IMPORTED FROM AMERICA INTO ENGLAND

Year	Cars	Value	Value of Parts
1907	555	$879,135	$135,410
1908	348	481,455	91,665
1909	427	607,100	124,000
1910	1,101	1,076,485	427,035
1911	3,734	2,961,320	1,332,890
1912 (6 months)	3,327	2,792,935	....

It will thus be seen that the total number of cars imported during the first 6 months of 1912 was nearly as many as the total importation during the whole of 1911, and the average value of these cars is about $1,000.

It is about 10 years since the small American cars first made their appearance in England, and at that time the American industry was quite in its infancy, and the cars produced compared in design and construction very unfavorably with the European article. Even then, however, the type and price of the goods were unique in their way, and were not in competition with anything European.

These two marks have ceased to exist as far as Britain is concerned. The cheap American car has entered a field hitherto untouched and unapproachable on account of the price question, and has shown that the large British middle class exemplified in the man of moderate means is the buyer of an automobile at a price. However, this does not exist to so great an extent in Britain as in America, as the cost of running a car in the former country is much greater than in the latter, and the facilities for storing are very inferior and generally expensive.

The tendency has been in England particularly toward the development of a small bore and very efficient engine, and this is due to the high rates of taxation. Such an engine is expensive to construct and it cannot compete in price with the less efficient American engine. Furthermore, the high finish which is usually demanded in Europe cannot be given at a low price.

The American car has taught the buyer to be satisfied with an automobile that will run with very little attention and at the same time will be reliable, and if he does not pay the price of a highly finished car he must be satisfied with utility, which, by the way, is the first consideration.

It has been rumored from time to time, that renewed efforts are being made by those American concerns having a very large output, to land their surplus production on the open British market at prices showing the minimum margin of profit. Such a dumping of goods is apparently a satisfactory state of affairs to the so-called free-trader, but the far-thinking Britisher sees English capital going abroad which could well be spent at home, giving increasel employment to the work people of his country.

The keen American business man is fully alive to the political state of Britain, and is raking in the dollars while he has this glorious opportunity of so doing. The foothold he is now gaining he will not be prepared to lose without a struggle, and whatever may be done by the Britisher in the way of a large local production of cheap cars will undoubtedly be met by retaliation from the other side.

Unfortunately, there is a class of British manufacturer aptly termed the Dog-in-the-Garage, who does not see further than the length of his nose, and he takes up the attitude that as his factory is full of work, and that he and his stockholders are making a comfortable income, everything is well.

He fails to realize that the progressive business man is never satisfied with things as they are at present, and that if his factory is full and prospects are good, it is policy to increase the size of that factory, and his output at the same time. By so doing each article he makes can be more cheaply produced on account of quantity production, his employment of labor increases, and his actions tend toward the prosperity of his country as a whole.

While considering this question of production there is one important point which must be borne in mind; namely, the labor question. In America, a machinist can earn practically what he likes unhampered by the unions, and a man is paid more or less on results.

In Britain, however, very strong trades unions exist whose policy is to limit output, and to keep up the wages of the inefficient. Under such circumstances large productions can only be carried out by means of a very strong policy, and in order to avoid any serious difficulty arising on this score, the writer has obtained quotations from large American manufacturers of standardized parts, to supply their goods to a British concern assembling the same on British soil.

The $2,000 car and upwards of American make cannot, at the present time, obtain any substantial footing in the British market, as that is a type of car upon which British manufacturers have specialized and can produce at very good value for the money. It may be, however, that the importation of the cheap car is merely the thin end of the wedge, and among some British authorities this is considered to be the case. The effect, however, on the British market is that the manufacturers of the $2,000 type of car are being hampered in their sales by reason of the decreasing demand for used cars. This is how the situation has arisen: Many owners of automobiles are in the habit of arranging with dealers to take over their used cars in part payment for new ones. The dealers now find that the market for used cars is rapidly falling off, buyers of cars at the old figure of a $2,000 used car have now the alternative of purchasing a completely equipped new American car at the same figure.

There is, therefore, considerable reluctance on the part of the dealers to take these cars into stock generally resulting in the loss of sale of a new car every time. The Dog-in-the-Garage type of manufacturer fails to see this, but the effect is growing rapidly to his and other people's detriment.

The other side of the question is that the low-priced American car has made motoring possible for a large population who would otherwise be unable to afford it, and has incidentally developed a motor feeling and way of thinking that brings into line a large number of people whose interests are allied. These beginners circulate money in the automobile industry and the majority will eventually become purchasers of more expensive cars.—*R. W. A. Brewer*, London, Eng.

It has been discovered that in the city of Philadelphia there are at present on the statute books thirteen separate ordinances governing and defining the rights of various classes of vehicles. The new ordinance now being considered is a composite of all the thirteen. Maximum speed of 10 miles an hour is provided within the city limits under penalty of a $25 fine.

Bronze Flame Welding

Experiments Show That Rapid Heating of the Metal Modifies Its Physical and Mechanical Properties

Conclusion of Tests Is That Autogenous Welding of Copper and Its Principal Alloys Is Practicable

A SERIES of welding tests was carried out recently with bronze, three ordinary types being used and for convenience here designated A, B and C. Their chemical composition was:

	Per Cent. A	B	C
Copper	94.2	87.9	87.1
Tin	5.7	11.01	9.3
Zinc	....	1.53	....
Lead	....	....	3.48

The metal used was in rods 25 millimeters, 1 inch diameter, cast in molds of well-dried earth to insure homogeneity of the alloy. As welding material very thin rods of bronze of exactly same composition were used. When the welding was done, in spite of all precautions innumerable vesicular cavities were formed in the zone of the weld over the entire surface of the weld.

The great heat to which the metal is subjected, and the sudden variations of temperature which occur within it during the process of welding and in the course of the subsequent cooling, each play their part in modifying profoundly the structure of the metal in the zone of welding. High temperatures, facilitating the oxidation of the fused metal by means of the action of the oxygen of the atmosphere, determine, in the first place, the oxidation of those constitutive elements of the alloy which have most affinity for oxygen—as, for instance, tin, zinc, and lead. This oxidation reveals itself in the decreased proportion of those elements which in part are volatilized, and in part pass into the slag in the form of oxides; also in the formation of bubbles or vesicles, arising from the partial reduction of these very oxides by the excess of metal (the metallic mass) present; also in the lowering of the mechanical properties of the zone of welding, caused by the innumerable vacuoles set up within it, and accentuated by the diffusion of tin dioxide (SnO_2) in the mass of the alloy, partly in the shape of acicular inclusions.

Moreover, the high temperature attained in the course of the process of welding, with alloys of low tin content (alloy A), in which really a single constituent is present—α mixed crystals of copper and tin—determines, as we have seen in the case of pure copper, a commencement of ignition of the metal, with the consequent formation of big granules.

Finally, the rapid variations of temperature during the process of welding, determine—in the case of bronzes of higher tin content, wherein two constituents are present, namely, the α and β mixed crystals of copper and tin—an irregular and very conspicuous subdivision of these constituents, imparting to the metal a heterogeneous structure.

The localization of the surface of fracture in the samples of welded copper to the margin of the chamfer is again observed in the case of the zone of welding of bronzes.

Admitting all that precedes, we may reasonably expect that an appropriate reheating of the welded portion will prove even more efficacious than in the case of copper, because, in addition to relieving the internal strains of the metal set up by the process of welding, it tends to restore to it an improved homogeneity of structure.

Brass—A third series of experiments was conducted, by the same methods with the types of brass fusible at high temperatures, here designated respectively as M and N. Their composition is as follows:

	M Per Cent.	N Per Cent.
Copper	60.2	55.18
Zinc	40.08	41.50
Manganese	....	3.2

The first mentioned was cast in rods, measuring 30 millimeters (1.2 inch) in diameter, in dry earth-molds; the other was wire-drawn into rods, 2.5 millimeters (1 inch) in diameter. The welding material consisted of very thin rods, in each case of exactly the same composition as the original alloy.

The phenomenon of the unwelcome vesicles, set up in large numbers within the welding zone, despite all the preventive precautions that could be taken, was intensified in the case of these alloys by the extreme facility with which the zinc contained in the metal oxidizes. In Table 3 are set forth the results obtained from shock tests and from chemical analysis of the various samples.

Microscopic examination, confirming the results here tabulated, leads to the same conclusions as those postulated in regard to the bronzes. In order, therefore, to avoid needless repetition, I will content myself with referring the reader to what has already been said on that point. We may note, however, in these alloys a diminution in the capacity, when heated, of absorbing the products of combustion of the welding flame; coincidently with this

TABLE III.—SHOCK TESTS WITH THE CHARPY APPARATUS*

No. of Sample	Thermal Treatment	Indicated Angle	Breaking Test Kgs. Mm.	Mean Chemical Analysis: Of the Metal. Per cent.	Mean Chemical Analysis: Of the Weld Zone. Per cent.	Remarks
M1	Reheated	128°	4.646	Cu = 60.2 Zn = 40.08	......	Not welded.
M2	Cooled in air after welding.	141°	2.112	......	Cu = 69.3	Welded; finely granular fracture; numerous vacuoles.
M3	Reheated after welding.	138°	2.646	......	......	Welded; finely granular fracture; numerous vacuoles.
N4	Reheated	128°	4.646	Cu = 55.18 Mn = 3.2	......	Not welded.
N5	Reheated after welding.	140°	2.286	......	Cu = 68.75 Mn = 1.2	Welded; medium-grained fracture; numerous vacuoles.

*See Table 1, page 885.

Digest of the Leading Foreign Journals

(*Continued from page 884.*)

usual construction is shown in Fig. 9. The loss comes from using the walls of the crucible or the walls of the housing around it as conductor for transmitting heat to the crucible and its contents. The innovation consists in producing the heat in the crucible 4 by bringing only the bottom 5 of the crucible in contact with the die 6 which is made of tungsten-copper, preferably and is highly conductive. The pressure of the die is regulated by the weight of the crucible and the melt and can be increased if necessary by adding the weight of the current-carrier 7. After the smelting the die and the carrier 7 may be raised by means of crank-arm 13 so as to permit the tipping or removal of the crucible. The invention is patented in Germany by Pfretschner & Company.

Filip Tharaldsen, of Norway, has also an improvement looking to economy in electric smelting. Owing to the continued high heat which is sometimes necessary in the reduction of ore, considerable quantities of valuable materials escape in gaseous form. To avoid this loss Tharaldsen builds a system of flues in which the gases are brought in contact with chemical reducing agents, with provisions for cooling, and are returned to liquid or solid state, in which form they fall back into the melt.—From *Metallurgie*, August 8.

diminution, the liability of the welded parts to fracture along the margins of the chamfer decreases.

CONCLUSION—The results obtained and the observations recorded in this triple series of investigations concerning the oxy-acetylene autogenous welding of copper and its chief alloys demonstrate:

1—That rapid heating and sudden fusion of the metal subjected to welding profoundly modify its physical and mechanical properties, developing within it internal strains and structural alterations which are of detrimental effect.

2—That the structural modifications which take place in the process of welding, apart from the alterations in composition of the metal, may be classified under two principal headings: *a* coarse crystallization of a single-constituent metal, and *b* minutely heterogeneous structure of an alloy consisting of two or more elements. We must also take into account the discontinuity of structure attaching to metals in which there are oxide inclusions or vacuoles.

3—That the deficiency in mechanical properties, most conspicuous in all that regards the tenacity and elasticity of a metal, is expressed in the case of copper by an average reduction of 50 per cent. in the capacity to resist fracture, and an increase of about 30 per cent. in brittleness, while the percentage ductility is reduced to about a tenth of the original. In the case of bronzes and brasses, the deficiency in mechanical properties is not susceptible of rigorous mensuration, but it is greatly intensified and proportionately detrimental as the number and variety of the constituents of the alloy subjected to welding are increased.

4—That, while mechanical treatment, such as hammering along the zone of welding, has practically no useful effect on the properties of the welded metal, thermal treatment, such as reheating, prolonged for a suitable interval at a fixed temperature, exerts an undoubted ameliorative influence, since in the first place it relieves the latent internal strain set up by the sudden temperature changes involved in the process of welding, and in the second place it restores homogeneity to the structure of the metal itself. Consequently, and more particularly in the case of alloys made up of several constituents, the conditions of cooling of the welded metal are of special importance, the slower the cooling the greater being the ameliorative effect.

5—That considerable variations—diverse according to the manner in which the process of welding is applied—occur in the composition of bronzes and brasses; these variations are the more extensive the greater is the number of constituents of which the alloy is made up, and also in proportion to the affinity of these constituents for oxygen and to the volatility of the oxides formed therefrom. Thus, for example, in the bronzes of type B (Table 4), in the welded zone, there is an average diminution of 19.0 per cent. in the proportion of tin; while the loss of zinc, a more easily oxidized metal than tin, amounts to 22.3 per cent. (the original proportion present being smaller than that of tin). In brasses, wherein the percentage of zinc is much higher, its decrease in the welded zone amounts to 28.7 per cent. We must also bear in mind that the oxides thus formed have a tendency to diffuse easily into the metal, modifying profoundly its properties. In pure copper subjected to the welding process changes in chemical composition cannot be traced, as the metal is made up of a single constituent; and it is only affected deeply by oxidation when the necessary precautions have been omitted in the process of welding, the suboxide then formed diffusing with great facility into the copper.

6—That taking into account the results obtained and the conclusions here postulated, we may assert that the oxy-acetylene autogenous welding of copper and its principal alloys has a practical application, limited to those parts of machinery which are not of large dimensions and are not subjected to severe mechanical stresses.

Contet's Formula for Countersprings

(*Continued from page 889.*)

ment of the subject, and it is therefore not so remarkable that both arrived at the same astonishing theory with regard to the action of countersprings.

The final formula presents some additional points of interest. Unless the numerical value of d_1 is larger than that of d the total value of D becomes negative, which is absurd and means that the counterspring must be more flexible than the main spring. If these values are equal, then D becomes infinitely greater than d, and the compound spring bends without resistance. These absurdities are obviated in practice by making the counterspring much shorter than the main spring. In this practical form its principal action is to brake the recoil of the main spring, an action which is not considered in the mathematical development of the subject at all.

In our opinion, Mr. Jones clouds the subject by presenting, in his Fig. 6, a type of compound spring which is used nowhere and with regard to which it is difficult to conceive that the counterspring can follow with its oposite tension the main spring throughout its range of deflection.—ED.

Two Moline cars driven by Joe Wicke and Frank Salisbury which finished the Chicago Motor Club's reliability run with perfect scores

Molines and Staver Win Tour Around Lake Michigan

Three Perfect Scores in Reliability Run of the Chicago Motor Club—Ten Cars Finish Out of the Field of Fifteen Starters—Velie Second in Touring Class and Bergdoll Follows Molines

CHICAGO, ILL., Oct. 28—Completing the 1,200-mile trip around Lake Michigan over roads that had been called impassable to automobiles in certain sections, the Moline pair in the roadster division and Staver No. 4, in the touring car class, finished with perfect scores and all three looked as if they could have stood a stringent technical examination, if such had been required by the rules. The Moline pair win the team trophy offered, and the individual prize in their class. The former was offered by the Chicago Motor Club. The class prize is the Morton J. Luce cup and if it is conferred upon one of the cars, a drawing will be necessary.

Ten out of the fifteen cars that started from Chicago, October 21, checked in after the trip as contestants.

The Staver entry captured the W. E. Stahlnaker cup for the best score in the touring division.

Of the touring cars, the Velie No. 1, driven by John Brolley, took second honors. This was the same car and the same driver that carried the pathfinding crew when the route was laid out 6 weeks ago. Staver No. 3, with G. Knudson as driver, finished third, the Case fourth, the Bergdoll No. 5 was fifth and A. M. Robbins' Abbott-Detroit No. 6 was sixth.

In the small car division, the Bergdoll No. 104, with Tom Rooney driving, was second to the two Molines, while Anderson in the Stutz No. 109, was the only other driver in this division to finish. Anderson, although heavily penalized on account of broken springs, wins the amateur driver's trophy, as he was the only driver entered who was not affiliated with the trade.

Overshadowing all the other features of the run was the consistent performance of the Moline team, the staunchness of the two cars and the masterly way in which they were handled by their drivers. It was to the credit of Salisbury and Wicke as much as to the quality of their mounts that the Molines finished without penalty. Few drivers could have put any car in 7 days over the roads which encircle Lake Michigan, without experiencing difficulties of some kind on the road. Other cars in the contest might have done as well had they been handled with the care shown by Salisbury and Wicke but not even the best driver could have put a mechanically weak vehicle over those roads, and at that speed without more or less penalty.

Monckmeier and his Staver are deserving of at least as much credit as the Moline drivers and their mounts, for not only did the little Swede finish his car with a perfect score but, like the Molines, could have withstood a final technical examination, had there been one, with very little loss of credit. Monckmeier's driving can be credited for his win over his team-mate Knudson, for had the latter used the care that Monckmeier did in driving through the heavy mud of northern Wisconsin he would not have been forced to clean out his carbureter, and also would have annexed a perfect score.

The driving rain and heavy mud of the first 3 days of the run were responsible for most of the difficulties encountered by the cars. It rained almost incessantly for 2 days and the clay roads of northern Wisconsin and the northern Peninsula of Michigan became perfect quagmires, necessitating a great deal of low gear work, particularly on the hills, and causing carbureters to become choked up with the mud and water that splashed against them. The rains which had made the first two days run from Chicago to Escanaba a most disagreeable and hazardous trip, probably saved the day for the tourists when they entered the heavy sand in the north woods and pine barrens of the northern peninsula and all around the head of the lake. Sand hills which had been reported as almost impassable by the pathfinder were negotiated with little difficulty because the rain had packed them so that traction was afforded the rear wheels.

The third day's run from Escanaba to Newberry, the northernmost point of the trip, is only 122 miles in length but was expected to be nearly the worst part of the route. The schedule

Velie, driven by John Brolley, second in touring class was reduced to 13 miles an hour for the touring cars and 11 miles an hour for the roadster division. This speed seemed to be none too low as it took the pathfinder 6 days to cover the distance. The road for the greater part of the way winds through the forests of mixed pine and hardwood and over great stretches of pine barrens and burnt over woods, with stretches of corduroy roads, merely logs laid side by side through the swamp.

For about 10 miles north from Escanaba the road built by the state from Marrinette to Escanaba is extended around the shore of Little Bay de Noc. The fine road came to an end suddenly between the towns of Gladstone and Kipling. After reaching Rapid River the real wilderness was encountered. From here on the road consists of wagon trails winding in and out through the woods with branches extending in all directions and the forest encroaching on the roadway as though begrudging the space it took. These branching trails, however, merely take a labyrinth course among the trees and finally come back into one road further on. The roadbed was alternating patches of sand and muck in which the cars dragged their mud pans. In places there was the corduroy through the morass and in other places the road is made out of bark which provided good going.

Right in the middle of the forest when the tourists had begun to lose hope of there ever being better going, a stretch of fine hard macadam was found, 5 miles in length, which began nowhere, passed through nothing but woods and ended nowhere. At a little trading post called Thompson's, the first sight of Lake Michigan since leaving Milwaukee was obtained. From there on the road is good, and within about 4 miles of Manistique another stretch of the state-built macadam was picked up.

At Manistique the tourist had the first taste of Michigan hospitality and began to realize the interest aroused in road building and motor cars in the north woods. The whole city turned out to welcome the tourists and they were tendered a luncheon at the Elks' Club. The macadam led the tourists northward from Manistique for a few miles and then abandoned them to the same sort of going as they encountered in the morning. Newberry, the night control, was reached shortly after dark. The road traversed for the day, though quite bad in spots, showed that work was being done upon it toward improvement and in fact men and teams were working on the road when the tourists came through. The county engineer of Delta county had gotten busy when the pathfinder went through, and in the 6 weeks intervening had done a great deal to improve the conditions. He had gotten out a route map and had it printed so that each of the drivers could be sure of striking the improved road which deviated somewhat from the route laid out by the pathfinder.

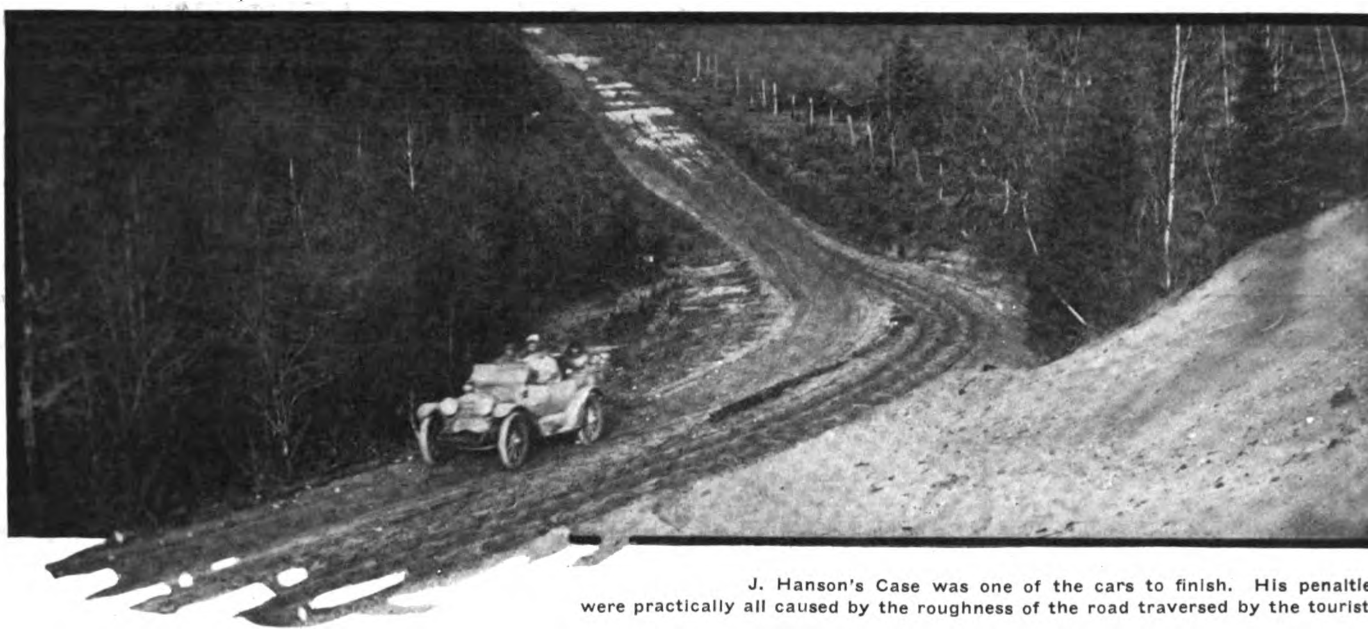
In spite of the condition of the roads only three cars were penalized during the day. Monsen had to refill his radiator three times because the jolting had started it to leaking, on account of the necessity of so much low gear work. Park's R. C. H., No. 7, stripped the gear in the gearset, in the heavy pulling, and did not get into Newberry until long after the tourists had checked out the next day. He was 12 hours late and consequently was automatically withdrawn. Park and his passengers were forced to spend the night in the woods but, although out of the contest, pluckily stayed in the game and by driving night and day caught up with the tour at Petoskey, and finished with the rest. In fact, the R. C. H. had the honor of acting as pacemaker as far as South Bend on the last day of the tour when the referee's car was temporarily out with a broken spring. Anderson's Stutz was forced to take on water twice the third day. At Newberry the tourists were treated to a chicken dinner, followed by a dance, at which the town fathers and county authorities told of their plans for making a motor boulevard through the woods and promised roads that would be good all the year round within 3 years.

Tom Rooney's Bergdoll, which was second to the Molines

From Newberry to St. Ignace, the fourth day's run, is but 65.2 miles in length but promised to be the hardest of all, as there is deep sand along the shores of the lake most of the way. However, less than 5 hours was consumed in making the trip. The only difficulty which was encountered by the cars as a whole was the trouble in following the trails through the sand plains. The whole party was lost completely for three-quarters of an hour and went about 12 miles off the course.

This was the day that spoiled two perfect scores. The Case got 3 points for replacing a magneto wire which had jolted off over the corduroy roads; the Abbott-Detroit dropped out of the perfect score class when it became necessary to refill the radiator. All the radiators had been drained the night before to prevent danger of freezing and the pet cock in the Abbott had been left partially open. In the midst of a vast expanse of brush and

The Staver team, G. Knudson and A. Monckmeier. The latter was the only driver to finish with a perfect score in the touring car division



J. Hanson's Case was one of the cars to finish. His penalties were practically all caused by the roughness of the road traversed by the tourists

second-growth timber the radiator went dry and Robbins' mechanic, Berry, scrambled 2 1-2 miles through the dense underbrush and sand to the lake. After the radiator was filled the party proceeded 100 yards when a turn in the road brought them onto a bridge under which flowed a stream of clear water. This day was Rooney's hoodoo, too, for in making a quick spurt through deep mud around one of the cars which was wallowing painfully through, Rooney ran into a tree and broke his steering knuckle. He walked back 10 miles and secured a repair part, which was put in, and by a wild night drive caught the tourists the next day.

Anderson, as well, had bad luck on the fourth day, as he stripped both low and intermediate gears and had to negotiate all the sand and mud and steep hills on high gear, with a gear ratio of about 2 1-2 to 1. The wild driving necessitated by this caused him a succession of broken springs which cost him over 1,100 points in penalty, and required that he drive all night to get into control before his time limit of 12 hours had elapsed.

Upon arrival of the cars at St. Ignace at about noon they were loaded upon flat cars and these run upon the ferry, which took them across the Straits of Mackinac to Mackinaw City. The trip on the ferry takes about an hour and another hour is consumed in loading and unloading a car. With the sixteen cars entered in the tour the entire afternoon was spent in getting the cars loaded and unloaded at Mackinaw City. It cost $6.50 to ferry a car across the Straits and 50 cents additional for each passenger. The railway authorities on the west side of the Straits are very accommodating and load the cars themselves, but the local officers at Mackinaw City, of the Michigan Central, seemed unwilling to render any assistance whatever and the tourists had to unload the cars without assistance. All the gasoline had to be drained from the fuel tanks before they were shipped across.

The night was spent at Mackinaw City and the start for Traverse City was made next morning at 9 o'clock. Once on the east side of the lake the tourists felt the worst of the trip was over and were inclined to take things easy. The late start enabled several of the cars which had been delayed to rejoin the tour and Rooney, Anderson and Park's R. C. H. took advantage of the opportunity. It was at Mackinaw that the tourists were overtaken by the Staver Dictator, a new 1913 Staver model, that had not been completed in time for the start from Chicago. With three men it left Chicago Tuesday night and caught up with the tourists at Mackinaw, making the 4 days' drive in 2 days. The car was pushed through night and day with one driver sleeping while the other piloted the machine and the third man read the route directions to the driver. The car was stopped only long enough for the men to get supplies of fuel and oil and food, except for 3 hours, during which the men slept on top of the warm boilers of a lumber mill in the north woods. From Mackinaw City to Traverse City was scheduled for the fifth day's trip. The distance was only 109 miles and was the easiest jaunt of the entire trip. The route lies through a beautiful rolling country, over fair roads all the way and fine macadam around Petoskey, the noon control. In the afternoon the route followed the lake closely and ran through a string of summer resorts almost the entire distance to Traverse City. The roads are very good and motor cars abundant. In spite of the easy trip, however, three cars accumulated demerits. The passengers in Hanson's Case had a very narrow escape from serious injury when a rear wheel loosened up and started to come off. By dexterous driving Hanson succeeded in keeping the car right side up and getting it stopped. The repair cost the Case 38 points. Monsen accumulated 52 points more for the Bergdoll who found a leaky radiator and had to clean the mud out of it and solder it up. He was having slight engine trouble as well, and the adjustment of the push rods also helped in his total. Stutz got 57 points more penalty on account of another broken spring.

From Traverse City to Grand Rapids, a distance of 207.3 miles, was the sixth trick, with lunch at Ludington. The route was through Manistee, Ludington, Pentwater, Hart and Muskegon. The roads were worse on this day's run than was expected, as there was a good deal of work being done on the roads and they were closed for miles in several places which necessitated detours through heavy sand, and in other places the newly worked roads made heavy going. The contesting cars had begun to show the wear and tear they had gone through and heavy penalties were acquired by several of them. Brolley's Velie stripped its first speed gear on a hill when stalled by a farm wagon in front of it and the strain of starting on second started the clutch to slipping so that it had to be adjusted. The Bergdoll No. 5 had a leaky radiator and was continually taking on water. One rear wheel loosened up as well and Monsen was assessed 54 points for the day. Robbins' Abbott-Detroit received the record penalty for any one day, when the car ran into a protruding branch which went through the radiator. Two attempts were made to solder it and the car came in very late at Grand Rapids, where is was decided to replace the radiator. Anderson got an additional 1,000 points for his regular trouble of broken springs.

The last lap of the tour around the lake was from Grand Rapids to Chicago. Good gravel and fine macadam was the rule and all cars were running far ahead of the schedule speed of 20 miles an hour. This was the longest distance of any day's run on the tour, 217.8 miles. The route lay through Kalamazoo, Niles and South Bend. At Michigan City the home-coming tourists were met by a delegation from the Chicago Motor Club which escorted them into the city. With two exceptions, all the contesting cars made the last day's run without penalty. Monson had to do a little work on the engine of the Bergdoll, and found it necessary to refill the radiator 3 times, which cost him 12 points. Anderson was delayed by the same old trouble of broken springs and did not get in until very late.

When Ludington was reached on the Saturday run, the tourists were caught by the National car which had started as No. 8. This car was the entry of the Chicago Spring Wheel Company and is equipped with solid tires and the spring wheels made by that concern. Also although most of the contestants had no stop at all this car carried a fully enclosed limousine body. There were three drivers, including R. B. Gray, and the car had been on the road night and day until it caught the tour. The original cause of its delay the first day which put it more than 12 hours behind the tour and so caused its withdrawal automatically, was the loosening of a wheel.

Not only did the contesting cars have their troubles, but the official cars as well were laid up at times. The official cars are subjected to harder service than are the contesting cars, but all succeeded in coming through in fairly good order. The pilot car probably receives the hardest service of any one of the cars connected with a tour of this kind. The pilot must carry the bags of confetti which is strewn along the way so the tourists will know the right road to take, and must nose out detours in case the road is closed, must stop whenever a dangerous or exceptionally rough spot is encountered and mark it so that those who come behind will have an opportunity to slow down or avoid it. At the same time, the pilot car must go fast enough so that with all of these stops it does not delay the tour. The six-cylinder Kissel-Kar, driven by Harry Branstetter, carried the pilot practically all the way, although the rough service resulted in several broken springs. The Staver roadster which carried the tour officials and acted as pacemaker was on the job nearly all the time with Vaught at the wheel. Broken springs made trouble once or twice. The Midland, driven by Kavanaugh, was the starter's car and carried starter L. A. Watts. Its chief duties seemed to be pulling stranded cars out of mudholes along the way. It was on the job all the time and gave no trouble. The press car was an R. C. H., and made a fine showing, comparing favorably with some of the more expensive machines so far as getting through is concerned.

The troubles that caused penalties were:

Velie No. 1—Carbureter air intake screen stopped up with mud; second day, driver cut hole in screen and finally removed it; sixth day, slipping clutch, adjusted it twice.

Case No. 2—Fourth day, putting wire on magneto; fifth day, rear wheel off; sixth day, broken spring.

Staver No. 3—Second day, carbureter stopped up with mud and water.

Bergdoll No. 5—Steering knuckle broken in deep mud on second day; third day, took on water three times; fifth day, cleaning the mud out of and soldering radiator, adjusting push rod, late at control; sixth day, filling radiator with water five times, loose rear wheel, late at control; seventh day, taking on water three times, work on engine.

Abbott No. 6—Fourth day, replacing water lost through open drain pipe; sixth day, radiator ripped open by stick; worked on radiator; refilled radiator several times and finally put in a new one.

R. C. H. No. 7—Third day, took on water outside control; fourth day, withdrawn account of stripped gears and transmission.

National No. 8—First day, loose rear wheel, over 12 hours late at control, automatically withdrawn.

Velie No. 101—Withdrawn second day, no penalties. Driver forced to return on account of business.

Stutz No. 102—Second day, stripped gears, withdrawn.

Bergdoll No. 104—Second day, stuck in mud hole, pulled out with engine driven winch carried on car, 30 minutes late at control; fourth day, broken steering knuckle caused by running into tree.

Stutz No. 109—Second day, slight battery trouble, work on fender bent by broken tire chain, and lateness on account of helping other contestants out of the mud; third day, taking on water and fixing fender; fourth day, two springs broken on account of having to run on high gear alone, other gears being stripped; fifth day, broken spring; sixth day, broken spring.

R. C. H. No. 110—Frozen motor, withdrawn.

22	Kissel	W. T. Coop	22:17:52

PHOENIX, ARIZ., Oct. 29—*Special Telegram*—Ralph Hamlin, in the now famous Los Angeles-Phoenix road race yesterday, realized the ambition of his life by winning this with a six-cylinder Franklin in 18 hours, 10 minutes 22 seconds for 511 miles across mountain and desert between these two cities. His speed averaged 28.1 miles per hour and he was nearly three-quarters of an hour ahead of his nearest competitor. In addition to the honor which goes with the winning of this the fifth desert race ending in this city Hamlin had to combat oceans of sand and mud and drive through torrents and over mesa where roads were washed away by one of the most severe storms in the history of the Southwest.

Second honors were taken by Charles Soules, in a Cadillac, whose time was 18 hours, 54 minutes and 5 seconds; a National, driven by Fred Fuller, was third, his time being 19 hours, 45 minutes and 6 seconds. Only two others of the original twelve cars entered in the contest finished. Both were Cadillacs, one was driven by W. W. Bramlette in 23 hours, 18 minutes and 27 seconds; and the other by S. A. McKee in 23 hours, 46 minutes and 31 seconds. It is a remarkable fact that all Cadillacs finished.

At Yuma, the halfway point where the cars were ferried across the Colorado River the position of the five winners was practically the same as at the end of the race. Hamlin put his Franklin in the lead just beyond Brawley and held his lead to the finish. His time at Yuma was 10 hours and 32 minutes. For 5 years Hamlin has been trying to win this race and each time after defeat he declared he would continue until victory rested with him. Today after his triumph he has announced that he is entirely through with the racing sport.

Conditions in this desert race were severe in the extreme. In many cases the roads were trails. Hamlin changed but two tires on his Franklin, both changes being made east of Yuma. Soules had little trouble with his Cadillac; Fuller's National had a few delays due to minor difficulties, and largely to the condition of the course; McKee lost his way and drove his Cadillac 8 miles off the course; he changed several tires.

Only one accident occurred in the race; at Vineyard Curve near Ontario, Cal., the Buick entry overturned and Louis Nikrent, the driver, had three ribs broken and Fred Nikrent, mechanician, was badly injured; both will recover. The Mercedes entry driven by Charles Bigelow, in avoiding a collision with the Buick on the curve, broke a radius rod which was temporarily repaired but which broke several times after, so that Bigelow lost 14 hours from this cause.

Several of the other entrants had various mishaps. The Schacht, driven by G. A. Ball, broke a rear axle near Glamis and lost 14 hours, and arrived in Yuma only 1 hour before the other cars left this control. Ball continued though he knew he was out of the money, and acted as a good Samaritan to other cars and had it not been for him some of them would never have reached Phoenix. The Schacht and Mercedes arrived late Monday night.

The Simplex, driven by A. G. Faulkner, had trouble with the drive chains and stuck several times in the mud. It spent Monday night on the desert 100 miles west of Phoenix.

One of the American entries, driven by Marc Bunnell, skidded into a viaduct before out of the city limits of Los Angeles and dished a wheel, causing the machine to pull out of the race east of Brawley. The other American entry, driven by W. B. Pipher, dropped out of the race about the same place supposedly due to axle trouble.

The Hupmobile entry, driven by Lonard Jones, withdrew near Brawley because of a broken axle.

While the race from Los Angeles to Phoenix was in progress there was also a race from San Diego to Phoenix, the two routes uniting a few miles west of Yuma, where the night control was established. This part of the contest, namely, San Diego to Phoenix, was won by D. C. Campbell, driving a Stevens-Duryea, his time being 16 hours, 49 minutes and 20 seconds for the distance which is a little over 400 miles. Six other cars finished in the race between the cities of San Diego and Phoenix, these being:

Car	Driver	Time	Car	Driver	Time
National	J. D. Houston	18:55:00	Simplex	J. C. Rice	58:53:00
Apperson	W. E. Ferguson	19:07:29	Stutz	C. E. Washburn	38:50:00
Mitchell	R. L. Greer	21:16.00	Kissel	W. E. Coop	22:47:52

Nearly all of the San Diego cars had trouble of one nature or another, many of the cars from San Diego never reaching Yuma where they joined with the racers from Los Angeles to Phoenix. The Columbia, driven by W. H. Smith, cracked a cylinder jacket before reaching Yuma. The Winton entry, driven by W. H. Carlson, got stuck in an arroyo near Arlington and has not yet arrived at Phoenix. The Pope-Hartford, driven by L. W. Griffith, broke its frame near Dome. The crew repaired the damage with fence posts and bailing wire borrowed from a farmer. A fence post was placed parallel with each side member and bound to the frame by wire. In this condition the car reached Phoenix today.

The start was made in the Los Angeles-Phoenix race Saturday night, October 26, the first car leaving at 11:05 and the others at 5-minute intervals, the last car getting away at midnight. The night was bitter cold, and drivers and mechanicians were wrapped in blankets. While cold leaving California the desert held its mysteries in store for them as a storm had been raging for hours on it. Much of the course was muddy, the California portion not being bad, as the storm centered chiefly in Arizona. Between Yuma, the crossing point of the Colorado River, and Phoenix, deep gullies had been washed across the roads, and in places the roads had been entirely wiped out. At the Hassayampa river, 50 miles west of Phoenix, and also at Agua Fria, 16 miles west of Phoenix, both rivers were running bank full Sunday morning. At one time it was thought an extra control would have to be established at Hassayampa, which would mean that the cars would have reached Phoenix Tuesday morning. Fortunately, the Hassayampa subsided and mules were used to tow the racing machines across. No changes in position were caused by this inconvenience as the cars all reached Phoenix in the same order they checked out of Yuma.

The troubles of the course were not all confined to the losing cars: The National, in the San Diego race, caught fire near Polamas on the Arizona side of Yuma, due to carbureter troubles and burned out all connections. A 2-hour delay resulted. Later it changed three tires near Dome. The Apperson had two punctures due to nails in the same place. The Apperson in avoiding a rear-end collision with the Stevens-Duryea, which won this race, did so at the expense of a broken radiator. The Stevens-Duryea was halted and the Apperson driver following closely had to go into a deep arroyo or over a bank to avoid a collision. He chose the former course and broke his radiator which, however, was soon repaired and he finished fourth. The Stutz had motor trouble.

For 3 years the race from Los Angeles was across the desert by Mecca, across the Colorado at Ehrenberg and thence on over the Arizona mesas to Phoenix. Last year it was changed to pass through San Diego and Yuma. This year still another change was made and San Diego was left off the course. On the California side the principal towns through which the route passes are Alhambra, El Monte, Puente, Lemon, Walnut, Spadra, Pomona, Ontario, Bloomington, Colton, Beaumont, Banning, Palm Springs, Mecca, Brawley, Mammoth, Glamis and Ogleby. The Yuma control is the first stop on the Arizona side of the Colorado. It was from this place that the cars in both races started Monday, passing through Dome City, Middle Wells, Palomas, Agua Caliente, Arlington, Buckey and on to the fair grounds, which are situated on the outskirts of Phoenix.

The crossing of the Colorado river at Yuma was accomplished without special incident. This crossing is a clumsy affair, the ferry service being antique. It progressed slowly on account of the high water but no accident was reported.

It is at Yuma that the two race routes converge. The San Diegans raced across the Southern California desert by way of El Centro and Holtville.

There is little to choose between the two courses. Up to 2 weeks ago 45 miles of the desert between Holtville and Yuma had never been crossed by an automobile. The first car to cross that waste was a Premier, driven by J. L. Fernando with M. J. Farlow as mechanician. Fernando and Farlow were lost a night and a day on the desert and had a terrible experience. They encountered sand so deep that even after they had deflated their tires the only way they could progress was to leap out and push from behind, letting the car steer itself.

Before the day of the race the routes were placarded thoroughly. Between Holtville and Yuma there was a flag every 2 1-2 miles and five gallons of water.

Only those who have participated in the long desert grind can know the fatigue and hardship which the drivers and mechanicians endure. To ride at a speed of 40 or 50 miles an hour over desert roads is to take one's life in his hands. During his trial trip Fernando threw out one mechanician in rounding a sharp curve and took him back to San Diego with several broken ribs.

The prize money offered for the Los Angeles event totals $5,-200, while the winners of the San Diego race will divide $6,275.

ENTRIES IN THE LOS ANGELES-PHOENIX DIVISION IN THEIR ORDER OF STARTING

Car	Driver	Time	Car	Driver	Time
1 Cadillac	S. A. McKee	11:05	7 Cadillac	W.W.Bramlette	11:35

Hoosiers Improving Speedway Stands

INDIANAPOLIS, IND., Oct. 28—The Indianapolis Motor Speedway is to tear down the present press stand, judges' stand, refreshment and executive buildings and all other stands grouped near the start and finish line and behind the pits.

One large, modern pagoda building is to supplant the entire lot. This building will accommodate those in charge of the race in the following way:

On the lower, or ground floor, will be located the telegraph and electrical appliances. On the second floor will be the timing and scoring devices. The press will be taken care of on the third floor, and on the fourth floor the judges and officials will have high, roomy accommodations. The fifth floor is for the management and executives.

These plans have been ratified by Carl G. Fisher, president of the Indianapolis Motor Speedway Company, and the building is now in progress.

Other changes being incorporated by the manager of events, Charles W. Sedwick, are the installation of more efficient scoring service and a general improvement in the utilization of parkage and paddock space.

Mr. Sedwick sails about November 1 for Europe, where he will discuss the May race meet with the most prominent European manufacturers. Entries are open January 1, and in the meantime Mr. Sedwick expects to have the greatest field of entries lined up that ever faced a starter.

Minor Contest News of the Past Week

Charles J. Glidden and party arriving at New Orleans

SEVERAL rulings were made at the meeting of the Contest Board of the American Automobile Association last week covering appeals, disqualifications, etc. The gist of the rulings follows: Studebaker Corporation appeal in Minneapolis-Winnipeg run against disqualification for cutting course was dismissed and class trophy awarded to Hupmobile.

The Pittsburgh-Mercer Auto Company was suspended until January 1 for mis-advertising contestants in a non-stock meeting as stock cars.

The George C. Brinkman Motor Car Company of St. Louis was suspended until January 1 for failure to start a Nyberg car entered at a recent race meeting.

Charles W. Canner, registered driver, was suspended until January 1, 1915, and E. V. Rickenbacher, January 1, 1914, for participation in various unsanctioned race meetings in Iowa and Nebraska, where Canner campaigned the Marshall Flying Squadron and met with some serious mishaps owing to the carelessness and disregard of the precautionary rules of A. A. A.

Three Clean Scores in Michigan Run

GRAND RAPIDS, MICH., Oct. 28—After a 400-mile trip through Western Michigan the reliability run given under the auspices of the Grand Rapids *Herald* and the Grand Rapids Automobile Club, pulled into Grand Rapids, bedraggled and mud-stained, but with three of the drivers happy in the fact that they had attained perfect scores. The final results showed points penalized as follows:

Car	Driver	Observer	Total penalties
Cutting	Riekse	Roth	234
Reo Fifth	Vandecar	Fiske	0
Ford	Vallade	Leonard	88
Cadillac	Eckburg	Wilcox	0
Overland	Oswald	DeWindt	868
Marmon	Kramer	Shank	1
Oakland	Austin	Bancroft	0

The first day's run was 114 miles to Ludington. The second day 98 1-2 miles were covered to Traverse City. The third day was from Traverse City to Cadillac and the fourth day brought the tourists home. Many courtesies were extended to the travelers by residents of towns along the route. The tour proved such a success that it probably will be repeated next year.

1,500 at York's Track Races

YORK, PA., Oct. 28—The race meeting held here on Saturday consisted of four events, the fifth race a free-for-all at 10 miles being declared off when Gillard's Pullman turned turtle after going 3 miles. The driver and his mechanic were seriously hurt. The fields were very small and the only close contest resulted from the running of the handicap wherein the Buick won on its time allowance.

The Lancaster Motor Club ran a sociability tour to the t and the participants were the guests of the York Motor Club the afternoon. About 1,500 attended the races.

The summary follows:

Car	Driver	Time	Car	Driver	Time
5-MILE, NON-STOCK, 201 CU. IN.					
Mercer	W. Freitag	6:29.25	Ford	C. Lambright	7:05.45
5-MILE, NON-STOCK, 451 CU. IN.					
Kline	John Menker	6:03.15	Pullman	Gillard	6:24
5-MILE, NON-STOCK, 601 CU. IN.					
Kline	John Menker	6:08.25	Pullman	Gillard	6:22.25
5-MILE, FREE-FOR-ALL HANDICAP					
Buick	J. W. Richley	7:09.45	Ford	C. Lambright	7:11.25
Kline	John Menker	7:12			

In this event Menker's actual running time was 6:02 or an average of one mile in 1:12. Menker broke the track record, which was held at 1:14.

Disbrow Stars on Louisville Track

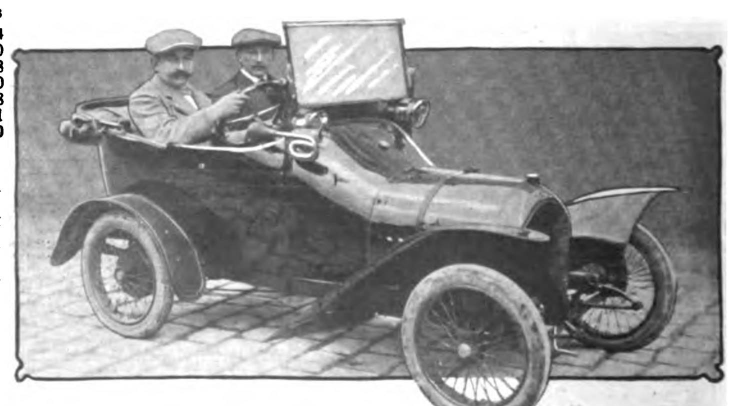
LOUISVILLE, KY., Oct. 27—Over the historic 1-mile dirt racing track at Churchill Downs, nine well-contested automobile races were run this afternoon. About 3,000 persons witnessed the events. The exhibition of Louis Disbrow, driving his Simplex Zip and his 290-horsepower Jay-Eye-See, was the feature. No records were lowered. The summary follows:

Car	Driver	Time	Car	Driver	Time
Exhibition Trials—1 Mile					
Simplex	Disbrow	:53.40	Case	Endicott	:57.20
Case	Nikrent	:57	Lozier	Martin	1:05
Hotchkiss	Kilpatrick	:57			
5-Mile Race					
Case	Nikrent	5:21.40	Case	Endicott	
1-Mile Exhibition					
Jay-Eye-See	Disbrow	:58			
Pursuit Race—5 Miles					
Simplex	Disbrow	5:45	Case	Nikrent	
Hotchkiss	Kilpatrick		Case	Endicott	
2 Miles					
Jay-Eye-See	Disbrow	2:08			

Disbrow also won a 5-mile race in his Simplex in 5:22 and Nikrent took the 3-mile handicap in a Case in 3:05.

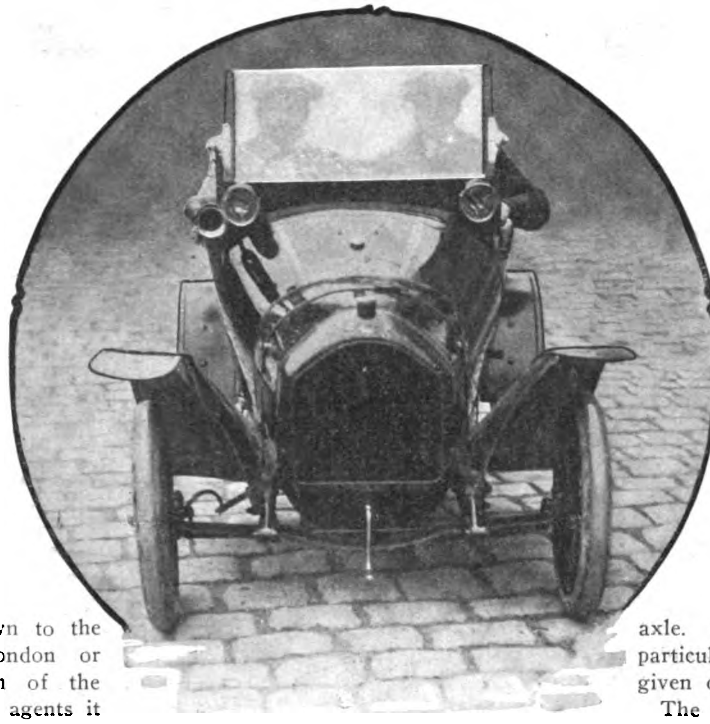
Glidden Arrives at New Orleans

NEW ORLEANS, Oct. 28—Charles J. Glidden, donor of the Glidden Trophy and one of the leading automobilists of the country, completed the route laid out for the abandoned national tour and arrived in this city on schedule time. The program that had been arranged to welcome the national tour was carried out in modified form in honor of Mr. Glidden's party.



Side view of the baby Lion-Peugeot

Lion-Peugeot Introduces Small Runabout



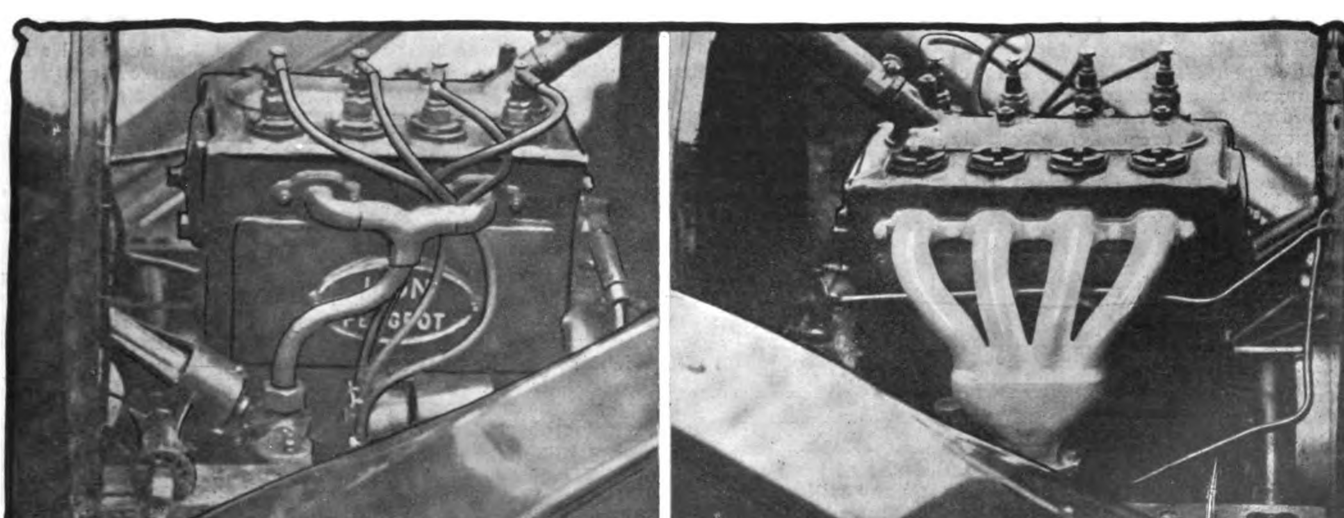
Front of Baby Lion-Peugeot

PARIS, Oct. 11—France is at present showing a decided preference for what have been termed baby cars—small, light, two-seaters, costing little more than a first-class motorcycle and having about the same upkeep cost. Up to recently these machines have been produced by firms of comparatively little importance. but rumor has had it that the Peugeot company, one of the most important in France, intended to enter the market with a big series of baby cars, the designs for which had been entrusted to Ettore Bugatti, a very successful engineer, and producer of the high-grade Bugatti car. It was not expected that the new Peugeot would be shown to the public before either the London or Paris shows, but by reason of the activity of one of the selling agents it was revealed at the agricultural motor exhibition just held at Bourges.

The baby Peugeot is built, so far as its external appearance is concerned, on big car lines; its dimensions, however, are decidedly diminutive, it being so low and light in appearance that it really has all the appearance of a baby car. The power plant comprises a four-cylinder block motor of only 2 by 3.5 inches bore and stroke. The valves are on opposite sides and are of large diameter; the timing gears are in front, with the magneto on the intake side having its shaft parallel with the motor shaft. The carbureter is a Claudel. A novel feature of the machine is the casting of the four cylinders and the whole of the crankchamber in one piece. The base plate is independent and is bolted on, and there are detachable end plates to receive the two main bearings, but on this point no definite information could be obtained from the agents in charge of the car, and an external examination did not reveal the exact nature of the construction. The motor is bolted directly on the underpan, this latter being of stiffer material than is usually employed and bolted to the channel section side-frame members. With this construction it is obviously impossible to make any internal examination of the motor without lifting it entirely out of the chassis, but owing to its small area and very low weight this is by no means a difficult task. The power is transmitted through a cone clutch, a two-speed gearset and a propeller shaft to a floating rear axle. The gearset is a special type, particulars of which have not yet been given out.

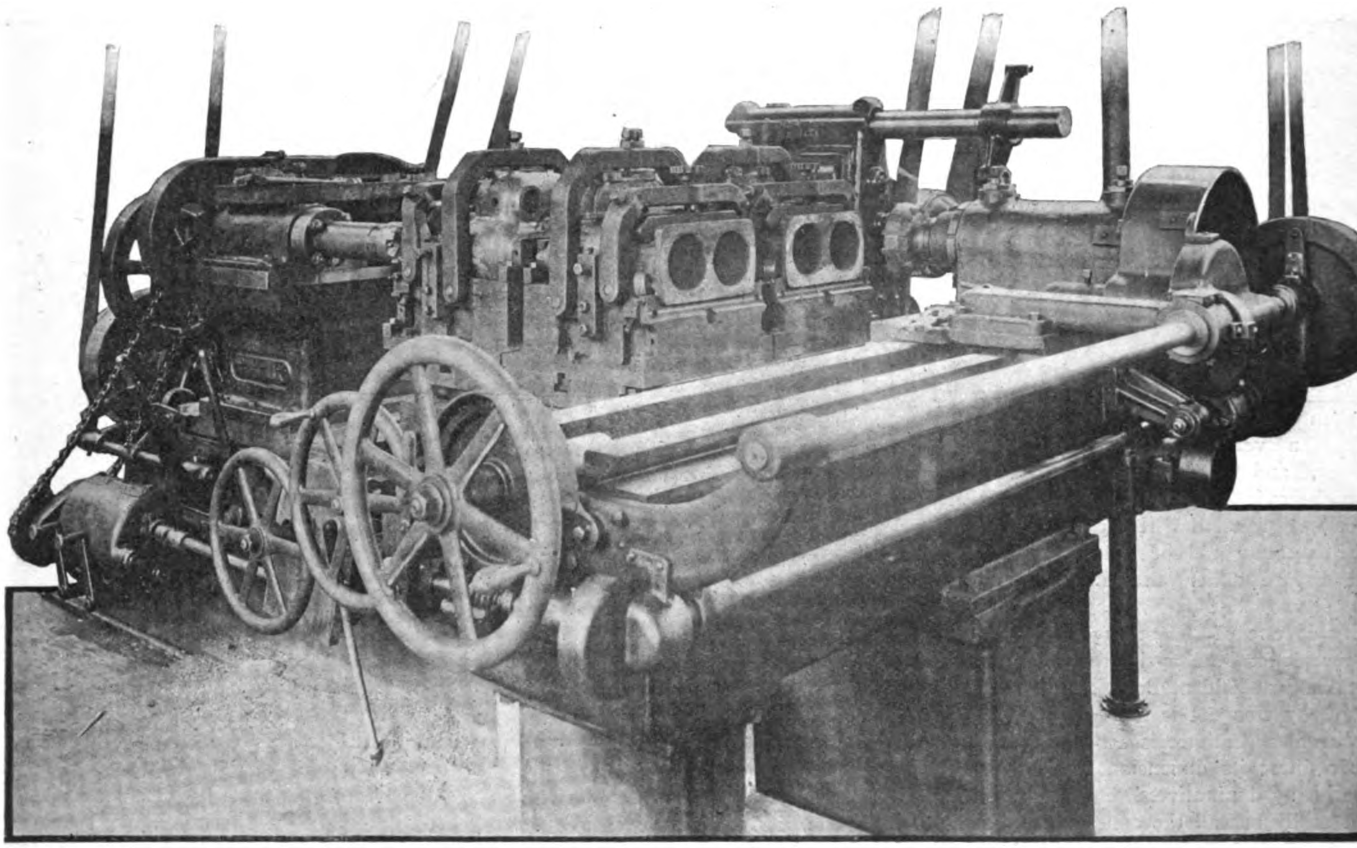
The motor is lubricated by splash, the oil tank being in the scuttle dash, with filler cap on the outside of the dash. The gasoline tank is built in the back of the rear seats, the top being polished mahogany and hidden by the hood when this latter is down. Front suspension is semi-elliptic and the rear springs are really the half of a semi-elliptic spring inverted, the thick end being attached to the frame member and the forward end of the main blade to the rear axle housing. Truffault shock-absorbers are fitted front and rear. The car is supplied with wire wheels having 22 by 2 1-2-inch tires, and is listed complete with two-seater body, three lamps, acetylene generator within the scuttle dash, horn and tools at $800 retail.

This car has been specially designed by the makers to meet the low-priced American car on the French market and in French, European and African possessions.



Intake and exhaust sides of Lion-Peugeot baby motor recently brought out for the French trade

Factory Miscellany



Machine used for boring and milling cylinders in the factory of the Lozier Motor Company, Detroit, Mich.

Boring and milling the cylinders, unless carefully handled, can become an enormous factor in the output cost of the factory. The above illustration shows the Beaman & Smith boring and milling machine as used in the Lozier factory at Detroit, Michigan. This shows the complete machine with the milling appliance in the foreground. Eight cylinders can be operated upon simultaneously. Four are bored, while the other four are in the milling part. As will be noted in the illustration, the cylinders are mounted upon a turntable, which permits them to be reversed when one of the operations is completed. After having completed the boring operation, the operator of the machine swings the turntable about and the cylinders which have just been bored are in position for milling. A fresh set of cylinders is inserted in the turntable for boring and the work proceeds. It takes but one man to handle the machine and the boring and milling of each set takes about 30 minutes. The machine can be run continuously throughout the working day, and in that time will turn out approximately twenty full sets. The size to which the cylinders are bored can be regulated on this machine by simply fitting into the boring chuck the cutter of the required diameter. The operation of the boring and milling divisions of the machine is entirely simultaneous and is to a great degree automatic in that after the job is set up it only requires the active attention of the operator when it becomes necessary to swing the set of cylinders from the boring to the milling side and to set up the new job, an operation requiring 4 minutes. It is estimated that the time saved on this job is more than 100 per cent.

Overland's Eight Additions—The Willys-Overland Company, Toledo, Ohio, is erecting eight new buildings. The largest of the group is a five-story concrete building, 102 feet by 127 feet in dimensions. Other constructions which are under way include a two-story concrete building, 50 feet by 140 feet, to be used as a repair shop; a three-story, 60 feet by 80 feet concrete building, for the varnishing and trimming departments; a three-story concrete structure 40 feet by 100 feet, for polishing, plating, pattern making and pattern storage; a two-story frame building covered with iron siding, 65 feet by 216 feet, for wheel painting and trimming; a 34 by 48-foot brick addition to boiler room for housing two 300-horsepower boilers; a one-story frame iron-covered addition to forge shop, 32 feet by 55 feet; a one-story steel and brick construction, 70 feet by 200 feet, to serve as a blacksmith shop. These buildings represent an outlay of several hundred thousand dollars and when finished will house 2,000 workmen.

Paige Company's Addition—The Paige Auto-Hoist Company, Grand Rapids, Mich., has purchased a site at that city on which a factory will be erected. The company will manufacture a device for lifting the weight of an automobile from its tires while not in use.

Jeffrey-DeWitt's Factory—The Jeffrey-DeWitt Company, Detroit, Mich., manufacturer of spark-plugs, has acquired an additional factory which it will operate in connection with its present plant. The new building will house the assembly and shipping departments.

Stewart's Plant—The W. F. Stewart Company, Flint, Mich., states that the plant which it is erecting will be used for the manufacture of metal automobile bodies for pleasure cars and is designed to produce 100 complete bodies per day. The company is interested in the purchase of metal automobile body making machinery.

Lavigne Leases Plant—The Lavigne Gear Company, of Corliss, Wis., and Detroit, Mich., which moved its plant and equipment from Detroit to Corliss about a year ago and which was reported to have been contemplating a return to the Michigan metropolis, has leased the big Racine plant of the Racine-Sattley Company, of Racine, Wis., and Springfield, Ill., and will occupy 50,000 to 75,000 feet, beginning Monday morning, October 28.

Kissel's Milwaukee Plant—The Kissel Motor Car Company, of Hartford, Wis., expects to be able to take occupancy of its new branch plant at Milwaukee, Wis., on or about November 15. The work of rearranging the new plant, formerly the Romadka trunk factory, is progressing rapidly, and some of the equipment is now being installed. Improvements to the main plant at Hartford are being completed, the new buildings having been equipped and put into condition for continuous operation.

Vinot Enlarges—The Vinot Car Company, Montreal, Que., is having plans prepared for a new factory.

St. Paul Company Builds—The Peteler Car Company, St. Paul, Minn., has acquired a site covering about 23 acres and will erect a factory.

Hudson Plans Additions—The Hudson Motor Car Company, Detroit, Mich., plans to add two more buildings to its plant, bringing the total floor space up to 363,611 square feet.

Ware Company Builds—The Ware Motor Company, Minneapolis, Minn., has under way the construction of a much larger factory than it has maintained and shipments will begin January 1.

Standard Oil Buys—Interests allied with the Standard Oil Company are said to be negotiating for the purchase of the factory and good will of the Knox Automobile Company, Springfield, Mass.

Deny Building Report—An official denial of the report that they are going to build a factory at St. Louis, Mo., is being sent broadcast by the Swinehart Tire & Rubber Company, Akron, Ohio.

Build Brick Factory—The American Automobile Trimming Company, Detroit, Mich., has made arrangements for the erection of a three-story brick building on Meldrum and Berlin avenues, that city.

Jackson Rim Adds—A contract has been awarded for the erection of an addition of a one-story factory 80 feet by 100 feet by the Jackson Rim Company, Jackson, Mich. The estimated cost is to be $40,000.

Another Body Plant—J. A. Fitzsimmons, Lindsay, Ont., will start work at once on a new two-story brick factory for the manufacture of aluminum automobile bodies. Complete new machinery will be purchased.

Chase Visits Havers Plant—A. F. Chase, Minneapolis, Minn., distributor of the Havers car, recently visited the factory of the Havers Motor Car Company, Port Huron, Mich., and after going over the line carefully placed an order for one hundred and fifty cars.

Detroit Adds Body Plant—With the addition of a body building plant to manufacture every sort of body, Detroit again gains. An organization of New York millionaires is at present forming a $200,000 corporation with John Mackay and H. D. W. Mackay as the leading directors.

Ford Leases Property—The Ford Motor Company, Philadelphia, Pa., has leased property at Sixteenth street and Washington avenue, that city, and will establish an assembly plant on the site. The acquisition of this property will also give the Ford company the benefit of its own railroad siding.

Cleanliness Garford Factor—Cleanliness is made an important factor in the Elyria, Ohio, plant of the Garford company. Every department of the plant is kept as clean and free from litter as a big force of shop white wings can make it. Parts and materials are neatly piled and the passageways are never obstructed.

Gramm-Bernstein's Truck—The first truck completed by the $500,000 Gramm-Bernstein Company, at Lima, was finished recently. It is of three and one-half tons capacity and the company will complete 250 of them by spring. The plant has been in operation for about four weeks and employs seventy-five men.

To Enlarge Plant—Additions and improvements costing $10,000 will be made by the M. E. Blasier Company, Utica, N. Y., to the building which it occupies at the present time. A four-story brick structure 21 feet by 60 feet will be built in the rear of the present plant, which will be enlarged by the addition of two stories. The company manufactures automobile tops.

To Make Automobile Tires—The Stens Manufacturing Company, Springfield, Mass., capitalized at $200,000, has bought land in the vicinity of Wood Pond on the line of the New Hampden Railroad and will build a three-story factory building 100 feet by 40 feet in size with basement, of brick and concrete. The company was organized last summer to manufacture automobile tires.

Adler-Werke's Increase—The Adler-Werke, Eagle Works, at Frankfort, Prussia, were formed by H. Kleyer, who commenced business in a small shop in 1880. His receipts in that year amounted to $2,248, whereas now the Adler Werke's annual production approximates $4,500,000 and is increasing from year to year, making enlargement of the plant frequently necessary. The works employ about 5,000 operatives and 500 clerks.

Calendar of Coming Automobile Events

Shows, Conventions, Etc.

Jan. 2-10	New York City, Importers' Salon, Hotel Astor, Importers' Automobile Alliance.
Jan. 4-11	Cleveland, O., Annual Automobile Show.
Jan. 4-11	Montreal, Que., Montreal Motor Show, Drill Hall and 65th Regiment Armory.
Jan. 11-25	New York City, Thirteenth Annual Show, Madison Square Garden and Grand Central Palace, Automobile Board of Trade.
Jan. 20-25	Philadelphia, Pa., Annual Automobile Show.
Jan. 25-Feb. 1	Montreal, Que., Automobile Exhibition, R. M. Jaffray, Manager.
Jan. 27-Feb. 1	Detroit, Mich., Annual Automobile Show.
Jan. 27-Feb. 1	Scranton, Pa., Annual Automobile Show, Hugh B. Andrews.
Feb. 1-8	Chicago, Ill., Annual Automobile Show.
Feb. 10-15	Minneapolis, Minn., Annual Automobile Show.
Feb. 11-15	Ottawa, Ont., Annual Automobile Show.
Feb. 15-22	Newark, N. J., Annual Automobile Show, First Regiment Armory, New Jersey Automobile Exhibition Company.
Feb. 17-22	Kansas City, Kan., Annual Automobile Show.
Feb. 24-Mar. 1	Cincinnati, O., Annual Show, Music Hall, Cincinnati Automobile Dealers' Association.
Feb. 24-Mar. 1	Omaha, Neb., Annual Automobile Show.
Feb. 24-Mar. 1	St. Louis, Mo., Annual Automobile Show.
March 3-8	Pittsburgh, Pa., Annual Automobile Show.
March 8-15	Boston, Mass., Annual Automobile Show.
March 17-22	Buffalo, N. Y., Annual Automobile Show.
March 19-26	Boston, Mass., Annual Truck Show.
March 24-29	Indianapolis, Ind., Annual Automobile Show.

Race Meets, Runs, Hill Climbs, Etc.

Oct. 31	Track—Phoenix, Ariz., Maricopa Auto Club.
Nov. 9	Sociability Run, Louisville, Ky., Louisville Automobile Club.
Nov. 29-30	Richmond, Va., Track Races, State Fair Grounds, Richmond Automobile Club.
May 30	Indianapolis, Ind., 500-Mile Race, Speedway.

Proposed Contests

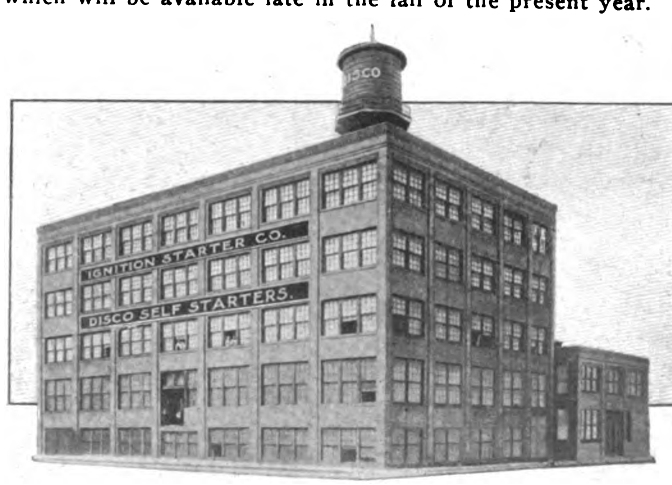
Nov. 3-5-6	Track—Shreveport, La., Shreveport Auto Club.
Nov. 15-16	Track—Richmond, Va., Richmond Automobile Club.
Nov. 28	Road Race—Visalia, Cal., W. H. Lipton.

Foreign

Nov. 2-3	Versailles, France, Splash Guard Competition.
Nov. 8-16	London, England, Olympia Automobile Show.
Dec. 7-22	Paris, France, Paris Automobile Show, Grand Palais.
Jan. 11-22	Brussels, Belgium, Annual Belgian Automobile Show, Centenary Palace.
April	Barcelona, Spain, International Exhibition.

Atlas Purchases Plant—Through the purchase of the Atlas Engine Works by the Lyons-Atlas Company, Indianapolis, Ind., recently the Knight sleeve-valve engine receives another impetus from a production standpoint which bids fair to place it on a more advantageous basis than ever before in this country. The new company will take possession of the new plant, which covers sixty-seven acres, at once, and will begin the manufacture of Knight engines for the trade.

New Departure Busy—The New Departure Manufacturing Company, Bristol, Conn., manufacturers of the well known American-made New Departure ball bearings, has been working 127 hours a week in all departments and 152 hours a week in some departments with day and night shifts of skilled mechanics to meet the large demand for these goods. Factory additions are now in process of construction. These additions will give nearly 75,000 square feet of floor space which will be available late in the fall of the present year.



New plant of the Ignition Starter Company, manufacturers of Disco starters, Detroit, Mich.

BAKER'S Sales Convention—Eighty-five dealers and salesmen were present at the Dealers' and Salesmen's Convention held at the Cleveland, Ohio, factory of the Baker Motor Vehicle Company, October 16, 17 and 18. Addresses were made by G. H. Kelly, W. P. Kennedy and other officials of the company. The accompanying illustration shows about two-thirds of the total number of men present asembled before the factory.

Barrett with Stratton—S. W. Barrett is now in charge of the stock department of the E. V. Stratton Company, Albany, N. Y.

Stromberg's Detroit Branch—The Stromberg Motor Devices Company has opened a Detroit, Mich., branch with N. H. Minniter in charge.

Baxter Sales Manager—William A. Baxter of Dayton, O., has recently been appointed sales manager of the Pan-American Motors Company, San Francisco, Cal.

Day and Night Service—M. E. Grable, Boston, Mass., who has been appointed New England district manager for the Universal truck, has inaugurated a day and night service for the owners of these vehicles.

Trade Men Organize Fraternity—A number of automobile owners, drivers and others identified with the motor car trade have organized the Fraternal Order of Honk Honks, which will have its headquarters at Anderson, Ind.

Tire Branches Consolidate—Since the consolidation of the Diamond and Goodrich companies of Akron, O., the two Columbus, O., branches have been consolidated with the former Diamond branch at 186 East Gay street under the management of H. S. Smith.

Goodyear's Indianapolis Warehouse—The Goodyear Tire and Rubber Company has begun the construction of a new business and warehouse building at Walnut street and Capitol avenue, Indianapolis, Ind. It will be 50 by 200 feet, of fireproof construction and will cost $107,000.

Columbus Wants Automobile—Bids will be received by Director B. L. Bargar of Columbus, O., November 4, for two gasoline automobiles for use in the fire department.

Will Build Garage—A building permit has been issued at Lima, O., for the construction of a garage on North Main street by J. A. Ireton.

Michigan's Good Road Campaign—The Michigan Good Roads Association has begun another campaign for membership and has become especially active in Detroit in its efforts to promote a good road along the Detroit and Toledo route through Monroe for which the Boards of Commerce of Toledo and Detroit have contributed $3,000.

Extend Minnesota Road—Business men between Rockford and Glenwood on the Soo line in Minnesota have organized to extend the state road from Minneapolis to Glenwood through Rockford under the Elwell road law which distributes one-half the cost to the state, one-fourth to the county and one-fourth to the property improved.

Mail Collectors Mechanics—Several months ago the Columbus, O., postoffice permitted the mail collectors which had been operating the automobile collection wagons, to take over the cars and gave each an allowance of $1,000 for maintenance. Since that time the collectors have become mechanics and are making quite a saving by making all adjustments themselves.

Mississippi's Road Improvement—Mississippi statistics show that during the past two years $5,867,900 in bonds have been issued for road improvement. In nearly every case the bonds brought par. This does not include expenditures for this purpose made from funds on hands. In addition automobile clubs and individuals have contributed considerable sums for road improvement.

Cost of Indianapolis Roads—More than $25,000 has been added to the Indianapolis, Ind., city treasury this year by automobile licenses. On January 1, 1912, there were 188 miles of paved streets in the city. Since that date contracts for paving streets have been awarded amounting to about $500,000. Street cleaning this year will cost the city $120,000; repairing and maintaining unimproved streets, $55,000, and repairing paved streets, $85,000.

Overland Helps Y. M. C. A.—The Willys-Overland Company has made possible the proposed complete course of instruction in the care and operation of an automobile to be offered by the Y. M. C. A. of Toledo, O., in its night classes, by presenting the association with a complete demonstrating apparatus. The use of this apparatus will give students a large amount of actual repair work in the shop. The school opened recently and is in charge of W. F. Morris, mechanical expert of the Union Supply Company.

San Antonio Dealers Move—Birdsong & Patchernick, Franklin dealers in San Antonio, Tex., have just moved into a new salesroom and service station at 104 Avenue D, near the new Alamo Plaza.

Closes Season with Tour—The Automobile club of Mankato, Minn., closed the season with a tour of fifteen cars and fifty-five tourists through St. Peter, New Ulm, Madelis, Hanska and Lake Crystal, a one-day run.

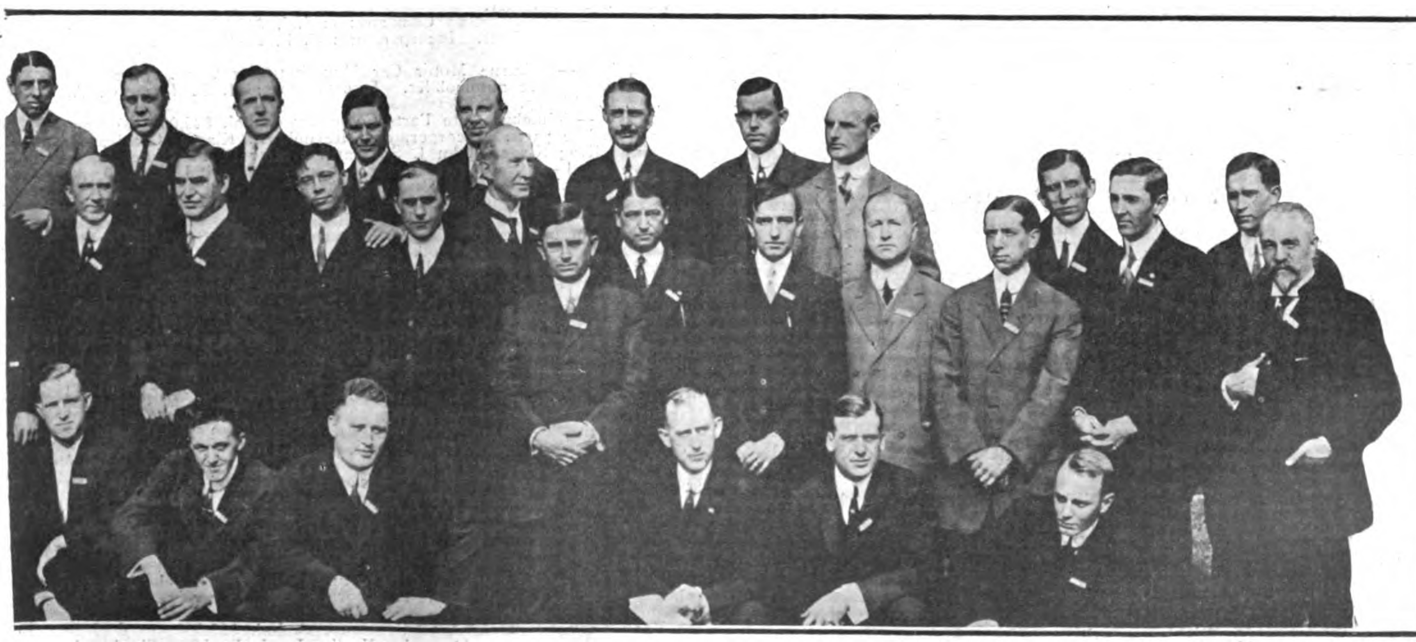
Membership Campaign Successful—That the membership campaign now being waged by the Vancouver, B. C., Automobile Club is meeting with success, was the statement made recently by O. I. Fox, secretary of the association.

Ottawa's Show Plans—Next year's automobile show in Ottawa, Ont., which will be held in Howick Hall February 11 to 15, promises to be the largest ever held in Canada. Practically all the space in the hall has been taken by local and other dealers.

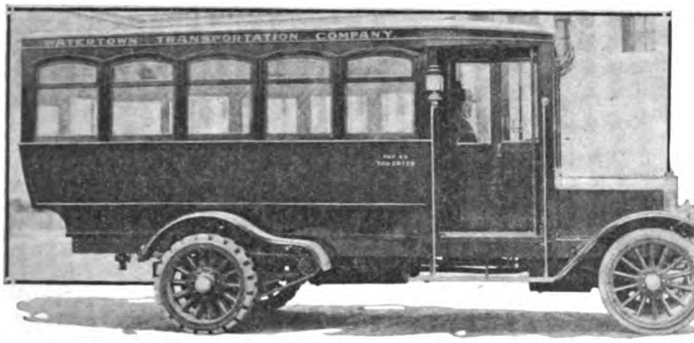
Ottowa Club Progressing—Seventy-two new members have been enrolled in the Ottawa, Ont., Motor Car Association during the past few weeks, according to the statement made at a meeting of that organization held recently. There are now about 550 automobile owners in the city.

Wireless on R-C-H—Highly interesting and exhaustive experiments involving for the first time the use of the automobile in wireless telephony have recently been made by E. C. Hanson of Los Angeles, Cal. One of the most recent experiments was a receipt on Lookout Mountain of a message sent over the ranges from Long Beach, 35 miles away. The car used was an R-C-H, current being supplied by the lighting storage with which the car is equipped.

Minneapolis Show Plans—The Minneapolis Automobile Trade Association, Minneapolis, Minn., has elected Walter R. Wilmot manager for the 1913 show in the Armory and annex and has executed a $5,000 contract with J. L. Hall company for the decorations. The space for the show has been doubled by the erection of an addition to the Armory which adds 27,000 square feet of space.



company at Cleveland for the purpose of studying the Baker electrics and of exchanging ideas on salesmanship and advertising



Atterbury truck fitted with a pay-as-you-enter car body, for use by the Watertown, N. Y., Transportation Company

Goodyear's Dayton Branch—The Goodyear Tire & Rubber Company has established a branch at Dayton, O., being located at 15 East Second street.

Alco Adds Shock Absorber—The American Locomotive Company, Providence, R. I., is to equip its cars with Truffault-Hartford shock-absorbers.

Turner with Wise—W. M. Turner has been engaged as manager of S. J. Wise & Company, Broadway and Fifty-eighth street, New York City.

Anderson Company Moves—The main office of the Anderson Engine Company, Chicago, Ill., is now located at 140 South Dearborn street, that city.

Osborn Manager Speedwell—C. E. Osborn has succeeded Harry Croninger as Pacific Coast manager of the Speedwell Motor Car Company in San Francisco, Cal.

Springfield Dealers Organize—The Motor car dealers in Springfield, Mass., got together last week and formed the Springfield Automobile Dealers Association.

Birmingham's Municipal Garage—A municipal garage may be the outcome of the Birmingham, Ala., controversy in regard to parking automobiles along the curbs.

Sweeney Kline Advertising Manager—C. E. Sweeney has been appointed advertising manager for the Kline Motor Car Corporation, York, Pa., and Richmond, Va. He succeeds W. P. Sieg.

Savannah's Mail Collector—An automobile is to be used in Savannah, Ga., for the collection of mail. The mail department has made an additional appropriation of $720 a year for the maintenance of the car.

Sturdy Adds Sta-Rite Line—The Sturdy Manufacturing Company, Chicago, Ill., has taken over the Sta-Rite line of ignition plugs, due to the failure of the R. E. Hardy Company, who has manufactured these plugs since 1900.

Daniels Moves Office—Smalley Daniels, operating as manufacturers' sales representative with main office for several years at Boston, Mass., has moved his main office to Detroit, Mich., and will make Boston a branch instead.

Franklin Company Moves—The Franklin Auto Company, Baltimore, Md., A. J. Miller, manager, will move to a larger home at 1919 North Charles street after November 1. The new location is now occupied by the D. C. Walker Auto Company.

Citizens After Speeders—To prevent speeding within the City limits a vigilance committee has been formed by citizens of Birmingham, Ala. Members of the committee will so arrange their hours that several watchers will be on duty night and day.

Replace Old Buses—Within the next few weeks the motor buses operated by the Metropolitan Coach Company on Sixteenth and other streets in Washington, D. C., will be replaced with new machines. An order will be placed for half a dozen new buses.

Road Tax Lower—In Los Angeles County, Cal., the tax for road work last year was 60 cents on every $1,000 of assessed property valuation. This year it is 50 cents, which will give the highway commission about $700,000 to expend on the roads of that county.

Baltimore Goodyear Moves—The Baltimore, Md., branch of the Goodyear Tire and Rubber Company will move into its new home at Cathedral and Preston streets within a few weeks. With the exception of a few finishing touches this new structure is practically completed.

Car's Novel Use—Elmer Sherman, San Francisco, Cal., has found a new use for his automobile. He was installing miles of heavy cable and the work was progressing slowly with two teams. Sherman used his Regal car as a wire stretcher and it took only 2 hours to finish the job.

Opens Service Station—The E. V. Stratton Company of Albany, N. Y., has opened a service building at 391 Hudson avenue for Everitt cars and Flanders sixes and electrics. A general repair shop for all makes of cars will also be conducted. Ezra Mickel will be in charge.

Unintelligent Road Improvement—Summing up the results of the Good Roads Convention, which was attended by more than 1,000 delegates representing every county in Alabama, it can be said that the keynote of the meeting was a warning against unintelligent road improvement.

Club Outlives Usefulness—A committee of five members of the Automobile Club of Washington, Washington, D. C., has been appointed by President Harrington Mills to consider the advisability of dissolving the organization, selling the club's country home and the formation of a new organization.

Holyoke Wants Motors—A committee of the Holyoke, Mass., Board of Aldermen, visited the Knox plant at Springfield, Mass., last week to inspect the motor apparatus that company makes as Holyoke intends to do away with some of its horse-drawn fire equipment and replace it with automobile engines and chemical wagons.

Drives His Own Machine—Chief Pomphret of the Chicopee, Mass., fire department recently bought a motor car in which to go to fires, and the Board of Aldermen, having refused to make an appropriation for a fireman to act as driver the chief has had the car placed in special quarters near his home and he will act as his own chauffeur.

Purchases Garage Stock—The Co-operative Auto Sales Company, a $100,000 corporation which was recently organized by Spokane, Wash., capitalists to carry on a wholesale and retail automobile and supply business on a co-operative plan, has purchased the entire issue of stock of the Regal Garage Company also of Spokane, at its par value of $10,000.

Washington's Show—The chances for a motor car show in Washington, D. C., are slight. The chief obstacle is the lack of a building of sufficient capacity to house the exhibits. Convention Hall, where the previous shows have been held, is the only available building, but there is some question about filling it with cars, many dealers believing it unsafe to use it for show purposes again.

Automobile Incorporations

AUTOMOBILES AND PARTS

Austin, Tex.—Oakland Motor Company; capital, $10,000; to sell automobiles. Incorporator: T. B. Cochran.

Benton, Ill.—Benton Motor Car Company; capital, $65,000; to manufacture automobiles and accessories. Incorporators: Harry Stotlar, W. S. Cantrell, A. H. Fraunfelder.

Boston, Mass.—Pope-Hartford Company; capital, $100,000; to manufacture and deal in automobiles. Incorporators: G. L. Dodd, C. W. Cousens, F. H. Lucas.

Cleburne, Tex.—Cleburne Motor Car Manufacturing Company; capital $10,000; to manufacture automobiles. Incorporators: H. E. Luck, G. A. McClung, O. L. Bishop.

Columbus, O.—Columbus Auto Parts Company; capital, $25,000; to manufacture automobile parts. Incorporators: Reynold E. Klages, Charles H. Krag, Corinne Krag Klages, John J. Stoddard, Walter D. McKinney.

Elizabeth, N. J.—Excelsior Automobile Company; capital, $50,000; to do a general automobile business. Incorporators: P. H. McCann, H. St. V. deRaismes, Peter Kern, Maurice Spewak.

Guelph, Ont.—C. Kloepfer, Ltd.; capital, $250,000; to manufacture automobiles. Incorporators: C. Kloepfer, Edward Halloran, George A. Scott.

Haverhill, Mass.—Rambler Motor Car Company; capital, $10,000. Incorporators: J. P. Mollay, G. A. Burnham, C. S. Goodwin.

Morgantown, W. Va.—City Automobile Company; capital, $4,800; to manufacture automobiles. Incorporators: J. Leonard Gates, S. S. Dearing, N. B. Yost, Margaret Smith, Cora B. Dearing.

Nashville, Tenn.—Jackson Motor Car Company; capital, $5,000; to deal in automobiles. Incorporators: H. C. Gillespie, D. D. Canfield, E. L. Bonne, W. H. Weakley, W. C. Sanefeur.

Newark, N. J.—American Auto Radiator Works; capital, $25,000; to manufacture automobile radiators. Incorporators: M. Steiner, S. Goldstein, A. Marcus.

Houston, Tex.—Cole Motor Car Company; capital, $12,500; to deal in automobiles. Incorporators: J. J. Settegast, Jr.; A. J. Binz, F. H. Buelow, David F. Burks.

Newark, N. J.—Lippard-Stewart Sales Company; capital, $50,000; to deal in automobiles. Incorporators: Benjamin P. Burton, Benjamin B. Burton, Robert C. Bennett.

Newark, N. J.—Continental Garage Company; capital, $10,000; to do a general automobile business. Incorporators: Littleton Kirkpatrick, Robert C. German, Stuart A. Young.

New York City.—Distributing and Importing Company; capital, $100,000; to deal in automobiles and biplanes. Incorporators: Paul Lacroix, Harvey T. Andrews, Henry A. Miller.

New York City.—Faissole Auto Company; capital, $25,000; to deal in automobiles. Incorporators: Alexander Karlin, Lewis Lapides, Charles A. Faissole.

Ford's Philadelphia Plant—The Ford Company, Detroit, Mich., has established an assembly plant at Philadelphia, Pa.

Guide Lamp's Factory—The Guide Motor Lamp Company, Cleveland, O., is erecting a new factory building on Madison avenue, between 114th and 115th streets, in that city.

Hartford Company's Addition—The Hartford Suspension Company, Jersey City, N. J., is planning an eight-story re-inforced concrete building, to be put up next to the Jersey City plant.

Portland Company Formed—The Beaver State Motor Company, Portland, Ore., was incorporated recently to manufacture motor trucks and motorcycles. A factory will be erected in the near future.

Marathon's Factory—The Marathon Tire & Rubber Company, Cuyahoga Falls, O., which is erecting a factory building, expects it to be completed and equipped to manufacture tires about November 1.

Cutting Enlarges Plant—The Cutting Motor Car Company, Jackson, Mich., has made arrangements for increasing the factory capacity. The new factory will probably be in course of erection by next spring.

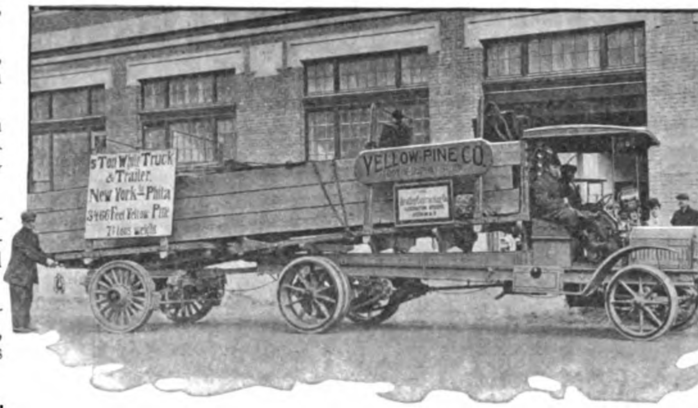
Premier's Addition—Two additions are to be made to the plant of the Premier Motor Manufacturing Company, Indianapolis, Ind. The buildings will be two stories high, one 40 feet by 140 feet and the other 48 feet by 140 feet.

Boon for Connersville—The Lexington Motor Car Company, Connersville, Ind., has agreed to furnish a tentatively-formed selling company with 1,000 six-cylinder automobiles in 1913. This order will keep the Lexington plant busy throughout the coming year.

Cincinnati Chauffeur's Club—The Ohio Chauffeur's Protective Association has been incorporated with headquarters at Cincinnati, O. Grover Bennett was elected president, Charles Eckert, vice-president, Roy Engelman, secretary, and George Puls, treasurer.

Editor Forms Company—Victor C. Parker, editor of *Modern Power*, Winnipeg, Man., has relinquished his position and removed to Detroit, Mich., where he has formed the Parker Motor Company, which will manufacture a rotary valve engine of which he is the inventor.

Ford Plant Manager—C. C. Hildebrand, formerly of the Chalmers Company, Detroit, Mich., will take charge of the Minneapolis, Minn., Ford plant, while H. C. Skinner, formerly manager of the Houston, Tex., branch of the Ford Motor Company, Detroit, Mich., will manage the assembling plant at Portland, Ore.



White truck used by large lumber firm, operated in conjunction with a trailer hauling a heavy load from New York to Philadelphia

Elmira's Fire Engine—The bid of the American LaFrance Fire Engine company, Elmira, N. Y., for the new hook and ladder motor truck for the fire department, has been accepted by the board of public safety. The machine will cost $6,000, will be equipped with a 70-horse-power engine, and will be thoroughly modern in every particular.

Leominster Chief Uses Motor—Chief Fred A. Russell of the Leominster, Mass., fire department recently bought a motor chassis on which he mounted a body supplied with a 32-gallon chemical tank, two hand fire extinguishers and a few other things needed in fire fighting and now he has a machine capable of doing good service in checking the spread of small fires.

Ford's Profits $7,000,000—To the Ford Motor Car Company, Detroit, Mich., belongs the credit of having made the largest 1912 net profits of any automobile concern in the country. Its production for the season to June 30 was at least 70,000 and probably nearer 75,000 cars which were sold at a net profit of slightly less than $100 per car, making the total profits amount to about $7,000,000.

Hadley Starts on Tour—W. K. Hadley, factory sales manager of the Lenox Motor Car Company of Boston, Mass., has started on a tour in the interests of the car and before he gets back he plans to cover about 10,000 miles and will visit New York, Philadelphia, Chicago, Indianapolis, Milwaukee, Denver, Los Angeles, Portland, San Francisco and other cities establishing agencies.

Visit Flanders Plant—In order to enable their distributors to inspect the new 1913 model of the six-cylinder, seven-passenger Flanders car the Flanders Motor Company, Detroit, Mich., will take a party of prominent dealers to Detroit in a special Pullman, so that they can inspect the new models and obtain a comprehensive idea of the magnitude of the new Flanders operations and the big scale on which the cars are now coming through the works.

Federal Supply Elects—The Federal Motor Supply Company of Cincinnati, O., has established its headquarters in the First National Bank Building. Plans have already been laid to open up branch houses in other cities throughout Ohio. The company will handle accessories and supplies for automobiles and trucks. George Platt, was elected president, Fred Beroldt, vice-president, Jesse Wozzencraft, secretary, Emil Schmidt, treasurer.

McNab Goes to Marion—The announcement is made by the Marion Motor Car Company, Indianapolis, Ind., that M. D. McNab, of Chicago, Ill., who until recently has been general manager of the United Motor Company, Chicago, has resigned that position to accept the vice-presidency of the Marion Company. In addition to filling this office Mr. McNab also will be director of sales. He will make his headquarters in Indianapolis.

From Agency to Branch—A change was made last week in the handling of the Chevrolet and Little cars in Boston, Mass., which had been taken on by the F. J. Tyler Corporation as an agency. The Republic Motor Car Company has been organized as a Massachusetts corporation with headquarters in the Motor Mart, Park square. The F. J. Tyler Corporation has moved next door where it will continue to handle the Columbus electric and later take on some other gasoline cars. W. C. Sills is in charge of the Republic company's branch.

Automobile Incorporations

North Tonawanda, N. Y.—Twin City Company; capital, $5,000; to deal in automobiles. Incorporators: W. A. Arenz, R. Leroy Herschell, F. J. Wallenberg.

Rockford, Ill.—Rockford Motor Truck Company; capital, $10,000; to manufacture automobiles. Incorporators: P. A. Peterson, Levin Faust, John Ledin.

GARAGES AND ACCESSORIES

Buffalo, N. Y.—Up-To-Date Auto Body and Specialty Company; capital, $2,500; to manufacture automobile bodies. Incorporators: Ludwig Dreyer, Emma H. Dreyer, G. P. Askin.

Columbus, O.—Independent Motor Inspection Company; capital, $10,000. Incorporator: V. A. Troxell.

Jacksonville, Fla.—Atkinson Tire & Supply Company; capital, $25,000; to carry on an accessory business. Incorporators: J. D. Cary, Lucien H. Boggs.

Newark, N. J.—Tri-Unit Electrical Company; capital, $100,000; to deal in automobile accessories. Incorporators: J. B. Stobaeus, Jr., B. W. Mathews, Wm. C. Stobaeus.

New York City.—Bryant Auto Painting Company; capital, $2,000; to paint automobiles. Incorporators: A. Berkowitz, Benjamin Davis, P. Ostruk.

New York City.—Atlas Tire Company; capital, $10,000; to manufacture automobile tires. Incorporators: R. W. Morrison, R. D. Placak, F. F. Nichols.

New York City.—Snowden Rubber Company; capital, $1,000; to manufacture tires. Incorporators: W. T. Snowden, E. J. Landgraff, A. Bidney Galitzka.

Richmond, Va.—Automobile Lighting Corporations of America; capital, $1,500,000; to manufacture a lighting device for automobiles. Incorporators: W. J. Simpson, Wailes Hank, A. D. Newcomb.

Richmond, Va.—National Automobile Top Company; capital, $15,000; to manufacture automobile tops. Incorporators: G. W. B. Crawford, R. V. Merchant, E. R. B. Crawford.

St. Matthews, S. C.—Calhoun Garage; capital, $3,000; to do a general garage business. Incorporators: C. H. Culler, N. E. Salley, J. M. Salley.

Yoakum, Tex.—Automobile & Garage Company; capital, $20,000; to do a general garage business. Incorporators: F. A. Mason, J. Lyon, D. J. Shall.

CHANGES OF NAME AND CAPITAL

Detroit, Mich.—Chalmers Motor Company; increase of capital from $3,000,000 to $5,000,000.

Indianapolis, Ind.—Motor Car Manufacturing Company; increase of capital from $75,000 to $150,000.

Middletown, O.—Crescent Motor Truck Company; increase of capital to $100,000.

Houk Q. D. Rim for American Wire Wheels

Rudge-Whitworth Type of Wire Wheel for Automobiles To Be Manufactured With Special Quick Detachable Rim for the American Trade in The Plant of the Standard Roller Bearing Company

THERE are strong indications that the long-predicted advent of the wire wheel into the automobile practice of America is to be fully materialized during the coming season of 1913.

The superiority of this type of wheel over the wooden artillery wheel has been amply demonstrated in both tests and actual practice on the road during the last 4 years. The most important of these tests was a series of destruction tests to determine the comparative strengths of the most commonly used kinds of wheels, carried out by the Rudge-Whitworth Company, of Coventry, England, the results of which were published a few months ago in THE AUTOMOBILE. Wire wheels have shown themselves to be stronger, lighter, more economical on tires and more flexible than wood wheels. Why, then, this tardy adoption of their merits in this country? Various reasons have been put forward, perhaps the most important being that as ordinarily made for the European market, wire wheels are provided with clincher type rims only, requiring tires with extensible beads, and this style of tire is becoming less easily procurable in the United States since the great advantages of the detachable rim were realized. In all probability the tire with inextensible edges for detachable rims will soon become the rule.

The George W. Houk Company, Philadelphia, Pa., has secured the American rights for the Rudge-Whitworth wire wheel and will combine with it the Sangster-Houk patent Q. D. rim.

The detachable portion of the Houk rim consists of a single split clinch ring, remarkable in that it is entirely free from bolts, nuts or clips of any kind. Its simplicity, in fact, renders a description other than that afforded by the illustrations almost unnecessary. As shown at A in the section, Fig. 4, the ring is stamped from the same stock as the rim proper and its attachment and detachment are as simple as its construction. The views, Figs. 1, 2 and 3, show the operations of removing the clinch ring. A special lever tool, used for this purpose, is shown with its method of application in the sketches Figs. 7 and 8. In removing, it is only necessary to start the ring from its seating at a point a few inches from the split end, as shown in Fig. 7, insert the small wedge-piece W, supplied with the tool, and after prying the raised end outwards over the top of the wedge with the handle of the tool, withdraw the ring by hand. To replace

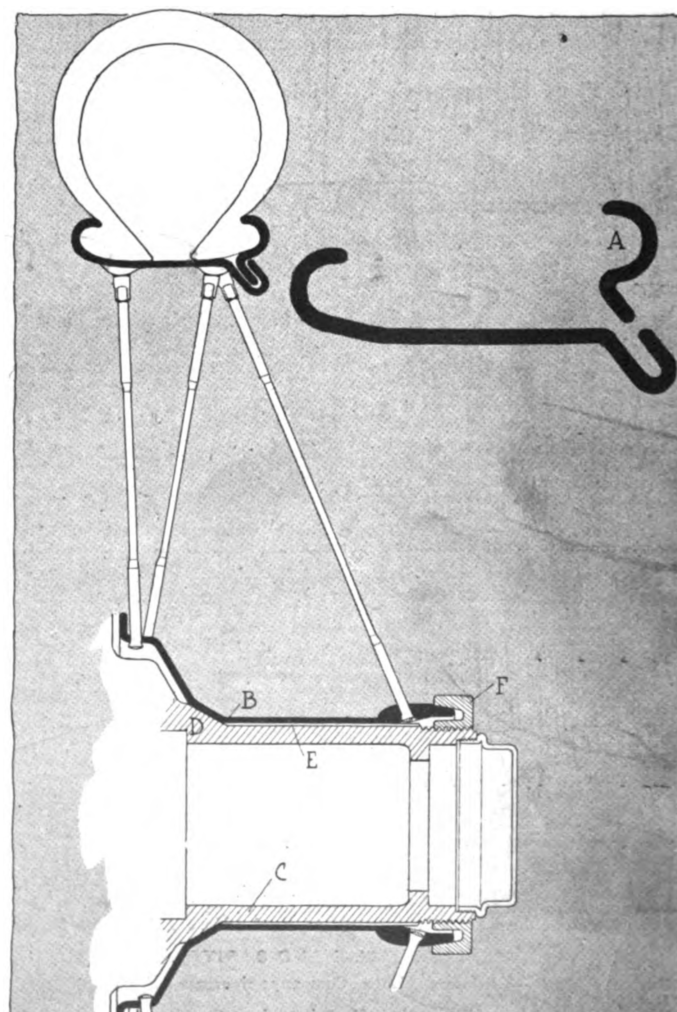

Fig. 4—Section through Rudge-Whitworth wheel and Houk rim

the clinch ring one end is first inserted in the groove, and the ring then worked in by hand around the rim as far as possible, the tool being required only to spring in a short length at the end.

The wheel itself, which will be turned out in all details exactly as the Rudge-Whitworth Company's product in England, will, in fact, be interchangeable with it, is of the triple-spoke order. A section is shown in Fig. 4.

It consists of a stamped shell hub B with a coned inner end to which the spokes are attached. This hub slides over an inner hub C mounted on ball bearings and provided with a flange D to take the coned surface of the wheel hub which is forced up against this flange by a single lock nut. The drive is transmitted through serrations E cut on the inner surface of the wheel hub and the corresponding outer surface of the inner hub. Great care is taken when cutting these longitudinal serrations to insure accurate alignment so that the wheel can be slipped on in any position with equal ease and fit.

When the R. W. detachable wheel was first introduced in 1909 it was held in place on the hub by the use of a special lock-nut with a double ratchet and pawl, one hand-operated and the other automatic. This device was absolutely fool-proof and has given perfect satisfaction so far as its action was concerned, but last year, after much experimenting, the makers replaced this device by the much simpler lock-nut shown at F, Fig. 6. This new nut has no second lock-nut, pin or other check, and yet once screwed up to the hub it remains automatically tight. Not only that, but if through carelessness or other cause the nut is not screwed home it will proceed to tighten itself as soon as the automobile is put into operation.

Reference to Fig. 6 will help to elucidate this peculiar action. Suppose the nut with its internally coned bearing surface is mounted on the hub but has not been screwed up tightly. It follows then, owing to the slight play of the wheel hub on the inner hub and the weight of the car on the axle, that the coned surfaces of wheel hub B and lock-nut F will meet only at a point, as shown at P. In other words, there will be a very slight degree of eccentricity existing between the two members, and as the situation of this contact point remains stationary, although the wheel is turning, it follows that a contact path is being mapped out on the inner circumferences of hub end and lock-nut. But, owing to the eccentricity, these circumferential paths are not of equal length and the outer, that of the nut, being the greater, there will be set up a differential creep betwen them, the nut lagging behind the wheel and so tightening itself up. It should be understood that the screw-thread for the wheels on the left side of the car is right-hand, while that for the right side wheels is left-hand. There is also a similar action, though of a lesser degree, taking place at the same time between the nut and the thread on which it is screwed. As the eccentricity of the various members decreases the action ceases so that finally the nut is right home and the wheel truly concentric on the hub.

Actual experiment has proved that the nut is sufficiently tight to resist the reversing efforts brought about by driving the automobile backwards for all ordinary distances.

Reliance Ratchet Horn; Universally Adaptable Fuel Gauge; Gasolock; Kerosene Spray Engine Cleaner; Mixer for Starting; Landophone for Closed Cars; Portable Recording Clock for Watchmen

A HAND-operated horn in which the signaling sound is produced by the intermittent contact of a ratchet wheel with a steel button secured to the center of a steel diaphragm is the latest addition to this line of instruments, being manufactured by the D. S. P. Automobile Specialty Company, 327 Adams street, Brooklyn, N. Y. The horn is shown in Fig. 2 and is dimensioned as follows: length, 9 inches; diameter of diaphragm, 5 inches; diameter of screened front of the horn, 6.5 inches; width of the squared middle portion, 2.5 inches. The outside of the horn requiring no explanation, we will proceed to deal with the description of the mechanism by means of which the signaling sound is generated. This mechanism consists of a train of gears made irreversible by the use of a pawl engaging one of them. These gears, of which there are five, are mounted on three shafts S1, S2, S3 in Fig. 3. The operation of the horn is as follows: A handle H, Fig. 3, is secured to the shaft S1 which carries gears A and B, and when this handle is turned toward the right, referring to Fig. 3, the gear B and with it the gear A is turned in that direction. As soon as the handle H has reached the limit of its movement which is determined by the shape of the casing of the horn the pressure on the handle may be released whereupon it returns to its original position due to the tension of the spring S4 which draws forward the pawl Rb engaging the gear or ratchet B. The transmission of the movement of the shaft S1 over the shaft S2 to S3 which carries the ratchet W is obvious upon referring to Fig. 3. Excepting gears A and B which are loose on S1, all gears are keyed to their respective shafts and are continually in engagement so that the operation of the horn is positive and the pressure on the handle H always causes the ratchet W to strike against the bottom D1 under diaphragm D.

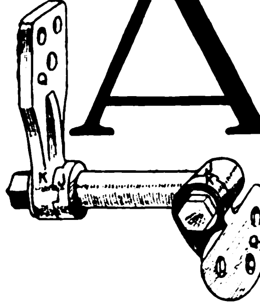

Fig. 1— Attaching piece for Reliance horn

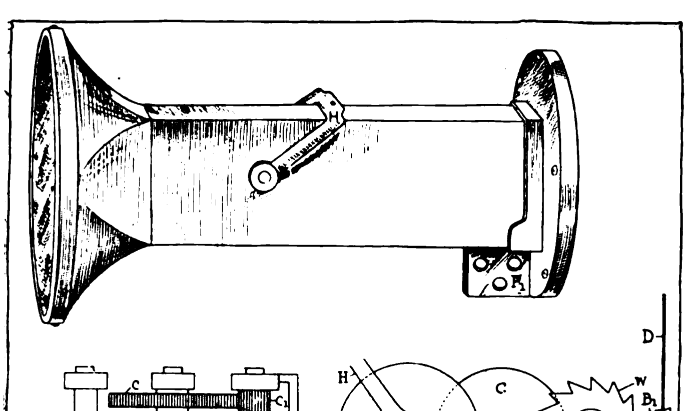

Fig. 2—Outside view of Reliance hand-operated, ratchet-and-button horn. Fig. 3—Schematic view of gears by means of which horn is operated

The horn is secured for any suitable portion of the body and in reach of the driver by means of an attachment piece shown in Fig. 1. This member is of an ingenious construction, giving the service of a ball-and-socket joint in combination with positive locking of its parts. The attachment consists of three pieces, one of which is formed as a bolt and is fitted with jaws J, while the other two are plates, each punched with three holes and engaging jaws J by means of jaws K. The jaws are held in engagement through the office of nuts. The piece Q is bolted with a part P1 of the horn casing, and the part Q1 is secured to the body of the car.

Imperial Gasoline Gauge

Automobilists are more and more coming to realize the value of a dash-attached gauge which always tells at a glance the quantity of fuel carried in the tank at the moment. An addition to the line of devices which have been designed as tell-tales is the Imperial indicator, made by the Imperial Fluid Gauge Company, Canton, O. This device may be used for gravity or pressure feed systems, and consists of a glass tube carried in high-polished brass. Fig. 6 shows the system as used for gravity feed, in which the interior of the gauge is simply brought into communication with the fuel line by means of two couplings and a piece of tubing. In case the gauge is desired to serve in connection with a pressure-feed system, the type shown in Fig. 4 is used, comprising in addition to the indicator tube, a well under the same which extends below the floor line and contains a cylindrical float carrying a wire with an indicator head. To the top of the indicator tube a compression connection is made to a return air line, and by this expedient the height of the gasoline in the gauge above the well is always the same as the height of the fuel in the tank. When ordering the outfit, it is necessary to inform the maker of dimensions of tank and feed pipe, shape of tank, class of feed used, etc., to obtain correct graduation.

Gasolock for Dash Control

To prevent the use of the car without the permission of its owner and to prevent leakage in the gasoline line at the point of the fuel cock, the Auto Lock and Specialty Company, 412 Scherer Building, Detroit, Mich., has constructed the Gasolock, Figs. 7 and 10. This device is attached to the dashboard and consists substantially of six parts, the Yale pin-tumbler lock cylinder, the ball head containing it, the socket for attaching the ball head to the dashboard, the cock which opens or interrupts the gasoline flow, the mechanical connection between cock and Yale lock and the reach or guard tubes enclosing the same.

The lock cylinder contains a double set of tumblers permitting of withdrawing the key when the lock is in the open position; the latter may be obtained upon inserting the key in the lock and turning the winged thumb-button T to the proper position, whereupon the key may be withdrawn; the lock may be closed by returning T to its former position, without using the key. In the end of the lock opposite to that fitted with the button T is a bevel gear segment engaging a similar gear which is carried by to the mechanical connection inclosed in the double telescoping tubes R. The ball head H incloses the lock cylinder which is held in place therein by a bayonet joint and kept from rotating through the use of a retaining screw. The socket which contains the ball head is formed with a boss on its back side which is fitted into a 75-inch hole of the dashboard. The attachment of the ball head is such that vibration between it and the socket is impossible. The connecting member contained in the reach tubes T consists of a tube T carrying the above-mentioned bevel gear; the end of this tube is squared and engages a rod of square section which has its other end pinned to the valve or cock plug contained in the casing C. The cock is formed with a bearing in its casing and its stem is surrounded by packing which keeps it tightly in place and guards it against leakage of the gasoline into the reach tubes. The cock plug is designed with an annular groove extending through an arc of 90 degrees, which is engaged by a stop screw, thereby limiting its angular movement to such an extent. The upper middle portion of the cock plug is formed cylindrically and seats in a suitably shaped portion of the casing C, being pressed down by a spring between it and the flanged portion of the casing.

National Primer and Mixer

A device which facilitates starting by thoroughly mixing the priming fuel with air before it is admitted to the cylinders is made by the National Manufacturing Company, Kalamazoo, Mich., The National Compound Mixer and Primer, Fig. 11, consists of two cylinders connected by a valve, one of which serves as a small fuel reservoir and the other as a mixer, being fitted with a device which mixes a certain amount of air when gasoline passes through the cylinder. In installing the mixer and primer, the inlet manifold is tapped with an .34375-inch drill and a 1-8-inch standard pipe tap, which permits of connecting the manifold to the outlet at the bottom of the mixing cylinder. The valves or cocks V and VI, regulate the passage of fuel from the priming to the mixing cylinder and from the latter to the inlet manifold, respectively. The device is attached to the dashboard of the car, which is drilled to permit of passing the tubing through it.

Romort Quick Engine Cleaner

The Romort Valve Company, 231 Worcester Building, Portland, Ore., manufactures a handy device which serves for rapidly cleaning the outside of the motor, being shown in Fig. 9. The cleaner is designed for use in garages, repair shops, etc., being operated by compressed air which is introduced by connecting the apparatus to an air line used in such establishment. The device consists of a cylinder shaped with a funnel-and-spout end and a nozzle, having an overall length of 20.5 inches and a diameter of 4 inches. The fluid which is used for cleaning and for which purpose kerosene is recommended, is filled in through a filler near the wide end of the funnel; while the compressed air enters through the tube T and its flow is regulated by a needle valve in V. An inclosed passageway for the compressed air traverses the interior of the cleaner, ending in an aperture near the end N of the nozzle where the air picks up the fluid which is sprayed against the motor to be cleaned. The knurled rod V enclosing the regulating valve is well packed to prevent leaks of air and the same holds of the packing nut P,. which is tightened on the compressed air tube to hold it securely in place.

Brown Automobile Telephone

One of the most recent novelties that have appeared in the British accessory field is the Landophone, made by Brown Brother, Limited, 22-34 Great Eastern street, London, E. C. This device is a specially designed telephone through which the passengers seated in a limousine or landaulet may give orders to the driver and which transmits messages loudly and clearly despite the noise of the street. The 'phone is constructed on

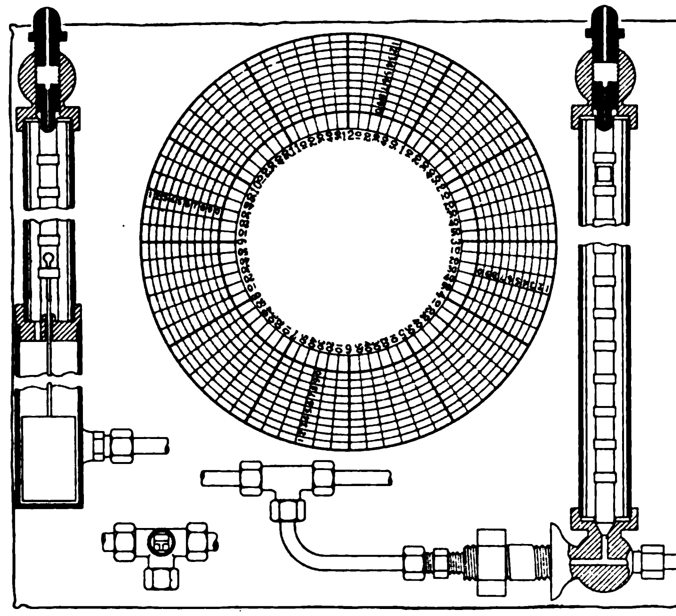

Fig. 4—Imperial gauge for pressure feed. Fig. 5—Dial of Eco portable watchman's clock. Fig. 6—Design of Imperial gauge for gravity feed

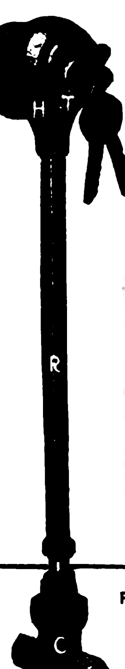
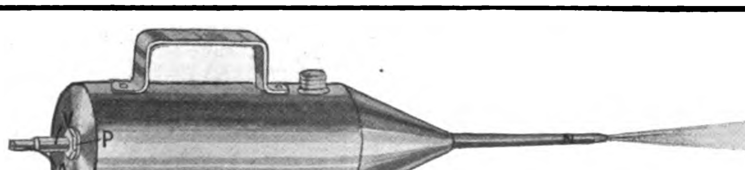
the telephone principle, but in addition to a speaking tube, coil box and 4-volt battery comprises a receiver which is fitted with a megaphone concentrating and strengthening the sound, after it has been transmitted from the interior of the car and has been reproduced by the diaphragm of the receiver.

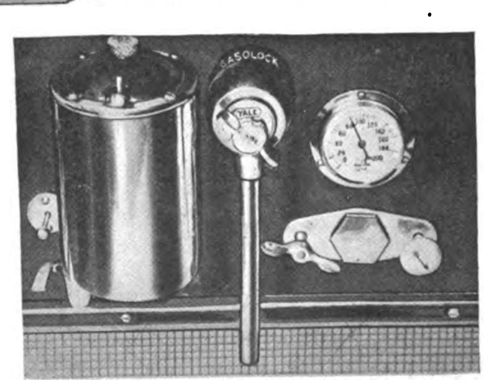
Eco Portable Watchman's Clock

The Eco Magneto Clock Company, 234 Congress street, Boston, Mass., manufactures a clock for watchmen who periodically have to inspect a number of given places in a factory or similar large establishment. This device consists of a clockwork which rotates with a paper dial as shown in Fig. 5, and from ten to thirty tumblers carrying punching pins, which are operated by Yale keys chained to the several places to be inspected. The number of the inspecting station is given by number on the circle punched, while the radius along which the dial is punched indicates the time of recording. The whole mechanism is enclosed in a leather bag fitted with straps, as seen in Fig. 8.

Correct Address of Cleaner—In the description of the Auto Vacuum Cleaner which appeared in this column, page 869, of THE AUTOMOBILE of October 24, the address of the maker was given as 253 West Twenty-third street, New York City. This address being wrong we herewith give the right address which is 253 Twenty-third street, Milwaukee, Wis.







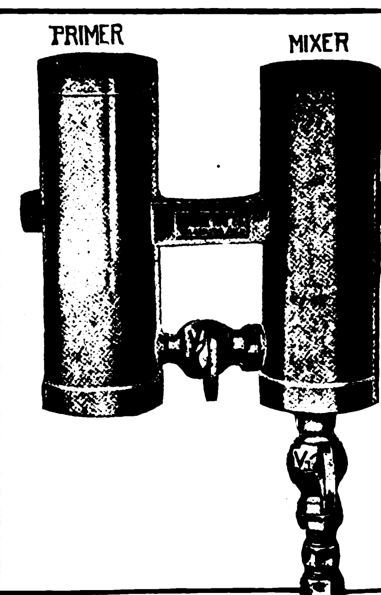


Fig. 7—Outside of Gasolock device. Fig. 8—Eco portable watchman's clock. Fig. 9—Romort engine cleaner. Fig. 10—Gasolock installed on dashboard. Fig. 11—National primer and mixer.

ROTARY Valve Design—Comprising a cylinder valve construction, with means for insuring tightness between individual passages.

This patent refers to a valve construction for internal-combustion engines, as illustrated in Fig. 1. The valve V is a rotary cylinder journaled in a cylindrical bed B, the interior of which is connected by ports P to the working cylinders of the engine. The valve itself is composed of an outer cylinder O and an inner one I, each of which is formed with a series of ports designed to register in turn with those in the valve bed, thereby providing passages between the manifolds and the cylinders. To prevent leakage of gas from one port to the other, an annular rib R is formed between each two neighboring ports; this rib extending into an annular groove in the inside surface of the valve bed.

No. 1,041,957—to George Bradford Brown, Warkworth, Ont. Granted October 22, 1912; filed May 2, 1912.

Dirigible Headlight Support—Describing a method of carrying the headlights which are operable to turn in parallel with the front wheels.

A headlight carrying design for lamps which turn when the front wheels of a car are turned to either side is shown in Fig. 2. This construction comprises a standard S for each lamp, a section S1 formed with a socket and fixed upon a post, and a second section S2 which has a complementary stem rotatable in the socket. Between stem and socket is anti-friction ball, and the stem is formed with an annular groove engaged by a screw which holds the sections S1 and S2 against separation.

No. 1,041,902—to Louis C. Thoeming, Benjamin H. Thoeming and Edwin A. Anderson, Newcastle, Wyo. Granted October 22, 1912; filed May 7, 1912.

Automobile Jack—Being of wedge design and lockable by means of a rack.

The subject-matter of this patent, shown in Fig. 3, is an automobile jack which is composed of a base frame F and a top frame T designed to be movable longitudinally in relation to the base frame. The frame T is normally arranged below the axle of a vehicle which is to be elevated through the use of the jack, and wedge blocks are secured to the top frame in such a position that they fit between it and the axles of the car when the jack is first applied. The wedge blocks W engage inclined track surfaces between top frame and car axles, and means are provided for moving T intermittently forward, for locking it in any suitable position, and means M for rendering the locking means inoperative. As the lower wedge blocks are attached to the base frame B and the upper to the top frame T, the vertical lever engaging a rack on the extension of the base frame permits of easily operating the wedges and lifting the car.

No. 1,042,154—to Herbert W. Seely, Selgman, Ariz. Granted October 22, 1912; filed March 30, 1912.

Shock Absorbing Device—Comprising an auxiliary spring fitted in a suitable manner between the inner surfaces of the elliptical spring leaves.

Fig. 4 illustrates the shock absorber construction which is described in this patent and which comprises, in combination with an elliptical automobile spring S and its bow-shaped members M provided with bracket carrying rollers R and an auxiliary, shock absorbing spring S1 which is disposed between the bow shaped members, one of its ends being fixed and the other traveling between rollers R.

No. 1,041,843—to Charles S. Moore, Danvers, Mass. Granted October 22, 1912; filed June 14, 1911.

Grip Wrench Construction—Comprising, in combination with the jaws of a wrench, means for holding the former in their relative positions when adjusted.

This patent refers to a wrench which consists of two members shaped with jaw ends and being pivotally connected to each other. Resilient means which are independent of the pivotal connection are provided for adjusting the relative position of the two members, and spring means serve for frictionally holding the wrench members in the adjusted positions.

No. 1,041,967—to William Cronk, Montour Falls, N. Y. Granted October 22, 1912; filed October 25, 1910.

Spring Wheel Tire—Comprising an inner and outer rim, between which coiled springs are located and which are braced in a suitable way.

The subject matter of which patent is a spring wheel tire. The construction includes an inner and an outer rim, the latter being resilient and spaced from the former one, and coiled springs each of which has one end connected to the inner rim and the other to the outer one. A number of brace chains connect inner and outer rims respectively, and a number of resilient braces are arranged in oppositely disposed pairs. One end of each brace is rigidly held to the inner rim, while the opposite end is slidably secured to the outer rim. To the latter flexible skirt members are connected with bear over the side of the inner rim and are detachably connected to the same.

No. 1,041,829—to William B. Mallory, Hermosa, S. D. Granted October 22, 1912; filed March 12, 1910.

Automobile Carbureter—Comprising slidably hollow cylinders as valves for regulating the admission of mixture.

The carbureter described in this patent comprises a mixing chamber with inlet and outlet ports and two independently movable hollow valves which are arranged adjacent to each other and adapted to slide longitudinally within the mixing chamber to control inlet and outlet ports. Each valve member has an open end and contains a compression spring tending to bear against the mixing chamber through the open end of the hollow valve member.

No. 1,042,077—to Clement Brown, Birmingham, Eng. Granted October 22, 1912; filed October 4, 1909.

Vol. XXVII — New York—Thursday, November 7, 1912—Chicago — No. 19

The AUTOMOBILE

United States Has 990,738 Cars

Increase in Registration of 266,670 Automobiles During First 9 Months of Current Year—Manufacturers Increase 163, or 38.8 Per Cent. and Dealers 3,463, or 26.2 Per Cent.

New York's Registration Passes 100,000 Mark—California Leads in New Cars With 24,526 and One Machine Per 28 Souls

SURPASSING all record of an industry which produces an intricate, sensitive and high-class mechanism and equaled only by the records of the producers of raw materials such as coal and steel, the automobile industry continues to keep its position among the principal lines of effort of the United States for the year 1912. In order to learn the present status of the automobile, its manufacture and trade in a quantitative way, The Automobile has arranged a detailed census. The objects of the latter were as follows: To obtain actual figures relative to the number of automobiles in use in the whole country and its several states, to the quantitative classification of these products under the heads of gasoline and electric pleasure and commercial cars; to obtain an exact knowledge of the fees contributed to the state treasuries by the automobilists of the United States; the number of manufacturers of each type of automobile in every state of the Union; and, likewise, the number of automobile and supply dealers, as well as garages and repair shops, all of which depend indirectly upon the automobile industry. The results of the census, which was carried out in a very painstaking manner, are as follows:

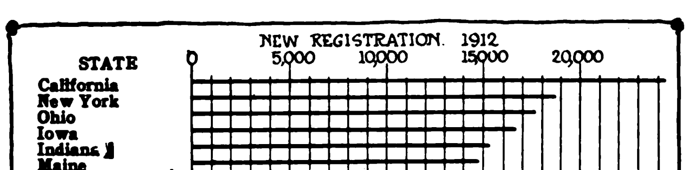

Diagram illustrating the respective gains in automobile registration up to October 1, 1912, throughout the various states of the Union over the number of cars registered during entire year of 1911

During the first 9 months of the present year, 275,293 automobiles were manufactured in the United States, and 266,670 of these were registered in the states and territories and in the District of Columbia. The total number of trucks made was 35,978, and that of electrics 33,842. The automobile owners of the Union paid to their secretaries of state or other registering officials a total of $5,229,459.65 as license fees for their vehicles, while an average price of $1,200 was paid in the purchase of the cars. The ratio of cars to the population is one car to every ninety-three residents of the country, if the results of the latest United States census is taken as the basis of such a calculation.

The total value of the cars registered in this country to October 1 is $1,188,88

Map showing the registration of automobiles up to October 1, 1912, illustrating the distribution of cars throughout the various states

or $12.98 per capita of the population. As to the distribution of automobiles in the various states, New York ranks first, being the only state in which there are more than 100,000 cars, but it is not gaining as rapidly as California, which is also making some progress as a manufacturing territory. While California leads in the actual maximum number of new registrations for 1912, West Virginia has the greatest per cent. gain, namely, 148. In regard to population per car, California is also in the lead, there being a car to every twenty-eight inhabitants.

A most careful census made to determine the present number of automobiles in the United States has led to the results which are compiled in the table on page 929 and the charts on pages 927 and 928. In order to obtain this information, THE AUTOMOBILE communicated with the secretaries of the various states and other state officials in charge of the registration of automobiles.

Tremendous Number of New Cars

There are at present 990,738 automobiles registered in the United States, including pleasure and commercial cars, of both the gasoline and electric type. Of these cars 920,918 are gasoline pleasure cars and 35,978 trucks, while 33,842 electric automobiles complete the total. Of this, 266,670 machines have been registered for the first time during the year 1912, in addition to the 724,068 automobiles in use last New Year, and this addition amounts to an increase of 36.8 per cent. on the latter basis. In other words, 26.9 per cent. of the automobiles used today throughout the Union have found purchasers since January 1 of this year. The commercial vehicles which numbered 25,451 last New Year have increased by 10,527, or 41.3 per cent., while of the 33,842 electrics now in use 5,550 have been added during the year, as a 20.4 per cent. increase. The 256,143 pleasure cars which comprise the addition to this class of vehicles during the first 9 months of this year represent an increase of 37 per cent. on the 692,494 cars in use on January 1.

Before dwelling on the distribution of cars in the various states, it might be well to illustrate these results by establishing a relation between the number of cars and the population of the United States. Taking the last census, which gives the population as 91,572,266 as a basis, there is one automobile to every ninety-two inhabitants of the country, which means, if the value of an automobile is set at $1,200 for the average, that there is $12.95 worth of automobile to every inhabitant. The ratio of automobiles registered to the population forms another interesting method of comparison and one which demonstrates even more forcibly than the percentage tables the remarkable progress already made by the automobile industry in this country.

On page 930 the several states are tabulated with the population per car registered. In this table it will be seen that California takes the lead with one automobile to every twenty-eight people, a figure which brings home to the mind very directly the extent of adoption that the self-propelled vehicle has achieved. This figure is closely followed by Maine and the District of Columbia with thirty and thirty-one respectively of the population to each car registered. New York stands midway among the states in this table, having one car to every eighty-nine people, this being largely due to the dense slum population of the cities. West Virginia shows 236 people to each car, while Kentucky ends the table with 602, a great contrast to the states at the head.

The map on this page simply illustrates the total registration in the forty-nine states and territories, including the District of Columbia, the information being duplicate to the first column of the table on page 929.

The 990,738 automobiles registered in the United States have a total value of $1,188,885,600, figuring the average price of each car as $1,200. The registration fees paid on all these cars total $5,229,459.65, or $1 on every $227.50 of car value, if the fees are looked upon in the light of taxation. Or, to express this fact in a different way an average taxation of $5.28 upon each automobile is levied by its state. The average automobile taxation per capita of the population is 5.7 cents this year.

In the distribution of the automobiles registered, the Empire State leads all others, having passed the 100,000 mark several weeks ago. There are now in that state 102,870 cars, compared with 83,969 at the end of 1911, an increase of 18,901 machines. Despite this tremendous increase, this state ranks but second in order of the magnitude of the additions, California being first with 24,526 new cars and a total of 83,728 automobiles. Great significance attaches to this fact, as it evidences the rapid economic progress of the population of the Golden State, a corroboration of which statement is found further below when the manufacture of automobiles in the various states is taken up. Then comes Ohio, being third in the number of cars registered with 63,550 machines, followed by Pennsylvania with 58,705, Indiana with 52,048, New Jersey with 50,112, Massachusetts with 48,651, Illinois with 47,904, Iowa with 44,692 and Michigan with 39,235. It is an interesting fact that the greatest automobile-producing state ranks but tenth in the number of cars owned by others than their manufacturers, although among the cars registered there are a great many used by the makers themselves.

The chart appearing on page 927 which illustrates the increase in the various states presents a vivid picture of how far California surpasses all others in this respect. New York, indeed, is second, but far behind the leader, and Ohio is third, Iowa, the ninth state in registration, is fourth in the order of gains, with 16,683 new cars registered during the past 9 months. Indiana, Maine and Pennsylvania all show increases of about 15,000 cars, while in Michigan only 11,439 automobiles have been added since the first of the year. Texas records a clean gain of 10,000 cars, being ninth and followed by Illinois, with 9,800 newly registered cars. Then follow the other states in order. New Jersey's increase of 2,762 cars is small, but may be explained by the new reciprocity law. Nevada is at the tail end of the line with only 280 new registrations, being incidentally the only state where there are less than 1,000 cars.

Perhaps the most amazing fact brought out in this investigation of automobile progress is the stupendous increase in registration of cars in West Virginia and Maine. The percentages of increase in these two states since January, 1912, are 148 and 147 respectively. These figures are almost incredible, especially that of West Virginia, which in July last registered only a 6.8 per cent. addition to the January figure. It follows, therefore, that this state has, in the short space of 3 months more than doubled its registration, a feat absolutely surpassing anything of this character in the history of the industry.

Increase Uniform in Most States

Referring to the table on page 930, it will be seen that the third place is occupied by New Mexico with an increase of 72.5 per cent. less than one-half of the preceding figures, a fact which further emphasizes the remarkable character of the increase in the two states at the head of the list. Then follows Texas with 64.2 and so on down the list with gradually decreasing figures to Colorado, which shows an addition of 20 per cent. since January to the present time. The final figure, 5.7 per cent., representing New Jersey needs special consideration, as, owing to the laws respecting registration in this state which were in force up to the end of last year, this percentage has not a parallel significance with the rest of the table. To obtain a correct impression of the increase in New Jersey it would be necessary to take the number of cars registered during 1912 and calculate the ratio with the number of native New Jersey cars previously registered. But this latter figure is unobtainable and it is therefore necessary to estimate on the total registration up to the end of 1911, a large proportion of which figure consists of the registrations of cars belonging to New York and the neighboring states. On July last the number of native New Jersey automobiles registered since the beginning of the year, although considerable, was not sufficient to render the percentage here dealt with a positive figure, showing actually a decrease of 11.7 per cent. from the 1911 registration. That this figure has been wiped out and supplanted by a positive increase of 5.7 per cent. will

convey some idea of the sharp upward trend of the registration of native cars in New Jersey.

A short review of the development of the automobile industry as measured by its output, since its infancy, might prove of interest. The following table shows how the manufacture of motor cars has grown from year to year, and how the production increased, at times at a moderate rate and then again with tremendous vigor:

Year	Cars built	Increase over past year	Per cent Increase
1903	9,000		
1904	12,000	3,000	33.33
1905	22,500	10,000	83.96
1906	30,000	7,500	33.33
1907	39,000	9,000	30.00
1908	50,000	11,000	28.67
1909	108,000	58,000	116.30
1910	173,000	65,000	60.25
1911	200,000	27,000	15.62
1912	340,000	140,000	41.20

The production figure for the year 1912 is estimated on the basis offered by the production figures now on hand, which would indicate that during the entire year 1912 about 320,000 new cars will be registered in the United States. A moderate estimate of the total exports for this current year would add 20,000 to the above number. This indicates that 1912 is one of the best years of the industry. Not only is the production increase of 140,000 cars absolutely unprecedented but the rate of increase is far ahead of that of every other industry.

As regards the manufacture of automobiles and motors, the census showed that there are 575 distinct manufacturing companies in the United States, quite a few of which operate more than one plant. As is shown in the table appearing herewith, fully 100 makers, or 17.4 per cent. of the total, are located in Michigan, which is still holding its own as the leading automobile-producing state. Second in magnitude ranks New York, having seventy-eight makers, while Ohio, with sixty-eight manufacturers, is third and Indiana with fifty-nine, is fourth. Pennsylvania has forty-one manufacturers, Illinois thirty-seven, Wisconsin, thirty-two and New Jersey, nineteen. The rate of increase is also greatest in Michigan and New York, there being twenty-four new makers in Michigan and thirty-three in New York, during the past year, or a gain of 31.6 per cent. in the Wolverine State and 73.25 per cent. in the Empire State.

On the other hand, the industry has fallen off in several states, prime among which is Iowa, where a 50 per cent. reduction has taken place, decreasing the number of makers from six to three. Connecticut has fallen off from nine to seven makers and the District of Columbia, Kansas, Kentucky, Tennessee and Virginia have each lost one factory. But the total difference between last November and this is still positive, there being an increase of 163 over the total number of manufacturers, which then was 420. This increase is equal to 38.8 per cent.

Of special interest is the increase in freight automobiles during the past years. The manufacture of commercial vehicles now and 1 year ago is best illustrated by the following figures:

Year	Makers of pleasure cars	Makers of commercial cars
1911	237	198
1912	286	312
Increase	49	114

Of course, this tabulation includes manufacturers who make both pleasure and commercial cars, but the effect on the number of each of these lines of products is the same.

Similar progress has been made in the number of garages and dealers, not only in the United States, but also in Canada, Mexico, the West Indies and Hawaii as shown on page 930. Such establishments have increased 26.2 per cent. in number since the beginning of the year and are doing a flourishing business, and despite the complaints which at times come from these quarters, hard facts as represented by figures show that these branches of the trade are undergoing an expansion fully as remarkable as that of the automobile industry proper. This statement is supported by the table on page 930 and the chart on the opposite page which illustrates its figures. As to the total numbers of such establishments in the various states, New York is far ahead of the next state, Illinois, the former having 2,057 against 1,230 of the latter. Pennsylvania follows with 1,097 and California with 945 is fourth, Ohio and Massachusetts with 932 each ranging closely after it. Iowa, New Jersey and Indiana follow, with 860, 764 and 611 places respectively. New York's total increase of 361 establishments again heads the list of gains, followed by New Jersey's 271 and California's 258.

I. C. C. Warns Railroads

Commission Serves Notice That Reform Must Be Instituted To Relieve the Car Shortage Situation

Wheeler Buys Out Schebler—Crude Rubber Down Again —Other News Notes of the Automobile Industry

GOOD news for the industry was contained in the optimistic statements issued by numerous representative railway officials as to the alleviation of the shortage of freight cars and the prospect for an adequate supply by the time the automobile shipping season begins. The net shortage up to November 2 was more than 40,000, but to the gratification of the automobile industry it is announced that the exceedingly heavy movement of grain during October has brought forward the peak of the railroad load so that it will probably be passed before the end of November. The total net shortage is 12,881 more than reported at the last fortnightly period. Presidents of the Atchison, Wabash, Illinois Central, Northwestern and Great Northern report full traffic but little congestion. The New York Central and Erie have more than they can handle, but both roads are hopeful about cleaning up in a few days.

The fine weather for shipping during the past 6 weeks is generally given as the reason for the degree of facility with which the situation has been handled. If the weather continues good through November and fairly good in December, the traffic problem will be normal during the automobile shipping season, according to railroad officials.

What amounts to unofficial notice has been served upon the railways of the United States by the Interstate Commerce Commission that the railways must adjust the present arrangements concerning the prompt return of freight cars that have been diverted from their own companies. Franklin K. Lane, of the commission, calls attention to the fact that it is little less than stealing for one railroad to withhold and use the cars of another railroad, particularly during periods of stress like that noted in the present grain movement.

The commission has issued a circular to the railroads to increase the speed of freight trains and calling attention to the fact that 25 miles a day is too small an average movement for freight cars. Another recommendation is for a higher per diem demurrage charge so that poorly equipped companies will have less motive for withholding the cars of better equipped roads.

James S. Marvin, traffic manager of the N. A. A. M., has a statement from one railroad which has 175 automobile cars, showing that on November 1 the company had only sixteen of the cars in service on its own lines. The remainder, 159 cars, were being used by other roads, needless to say that their service is not in the shipment of automobiles.

The attitude of the Interstate Commerce Commission is simply that it insists that the railroads remedy an inexcusable situation themselves or else the commission will take jurisdiction.

It is estimated that the total net shortage of cars at the peak of the load will be not more than 50,000.

Wheeler Buys Out Schebler

INDIANAPOLIS, IND., Nov. 4—Frank H. Wheeler has bought out the interest of his partner, George M. Schebler, in the firm of Wheeler & Schebler, manufacturers of the Schebler carbureter. The business will be continued by Mr. Wheeler without a change in firm name, Mr. Wheeler to be sole owner. The consideration has not been made public.

The growth of the company, which has been conducted as a partnership, has been almost phenomenal. Mr. Schebler, who was a mechanic in moderate circumstances, brought out the Schebler carbureter and found himself without sufficient capital to develop and manufacture his invention. Mr. Wheeler became associated with him, and the two started in an extremely modest way in small quarters on the second floor of a building in North Alabama street.

In a remarkably short time the business outgrew its quarters and it was found necessary to erect the enormous plant that is now operated on the south side of the city. This plant is said to be one of the largest of its kind in the world.

Mr. Schebler has been obliged to retire from the firm on account of ill health. He may devote most of the next few months to traveling, in the hope of improving his health. His physicians have advised him for some time that he must retire from business.

Crude Rubber Continues to Sag

Crude rubber was easier again in the world's markets during the past week. The price level sagged to a basis of $1.01 1-2 for up-river fine and was steady in the plantation grades, pale crêpe standing at $1.02 1-2. While actual sales amounted to practically normal volume of business there was little selling pressure and less active bidding. Receipts continue to increase from both plantations and indigenous fields.

Receivers Framing Maxwell Schedule

The manufacturing schedule of the Maxwell-Brisoce Motor Company for 1913 is being framed in accordance with the action of the United States District Court, which authorized the issuance of $1,500,000 of receivers' certificates to finance the undertaking.

Automobile Securities Quotations

SPECULATION and investment in automobile securities marked time throughout the past week, while the tire companies monopolized the center of attention. Goodyear sold ex-dividend and so did Goodrich. Ajax-Grieb, which is now closely held, was marked up sharply on small trading. Firestone bulged up and then came back and Miller and Swinehart each went up and stayed up. International seems to have turned the corner and is on the up-grade again. The automobile list was steady as a general thing. The following tabulation shows the current level compared with that a year ago.

	1911		1912

*Old. †New. ‡Ex-div.

Progress was reported by the officers who have the work in hand but no inkling of its scope has been made public. The whole enterprise is a temporary expedient for the purpose of advancing the work so that it will be possible to turn out Maxwell cars for 1913 at the beginning of the marketing season.

The sale of the property to a reorganizing corporation and the continuance of its activities so that a sale can be made on a better basis than scrap are said to be the immediate objects to be attained.

The deal with the Flanders Motor Company remains in a state of uncertainty. It has been announced at United States Motor headquarters that appraisements have been made on each side and that agrement as to terms is a matter of negotiation. It was positively stated that no official development would be announced prior to November 11, when the form of the decree of sale will be discussed before Judge Hough.

In the meantime the outstanding stocks of the parent corporation and the claims of the creditors are being deposited with the Central Trust Company and it is said that the total of claims now deposited amounts to nearly 75 per cent.

A. B. of T. Holds Monthly Meeting

The regular monthly meeting of the Automobile Board of Trade was held Wednesday morning according to schedule. On account of the election a small attendance was present and the program contained nothing but matters of routine. The Board of Trade meeting had been tentatively scheduled to be held in Detroit next week when the National Association of Automobile Manufacturers assembles for a quarterly session, but it was decided that the merger matter and other important business had not progressed sufficiently at this time to warrant such a proceeding.

Market Changes for the Week

FEW materials changed their prices during the past week despite the fact that a satisfactory degree of activity prevailed throughout the market. Tire scrap rose \$.00 1-4, due to trading conditions. Lead dropped \$.25 per 100 pounds and copper electric rose \$.00 1-8. Rubber experienced a slight lowering in price, owing to lack of trade, closing at \$1.02 at a loss of \$.01. Tin, beams and channels, gasoline, Bessemer and open hearth steel remained constant throughout the week. Cottonseed oil rose to \$5.79 and then dropped to \$5.76, experiencing a loss of \$.04. Rapeseed oil rose \$.01. Sulphuric acid and cyanide of potash remained unchanged.

Dynamo Patents In Test

General Electric Company Sues Rushmore for Alleged Infringement of Winding and Regulating Rights

Defense Will Set Up Rushmore's Own Patent as a Bar to the Action and Technical Battle Impends

TRENTON, N. J., Nov. 4—Suit has been entered in the United States District Court for the District of New Jersey by the General Electric Company against the Rushmore Dynamo Works charging infringements of the Barry and Steinmetz patents, numbers 884,555 and 713,523, which are alleged to cover certain principles of winding and regulating electric dynamos involved in the electric lighting and starting systems used in the automobile art.

The Rushmore company has proceeded on the principle that patent 1,016,037, granted to Samuel W. Rushmore, Jan. 30, 1912, for an electric lighting system for automobiles does not infringe the rights of the complainant's patents.

The suit has been started but the matter is not likely to come to an issue before the middle of January and may not be heard before vacation in 1913, although this is by no means certain.

The Barry patent was granted April 14, 1908, and is for a system of regulating dynamo electric machines. The chief element of the idea is its provision for limiting maximum voltage of the generator, irrespective of its speed or load. The device was primarily intended to cover generators driven from the axles of railway cars, but the principle is said to cover automobiles as well. In accomplishing the object the inventor resorts to two windings with a system of balances to control the voltage.

The Steinmetz patent was granted for a compound wound generator, November 11, 1902. It covers a method of compensating for the variation in voltage due to variation in permeability of the magnetic circuit. This is accomplished by automatic compensation; diverting current from a field coil; using parallel circuits; two magnetomotive forces and by passing current through a field coil.

On behalf of the defense it is stated by Mr. Rushmore that the Rushmore patent, granted specifically for an electric lighting system on vehicles, does not infringe either of the other patents cited in suit. The dynamo is driven from the propelling axle or engine at widely differing rates of speed. In order to prevent the burning out of the lamps when the voltage is high, due to the high rate of speed of the propelling mechanism, or the destruction of the storage battery from overloading, some system of compensation is required. Rushmore's invention consists essentially of a ballast coil made of iron or other metal having a high positive resistance temperature coefficient when heated and so arranging the various parts that sudden rises in voltage and consequent rushes of current are opposed by the ballast coil, proportionately to the rises in voltage, and the fluctuations are absorbed by the battery.

According to the statement of Mr. Rushmore his patent was granted after a close scrutiny and familiarity with the prior art and the claims of his patent were drawn by Dr. Albert F. Ganz, of Stevens, and George Cooper Dean, electrical and patent law expert.

In commenting on the Barry and Steinmetz patents, Mr. Rushmore says that in the Barry device it is attempted to control the voltage of the dynamo irrespective of current output, with individual ballasts to protect each lamp. The Steinmetz patent seeks merely to compensate for variation in magnetic permeability of his dynamo when driven at constant speeds in order to maintain constant voltage at widely varying loads, according to Mr. Rushmore.

M.A.D.A. Preparing To Pay Its Creditors

Asks Extension Until March so That Profits of Show May be Applied To Racing Debts

Daimler Company Aggressive in Enforcing Patent Rights of Licensees But Inactive as Trade at Large

MILWAUKEE, WIS., Nov. 4—A plan whereby every creditor of the Automobile Dealers' Association, promoter of the 1912 international road races at Milwaukee on October 2, 3 and 5, will be paid dollar for dollar, is now being brought to consummation by the association's committee in charge of financing the $43,000 deficit incurred by the conduct of the speed carnival. The basis of the plan is to extend the time of payments until March 1, 1913, and the arrangement is contingent upon the acceptance of it by at least 90 per cent. of the creditors. In the meantime the association will be able to earn sufficient funds to cover the entire deficit, it is stated. The annual motor show will be held under auspices and management of the M. A. D. A. some time in January and is always the source of a neat profit, which will be applied to the general funds to cover the indebtedness.

Creditors have received extension agreement forms to fill out and mail to the offices of the association without delay and the plan will become operative if 90 per cent. of the claimants come forward. The agreement reads as follows:

"Representations having been made to the undersigned as creditor of the Milwaukee Automobile Dealers' Association that said Association, as the result of the automobile races recently held by them in Milwaukee, have liabilities far in excess of their ability to pay; and,

Whereas, if a pro rata settlement to all creditors of said Association were made at the present time the same would result in an exceedingly small dividend to creditors; and,

Whereas, representation has been made to the undersigned creditor that said Milwaukee Automobile Dealers' Association have plans in mind, which, if carried out during the next few months, are likely to result in profit to said Association, which, together with other funds which they may be able to raise, will enable said Association to make a substantial, if not a full, payment of their obligations at a subsequent date:

Now, therefore, the undersigned, in consideration of the mutual promises hereby made, do hereby extend the time of payment of the amount due from said Milwaukee Automobile Dealers' Association to the undersigned respectively to the amounts set opposite their several names until March 1, 1913, and hereby agree to take no action or legal steps or proceedings of any kind whatsoever against said Milwaukee Automobile Dealers' Association, or any of its debtors, upon said account until after March 1, 1913.

This extension shall be valid and binding upon the undersigned only upon condition that ninety (90) per cent. in amount of the present indebtedness of the Association is so extended.

Mercedes Patents Not In Issue

The campaign recently instituted by the Daimler Manufacturing Company to protect its licensees under the Daimler patent rights has been confined so far to owners of Mercedes cars which have been purchased without recourse to the American licensees. So far no aggressive action has been taken to assert the patents themselves against the rest of the trade. But that such action is not impossible is suggested by the notices that have been sent out to automobile owners on behalf of the Daimler Manufacturing Company.

The patents are very broad and apparently cover a number of elements in common use in the industry. Thus far none of them has been finally adjudicated in the United States Courts, although the foreign courts have passed upon some of them.

According to the company, the present action is to affect only those owners of Mercedes cars who made their purchases from foreign agencies and imported the cars direct. These number only a few, compared with the large number in use in the United States.

The bankruptcy proceedings against the Daimler Import Company are still in the courts and a final adjudication may not take place until December.

Olympia to Set New Show Record

LONDON, Nov. 4 (*Special Cable*)—The Olympia Show will be the greatest motor trade exhibition the world has ever seen, according to the opinion generally expressed in automobile circles of Great Britain. Every available foot of space has been utilized in the vast hall and the value of the exhibits amounts to $1,250,000. Many of the notable importing firms and corporations have been squeezed out by reason of the extraordinary demand for space from British manufacturers. There are 353 exhibitors duly installed. This constitutes an entirely new record.

In the car section there are 119 exhibitors; in the carriage section, thirty-five; in the component and accessory section, 150; tire and wheel, thirty-nine; press, eight, and associations, two.

Great Britain has 45 per cent. of the exhibits; France, 23 per cent.; Germany, 10; Italy, 7; Belgium, 6; the United States, 6; Switzerland, 3 and Holland 3 per cent.

The show will be opened formally on Friday night and all indications point to the establishment of a new set of show records.

Hoosier S. A. E. Elects Officers

INDIANAPOLIS, IND., Nov. 4—At the first of the winter meetings of the Indiana branch of the Society of Automobile Engineers, held in Indianapolis on the evening of October 31. officers for the ensuing year were elected as follows: George A. Weidley, of the Premier Motor Manufacturing Co., chairman; Herman G. Deupree, of the Remy Electric Co., secretary, and Chester S. Ricker, of the Henderson Motor Car Co., treasurer.

The topic of the meeting was self-starters, the speakers being W. G. Wall, of the National Motor Vehicle Co.; W. E. Raiguel, of the Ignition Starter Co.; Chester S. Ricker, of the Henderson Motor Car Co.; Joseph Lamb, of the Ignition Starter Co.; E. V. Hartford, of the Hartford Suspension Co.; Charles Crawford, of the Cole Motor Car Co., and Howard Marmon, of the Nordyke and Marmon Co.

Dodge Company To Handle Buffalo

BOSTON, MASS., Nov. 2—The Dodge Motor Vehicle Company has taken on the Buffalo electric as an exclusive line in the territory included in Norfolk, Suffolk, Essex, Plymouth, Middlesex and Worcester counties, the deal having been closed by H. W. Russell on behalf of the Buffalo company. The Dodge concern has handled gasoline cars at Cambridge and in Boston. The order provides for an allotment of 100 cars.

New Starter Company Incorporated

INDIANAPOLIS, IND., Nov. 4—With an authorized capitalization of $150,000, the Ham-Meix Manufacturing Company has been organized and incorporated in Indianapolis to manufacture self-starters for gasoline motors. Those interested in the company are: Harry W. Hamilton, Benjamin F. Meixell, Harold Taylor and Samuel B. Sutphin.

18,000 See Brighton Beach Election Derby

Mason Racers of Milwaukee Fame Defeat a Dozen Veteran Performers—Racing Extends Until After Sunset

French Sealed Car, 3,000-Mile Run Planned for March—Christy Establishes Arizona Track Record

BEFORE a crowd estimated at nearly 18,000 a program of races was given at Brighton Beach on election day, the feature of which was the Election-Day Derby at 100 miles. This brought out a ponderous field of thirteen starters and stretched out so far that darkness fell during the last third of the distance, causing the finish to be drawn in the dark.

The Mason pair finished the full course and were awarded the two chief purses; Wishart's and Pullen's Mercers came next with ninety-eight and ninety-five laps respectively; Menker's Kline covered ninety-two laps and the Le Cain Stutz made ninety. Costello's G. J. G. was still running at the end but it was several laps behind the Stutz.

The race developed a number of mishaps and while nothing should detract from the honors won by the Masons, the Stutz, driven by Dave Lewis, was eliminated at a fortunate point for the winners. The same may be said for the National and two of the Mercer cars besides the ones that were placed.

The start was delayed about 30 minutes too long and the field was too large for the course, but fortunately no fatal accidents marked its running. At the end of the first 10 miles the National led with the Stutz pair close up. At 20 miles the Le Cain Stutz showed in front with Thebaud's G. J. G. second and the Ferguson Mercer third. At 30 miles the Lewis Stutz was out in front and running swiftly and steadily. His teammate was second and the G. J. G. third. The Le Cain Stutz blew a tire on the first turn and lost two laps, the G. J. G. and Mercer (Ferguson) moving up a peg. Whalen went over the embankment in mile 31, breaking the wheel of his National and putting it out of commission. Whalen and his mechanic were shaken up but not seriously hurt. The next striking happening was when the Lewis Stutz turned over at the head of the stretch, bending its front axle and eventually putting it out.

The last 30 miles were run in the growing darkness and the finish found the steady-going Masons at the head of the procession.

Besides the 100-mile race, a 10-mile event for cars with less than 300 cubic inches displacement was run, and was won by Lewis in his Stutz, against a field of eight contenders. A 10-mile free-for-all handicap was taken by Mitchell in a Mason, who defeated a field of nine contestants, while the 5-mile handicap for cars of less than 300 cubic inches piston displacement went to Ormsby in a Kline.

Throughout the race both the cars were prominent, but not in the first flight. They suffered little tire trouble and the Mitchell Mason was in front until near the end, when Mulford came along and wrested it from his teammate. The record was not disturbed owing to the caution necessary in the latter stages.

The policing was inadequate to handle such a large crowd. It is estimated that 1,200 automobiles were parked at the track.

Sealed Cars to Compete in France

PARIS, Oct. 12—With bonnets nailed down and all essential parts sealed, medium-powered French cars having a chassis price of not more than $1,600 will take part in a 15-day 3,000 miles endurance test round France next March.

It is believed that the maintenance of all the seals intact for 15 consecutive days will not serve to prove the greater worth of the cars, while it will prevent the drivers giving those daily attentions necessary for any piece of mechanism, and which owners are quite willing to give at the beginning of a day's run. On this account the front and rear axles and the steering gear will be permanently sealed. The bonnet, the radiator filler cap, the underpan and the footboards giving access to the clutch and gearbox can have their seals broken for 10 minutes only every mornig. At the expiration of this time the seals will be replaced and cannot be broken without the loss of points.

The arrangement will allow drivers to screw down grease cups, verify their motors, fill the tanks and make slight adjustments, but the time will not be long enough to make any repairs. The breakage of the radiator filler cap will entail a loss of 2 points; if the underpan of the footboard seals are removed, 3 points will be deducted for each; the lifting of the bonnet will cause a loss of 4 points. If the permanent seals are lost the car will be eliminated, and failure to maintain an average of 18 1-2 miles an hour on any of the stages will also entail disqualification.

With a $1,600 limit the whole of the popular medium-powered cars will be admitted. The limit has been fixed on the chassis instead of the complete car because of the wide difference in body value on this type of European chassis. They vary, indeed, from two-seaters worth about $150 to handsome inside-steering limousines listing at $600 to $1,000. In all cases the competing cars must be completely equipped touring models having not less than two seats with hood, windscreen, horn, running boards, lamps, headlights, etc. Numerous entries have already been received for the tour.

Christy Set New Arizona Record

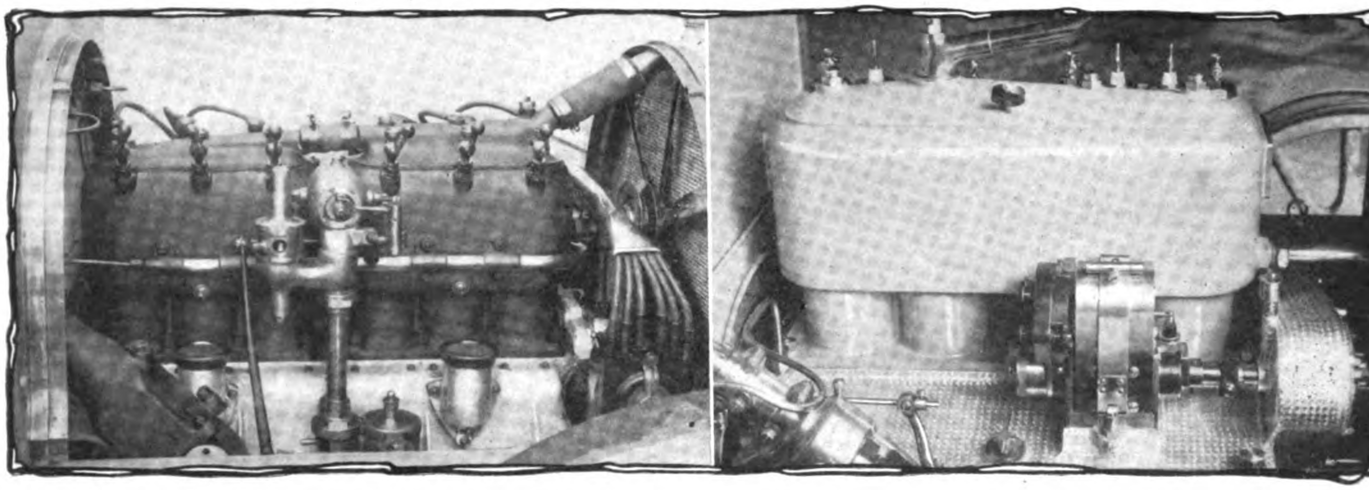
PHOENIX, ARIZ., Nov. 4—*Special Telegram*—Driving a Christy, rated at 120 horsepower, Barney Oldfield established a new mark for the mile on an Arizona circular mile track. The Christy finished the trial in 50 1-2 seconds, which is 1 3-10 seconds faster than Tetzlaff's time with the big Fiat last Thursday.

PHOENIX, ARIZ., Oct. 31—*Special Telegram*—Breaking the Arizona circular dirt track record for the mile, a Fiat 120-horsepower car driven by Tetzlaff set the new mark at 51 4-5 seconds. In the 50-mile feature event for cars over 300 cubic inches piston displacement, a Fiat driven by Tetzlaff won in 51:51 without difficulty of any kind. Another Fiat, Hill driver, was second in this event. Tire trouble delayed the Benz entry, driven by Meloane and the Cadillac handled by Soules. A broken steering knuckle caused the Cino, driven by Heinzmann, to plunge through the fence, smashing a wheel and shaking up the driver.

The Hill Fiat won the 15-mile handicap free-for-all in 15:57 while the National was first in the 15-mile event for cars that participated in the Los Angeles-Phoenix race having more than 230 cubic inches piston displacement. The time was 15:58 1-5. The Soules Cadillac won the 10-mile handicap in 10:44.

Boston Dealers Finish Race Meet

SALEM, N. H., Nov. 4—The uncompleted program of motor races which were originally scheduled for October 12 at Rockingham Park race track was run off here Tuesday, when the Boston automobile dealers who had cars entered conducted the events under their own auspices, no admission being charged. There were five events on the program. The first was the 1-mile time trials, in which Harry Grant won first and second places and Harry Cobe in a Jackson third. Their times were respectively: :57 3-5, 1:01 1-5 and 1:02 2-5. Harry Cobe in a Jackson won the 10-mile race with another Jackson driven by Charles Basle taking second. The 25-mile vent was captured by Jack Le Cain driving a Stutz, with Cobe in a Jackson second. The 20-mile match race between Grant in a Stutz and Le Cain in another Stutz was won by the former. The final event was a time trial for amateurs with George Downs in a National, the only entrant, his time being 1:05. The races were well atetnded.



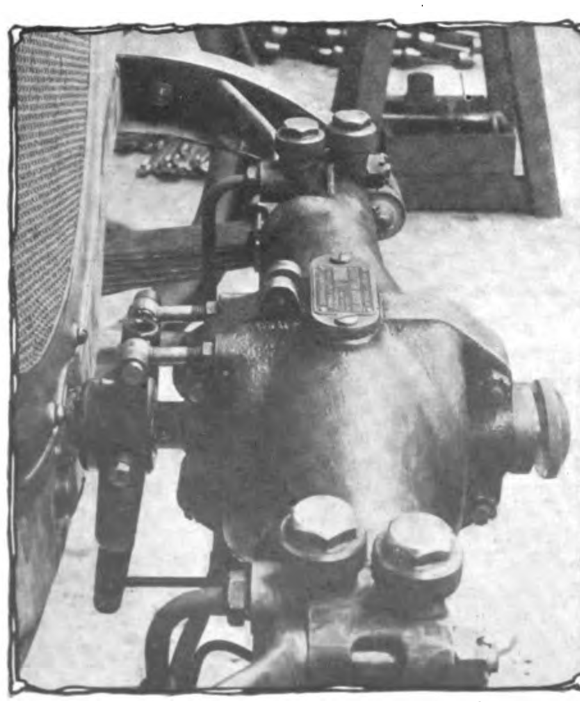
Delaunay-Belleville motor for 1913 on the left and the Unic 1913 on the right with chain-driven timing gear

European Manufacturers Still Like Small Motor

Single-Cylinder Motors Abandoned and Small-Bore Fours Substituted in De Dion, Delage, Sizaire-Naudin and Peugeot Factories; Demand for Twin-Cylinder Motors Also Dropping Rapidly; Many Have Increased Stroke

EUROPEAN shows have not yet thrown open their doors, and as it is the practice of the English, French and German manufacturer to keep his new types back to the last possible moment, full data on next year's models are not yet available. Sufficient information has been secured, however, in the various French factories to indicate the general trend for the coming year. Following the example of the last two seasons, 1913 will be a year of detail but none the less real improvements, without any landslide toward non-poppet valve motors or the adoption of any of the wonderful hydraulic transmissions rumored in various quarters.

The 1913 season will see the abolition of the one lunger, and, to a very large degree, of the twin-cylinder model. Economic considerations have kept them well to the front, but after gradually falling off in public favor they have at last been dropped as unprofitable and replaced by small four-cylinder types. This statement should be supplemented by the explanation that the single and the twin may obtain a new lease of life in the very light, cheap class of car officially known in England as the cycle-car, and having more relation to the motorcycle than to the full-grown touring car. The Panhard company, which has never been accused of acting rashly, has abandoned its only twin-cylinder type and replaced it by a four-cylinder of 2.7 by 5.5 inches bore and stroke. It is the smallest four-cylinder ever produced at this factory. De Dion Bouton, a world-famed maker of singles, will build these for stationary purposes only, and although retaining the twin, will add an 8-horsepower four, from which it can be inferred that the twin will be stifled out after another year. Gregoire has abandoned the twin for a new four; Delage has ceased making singles; Lorraine-Dietrich has practically abandoned the twin model. Renault is peculiar, for he has a big demand for twins to be used for taxicab purposes. Even he, however, has been obliged to produce a four-cylinder for the London market, and is supplying nothing but fours and a smaller number of sixes for touring purposes. Sizaire-Naudin, after making nothing but singles, now produces nothing but fours; Peugeot and Lion-Peugeot, another single-cylinder enthusiast, has dropped the one lunger, retained the twin, and put on the market a four-cylinder of only 2.1 inches bore.



Compressed air starter on the Delaunay-Belleville

French manufacturers stand firm for the small and medium motor. There is no tendency whatever towards bigger motors, although every effort is made to get increased power out of existing dimensions. Four-cylinder motors of more than 4 inches bore are in a very small minority. There are a few firms, notably Delaunay-Belleville, producing six-cylinder cars of 3.8 by 5.5 inches bore and stroke, but even these are largely outnumbered by the fours and sixes from the same factory of only 3.3 by 5.1 inches bore and stroke. To the French idea a motor of 3.5 inches bore, four cylinders, is big enough for any load; to the majority it is too big, and 3.1 is sufficient for any reasonable person.

There has been a general increase in piston stroke without any extremes. Such firms as Hispano-Suiza, Gregoire, Sizaire-Naudin, Ballot, having ratios varying from 2.2 to 1 to 2 to 1, have not changed their position, but a large number have moved up from 1.3 to 1.5 or 1.6, and there is a notable convert in Panhard with its new small four-cylinder having a stroke-bore ratio of 2 to 1.

Silent chain drive for cam and magneto shafts, etc., has increased in popularity. There is not an example of any manufacturer who has tried chains going back to meshing pinions, but there are a number having formerly made use of pinions who now carry chains. In a few cases, where the chain has been refused, manufacturers have adopted a spring drive for the crankshaft pinion.

Probably 75 per cent. of French manufacturers now use forced-feed lubrication through a hollow crankshaft. The remaining 25 per cent. is largely made up of big manufacturers who, having developed various types of pump circulating systems refuse to drop them for the increasingly popular forced-feed type. Among the younger progressive firms, the firms specializing in small high-efficiency motors, forced feed is invariably adopted. Attention is being paid to detail refinements of the forced-feed system. Attempts are being made to automatically maintain a constant level in the sump or crankcase reservoir; to cool the oil by ribs on the base chamber, or otherwise, to adopt a greater number of filters and make them easily dismountable; to give facilities for regulating the oil pressure at will; all oil leads are being made internal, and in a large number of cases are steel tubes cast in the crankchamber.

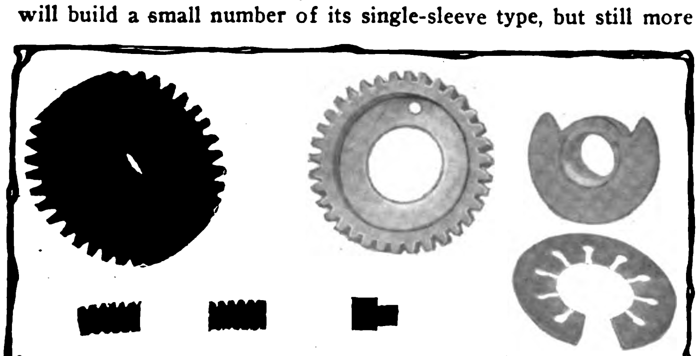
There will be no change in the situation regarding clutches. Where three speeds have existed manufacturers are now providing a fourth. It is a claim on the part of the public which has to be met, and is often met reluctantly. The worm gear has made slight progress. Those manufacturers who have taken it up have probably done so more to meet the requirements of the English market than that of their own country, for it must be admitted that the French motorist is generally satisfied with bevel gearing. The De Dion Bouton has adopted worm drive for three chassis—two eight-cylinder type and one four-cylinder. Gregoire is using it on all their chassis fitted with the Knight motor and also on a new small four-cylinder car; Bayard-Clement has a worm drive for a Knight-engined car; Darracq built a small number of cars with worm drive, but is not pushing the idea. The majority will adhere to the bevel.

There have not been the practical developments that were expected in the non-poppet valve field. Panhard will use Knight motors for at least three-quarters of its 1913 output; Gregoire will produce about 250 cars with the Coventry-built Knight motor; Mors will build rather more; Bayard-Clement will produce probably 200 or 300 chassis with Knight motors. After having bought the patents for the Reno-Bois valveless motor Unic has decided to do nothing, at any rate for the 1913 season. C. L. C., at present building a single-cylinder rotary-sleeve motor, will have a four-cylinder on the same principle at the Paris show. Buchet will bring out the Dubois-Rousseau reciprocating ring type; Vinot-Deguingand has abandoned the same. Delahaye has a valveless motor in preparation, but it is very doubtful if it will be ready for the Paris salon. Rolland-Pilain will build a small number of its single-sleeve type, but still more poppet-valve types. Schneider, after a lot of experimenting with a valveless motor, appears inclined to confine his efforts to one semi-racing model, all the others having poppet valves. C. I. D. will make rotary-ring types exclusively, but the total output of the factory is not very high. Darracq will have two small rotary-valve motors and one big poppet-valve type. There may be others in the experimental stage, and it may be found, when the show opens, that I have overlooked some notable exception.

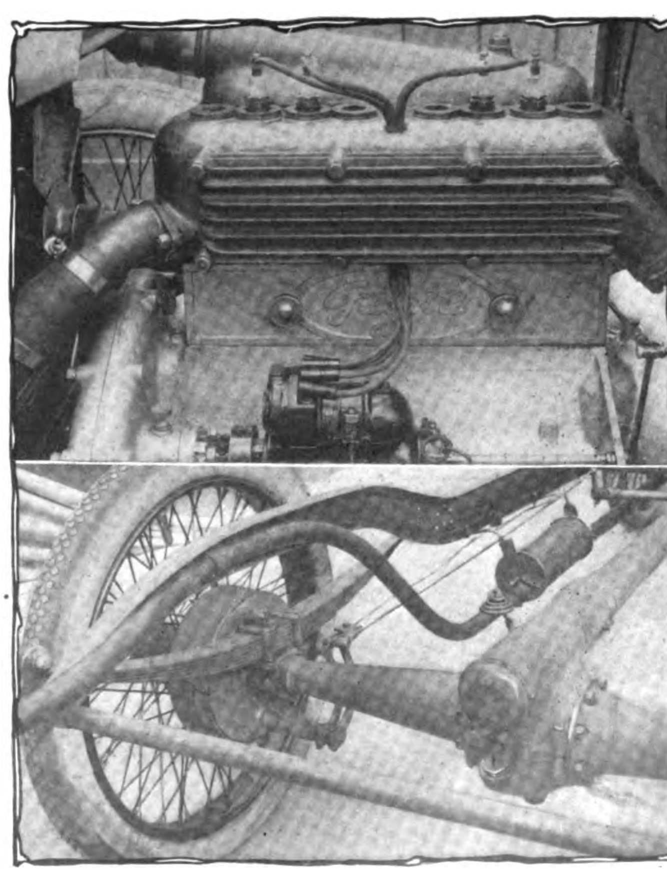
In the transmission there is a tendency towards the abolition of torque and radius rods, all the propulsive effort being transmitted through the rear springs. In the matter of springing the tendency is towards three-quarter elliptics, but this is doubtless more a concession to fashion than because of any inherent superiority in this type. Whatever the type, springs are being made broader and longer with a view to easy riding qualities.

In France no great enthusiasm has been shown for either the self-starter or electric lighting. Delaunay-Belleville appears to be the only firm making use of a self-starter, and this is not a standard feature, but is fitted as an extra. It is of the compressed-air type mounted across the frame just at the base of the radiator and connected up to the front end of the crankshaft by means of a coupling operated from the dash. The electric lighting situation is different, for a very large number of owners have a dynamo and lighting equipment installed when the body is fitted, but no manufacturer appears to have thought it necessary to include such a fitment as an integral part of the chassis.

Wire wheels are growing in favor, a number of firms making them a standard equipment and others, while prevented from doing so by reason of the extra cost, making the fixed hubs to be interchangeable with those of the type of wire wheel in which they are interested. Thus, if wire wheels are preferred, the owner has only to pay the extra cost of the wire type compared with the artillery pattern, and is put to no additional expense for the changing of the hubs. In addition to Rudge-Whitworth and Riley, who were the first to get on the French market, there are several makes of wire wheel manufactured in France and a few makers who supply detachable artillery wheels.



Details of spring drive pinion on end of crankshaft in Chapins and Dormer motor



Four-cylinder Gregoire motor and the double brakes mounted on rear wheels

Question of Wear and Durability of Long Stroke Motors Argued by the Hypothetic Method—New Near-Quartz Glass Figures in Lamp Improvement—Popular Views on Waste of Fuel—Heavy or Light Omnibuses—Late Type of Fire Engines

ON WEAR of Long Stroke Motors—In order to compare the mechanical efficiency of long and short stroke motors, with which question that of wear and durability is intimately connected, Mr. Faroux, the well-known authority in France, analyzses the conditions arising in two motors supposed to be of equal power, equal bore, equal cylinder volume and equal mean effective piston pressures. This supposition eliminates divergencies whose effect it would be difficult to estimate convincingly. Now, if one of these motors has a short stroke, say 90 millimeters, and the other a long one, say 180 millimeters, the supposed data have to be mutually reconciled by a difference in the number of revolutions. As the mean pressures are the same in both motors, the power is determined by the equation

$$W = KpSv$$

in which K is the coefficient of mechanical efficiency, p the mean pressure, S the piston area and v the linear piston speed per second, the latter equalling double the stroke l multiplied by the number of revolutions per minute, n, divided by 60; or

$$v = ln \div 30.$$

If the mechanical efficiency of the two motors were equal, their piston speeds would have to be equal, and for purposes of comparison it is therefore fair to assume provisionally that the short stroke motor, in accordance with the formula, must make twice as many revolutions per minute as the long stroke motor; and then to consider what happens.

In the first place, whatever the length of the stroke, the crankpin never makes more than one revolution in the bushing of the connecting-rod knuckle for each turn of the crankshaft. And, as piston pressures are equal, the two crankpins will be of practically the same diameter and the distance traveled by a point on their circumference will be the same for each turn. The work spent in friction in the connecting-rod bearings will thus be twice as great in the square motor as in the long one.

As the piston changes direction twice as often in the square motor as in the long one, the destructive effects of inertia will be greater in the former. To be sure, the latter will have a longer and therefore a heavier connecting-rod, but this cannot offset the disastrous effect of doubled rotary speed. Under the combined action of doubled friction in the crankpin bearings and twice as many arrests and accelerations of the reciprocating parts, the square motor will begin to knock earlier than the long one. And once play in the bearings has been started, the effects of interrupted inertia will aggravate themselves progressively.

The valve action gives rise to another loss of power. The valves of the square motor in order to function, for example, 2,400 times per minute must be equipped with much stronger springs than required for the long motor, where the valves serve only 1,200 times per minute. The gas tension remaining in the cylinder at the end of the power stroke is practically the same in both cases. Hence a greater power is needed for raising the valves of the short cylinder, and this power must be applied twice as often.

As between two motors of equal power and equal bore, the mechanical efficiency will thus be inferior in the short motor; it will wear more rapidly and will be less silent. A second example may be offered. Two motors of the same cylinder volume, the same average piston pressure and turning at the same angular speed may be compared. The first one may have a bore and stroke of 98 by 98, for example, and the second one 78 bore by 156 stroke, which will give both a cylinder volume of 3 liters. The piston area of the first one will be 75.43 square centimeters and that of the second 47.784, which figures are in the proportion, approximately, of 1.6 to 1.

Now, if the crankpins in the two motors were of the same diameter, the short motor would spend in friction in the crankpin bearings 1.6 times more work than the long one. But as the short motor has the larger piston area, the bearings of its crankshaft must be of larger diameter to resist the impulsion of the explosions. Assuming a pressure from the explosion of 30 kilograms per square centimeter, one crankshaft must sustain 2,250 kilograms and the other 1,410. The larger diameter of the pin will make the circumferential speed proportionately greater in the short motor, and consequently the friction in its bushings will be greater, as well as the wear resulting from it. The short motor will, then, also in this case reach the knocking stage earlier than the long one. [However, the wear is also distributed over a larger surface.—Ed.]

The forces of inertia are also to the disadvantage of the short motor. Its connecting-rod has to transmit a force which is 1.6 times higher and it must have a larger section. This is offset in part by the greater length of the connecting-rod of the long motor, but the end which follows the reciprocating motion of the piston must be heavier in the short motor and the piston itself likewise, since it is larger and transmits the same power by a slower movement. Finally, in order to guide the larger piston as perfectly as the smaller one is guided its length should be in proportion to its diameter.

The reciprocating masses are thus seen to be larger in the short motor and consequently the forces of inertia are more destructive. [However, their linear speed is much smaller, which is after all the element which counts for most.—Ed.]

In the matter of the piston and cylinder friction the short motor suffers by comparison, too. If the connecting-rods work with the same angularity, the amount of friction is essentially equal in the two cylinders, but it is distributed over a longer cylinder wall in the long stroke cylinder, and there is therefore smaller tendency to ovalization. [However, the area of the cylinder wall in the long stroke cylinder being smaller, under the supposition of equal cylinder volumes, and the degree of concavity greater, this point does not seem conclusively settled. —Ed.]

Reverting to the comparison of motors with equal bore, piston speed and mean effective pressure, the amount of friction for each stroke is also here the same, but the number of strokes in the short motor is twice as high as in the long one and the wear and ovalization of the cylinder therefore more rapid.

At both extremes of design the short motor is thus found to be inferior to the long stroke motor of the same power in mechanical efficiency and resistance to wear.—From *La Vie Automobile,* October 19.

—

MANY Ways of Wasting Gasoline—It stands to reason that waste of fuel may be due to faults in the gas mixture, faults in the use of the gas mixture, faults in the motor, faults in the use of the motor, faults in the vehicle and faults in the use of the vehicle; and this list of possible causes may be further subdivided. If the gas mixture is too rich the waste is self-evident; if it is too poor and does not give power enough for the work on hand the practical consequence is that the throttle is opened or that the gear is lowered, so that either larger charges are used or more of them, in both cases with the result that more gasoline is used than would be the case if the mixture were at its best for the work on hand. At this point the fault may lie in the carbureter or in choosing the wrong gear for the desired vehicle speed; it may also lie in wrong gear proportions making it impossible to choose a degree of throttling and a gear which work together for fuel economy at a desired vehicle speed. In the use of the gas mixture the question of ignition is uppermost, it being always understood that when the best possibility for power development is missed then gasoline is wasted. Weak ignition, resulting in a slow explosion, and late ignition both result in hot exhaust in which the heat units of the fuel are dissipated. Lack of efficiency due to indifferent motor design is by far the most important cause of fuel waste. The best motors of this day show by tests that not more than one-half the amount of fuel is used in them for a given power, as compared with the amount used in motors of antiquated design or the motors which were the best found in any automobile constructed 6 or 7 or even 4 years ago.

Under faults in the use of the motor, as distinguished from faults in choosing the gear with which the motor is to work, the most important is the employment of a motor which is too large for the kind of work asked of it. However, nearly all automobile motors are too powerful for their average work, so as to be powerful enough for emergencies and fancy performances, and the highest possible fuel efficiency can therefore not be expected of them. Similarly the four-cylinder motor and, in still higher degree, the six-cylinder motor use more gasoline for a driven amount of work than a good single-cylinder motor, the thermic and the mechanical losses being all greater than in the simpler machine with a suitable flywheel, yet no one wants to return to the older type. Fuel efficiency is not an absolute requirement when conflicting with style and convenience.

The fuel waste which is of greatest interest to the motor car owner is that which is due to causes which it comes within his province and competence to remove or obviate.

Many of these relate to his own manner of using his vehicle, and some of these may be enumerated. In ordinary pleasure cars the valves are not large and the average carbureter is made or adjusted to feed its mixture in a manner conforming with this fact. These relatively small valves act as brakes on the motor power, by strangling the flow of gases, long before the highest motor speed is reached. Now, if the driver wants to speed up and opens his throttle accordingly, he frequently opens it more than necessary for getting the speed he wants and thereby sets the motor to work partly against itself. This source of waste occurs practically only with motors of old design and small power or motors equipped with a governor not properly co-ordinated with the throttle.

In using the brake for stopping the vehicle on every occasion when the throttle might better be resorted to for slowing up gradually a considerable waste of fuel is incurred in the aggregate, some of the wasted fuel slopping over from the fuel jet.

Poor compression in the motor is a prolific source of waste by reducing the power obtained at a given position of the throttle. Many motors are tight when cold but leak compression when hot, a condition most frequently due to poor lubricating oil. It may be recognized most readily by observing the breather tube. If visible grayish gas is discharged from it a piston leak may be inferred, even though none is noticed in cranking the motor. Valve leaks and all other leaks in the economy of the motor are in the same class of causes.

Clutches which slip a little all the time, without it being noticed as a rule, and neglected lubrication throughout the mechanical working parts of the vehicle are often forgotten as possible causes of fuel waste when a car owner notices that his gasoline bills are running higher than they used to or higher than those of his neighbor who perhaps has a similar car and a similar carbureter.—From *Automobil-Welt,* October 11 and 18.

—

Reflector System for Lamps—A new German construction is shown in Fig. 1. It is one of the industrial upshots of that practical manufacture of near-quartz glass which is already assuming considerable proportions, in so far as a similar design with ordinary glass in the small auxiliary reflector scarcely would be practicable owing to the proximity of the flame. The heat in conjunction with unavoidable irregular cooling from air currents would color and crack it, while the near-quartz, as it might appropriately be called, shares with pure quartz its indifference to heat and heat-changes in a large measure. Its expansion and contraction are almost nil, and it has been claimed that its mechanical strength has been made equal to that of glass lately. The same material is used for the one-piece face crystal of the lamp. The two reflectors are backed with silver. With a diameter of 25 centimeters (10 inches), not counting the rim portion covered under the metal flange, the large reflector which is always behind the flame has a focus of only 9 centimeters, and will thus send out a compact bundle of light rays when the flame is placed within this distance, while the percentage of light received directly from the flame is increased in proportion to its nearness. The small reflector intercepts only the least valuable of the reflected rays, viz., those striking the main reflector at nearly right angles, and, on the other hand, adds much to the total volume of light emitted by throwing an inverted image of the other side of the flame back into the main reflector, which thus practically receives light from two flames. If it is now desired to remove the strong glare, out of consideration for traffic coming in the opposite direction, or if it is wanted to send light out at a wide angle so as to illuminate a sharp curve, the small reflector is turned right about by means of a Bowden wire connection to the driver's seat and takes the position as shown at the right side in Fig. 1 and in dotted lines in the central drawing of the same, in which it cuts off all rays from the flame to the large reflector. The light now comes from the small reflector only and the rays from it are highly divergent, as indicated by the drawing, while throwing a strong light over a wide scope of the ground immediately in front of

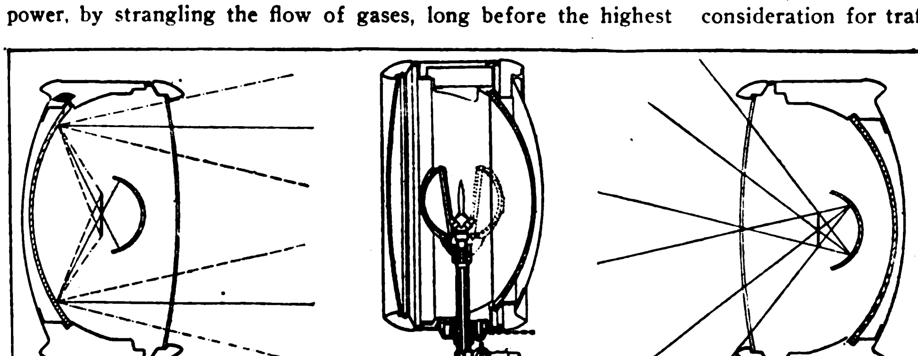


Fig. 1.—German searchlight acetylene lamp with reversible auxiliary reflector to kill glare and light turns of road

the vehicle. The central crossing of rays kills the glare straight ahead. Different effects may be obtained by having the axes of the two lamps which are ordinarily carried on a vehicle either slightly divergent or parallel or slightly converging, the latter arrangement giving a very strong illumination of the middle of the road by overlapping of rays. This reflector system is intended for use with an acetylene light source and gives the best results with dissolved acetylene and a two-jet burner. When an acetylene gas generator is used, the gas pressure is liable to vary considerably—with the small care ordinarily given to generators by the average driver—and this variation affects the quality and volume of the reflected light detrimentally. For use with a generator a single-jet burner is found most suitable. The gas consumption for a lamp of 10-inch diameter is about 25 liters per hour.—From *Zeitschrift d. M. M. Vereins*, Sept. 30.

—

HEAVY or Light Motor Buses—As very few motor buses for public traffic have been built in the United States while they have been in general use in France and England since 1907, it appears likely that the type of construction which has been developed in one of these countries will be taken as a model whenever a project for the establishment of motor bus lines shall have reached the point of actually impending realization in America, and it becomes interesting to note that the heavy type of omnibus used in Paris, for example, is not looked upon with undivided approval, but that on the contrary several important shortcomings are charged against it, although nothing better to take its place has so far been developed in practice.

Mr. Contet presents in *La Technique Automobile* the characteristics of this type which is used in two varieties, one the Schneider-Brillié and the other designed and made at the Dion-Bouton works. The motors are placed under the driver's seat to reduce the wheel base. They have four cylinders in three different dimensions: 125 by 140, with a maximum speed of 900 revolutions, 115 by 140 turning at 1,050 revolutions and 120 by 130 (the Dion vehicle), the latter also of what is now termed slow motor speed like the others. The compression was originally 4.75 kilograms per square centimeter, but this was reduced to 3.6 kilograms. The cooling is by thermo system and Solex centrifugal air-pump radiator which gives complete satisfaction. The drive is by shaft to the differential and from the differential shafts by small pinions to spurwheels secured upon the driving wheels. The driving thrust was at first transmitted by rigid rods of pressed steel, but these vibrated enormously and now the thrust goes through the main leaves of the rear springs alone, with perfectly satisfactory results. The fuel first used in 1906 and 1907 was carburetted alcohol, which proved too expensive. Subsequently benzol was adopted and the consumption of this fuel has been gradually reduced to 50 liters per 100 kilometers. The vehicle seats from 28 to 34 passengers.

The defects of this type have largely to do with its weight. The chassis for the 34-passenger vehicle weighs 4,400 kilograms, the body 1,600 kilograms, making a total for the empty vehicle of 6 tons and with passengers considerably more than 8 tons. The double-deckers were still heavier. As a result of this weight the macadamized streets where the buses pass with some frequency are rapidly deteriorated, and the inhabitants of apartment houses on the stone-paved streets complain of the trembling and shaking of the houses caused by this traffic. In several instances damages have been legally collected from the omnibus company on this account.

To ease the steering of the vehicles it has been necessary to use a very low steering gear ratio, rendering necessary a large movement of the steering wheel and resulting in veritable gymnastics by the drivers, to which new drivers have to become accustomed before a vehicle can be entrusted to them. As the streets where the buses mostly travel are naturally—in other cities than Paris—the narrow ones where street car tracks are objectionable, the presence of vehicles measuring 7.5 meters in length and 2 to 2.3 meters in width is fraught with many inconveniences.

With a view to remedying these defects it may be considered, says Mr. Contet, if the development which has taken place in motor construction since the time when the heavy type of bus was first placed in commission does not now justify a radical departure from the principles which were then laid down and which have dominated this branch of automobile construction ever since.

The progress made involves, for example, that motors of high speed and high compression and generally of a power and fuel efficiency far superior to that of the motors still used in the buses can now be made quite as durable as the older type. Especially with benzol as the fuel, the high compression of modern motors would lead to much smaller consumption than 50 liters for 100 kilometers, the combustion would be more perfect and considerable money now spent for removing carbon deposits in the bus motors—a feature which has been blamed upon the benzol—would be avoided.

By using a high-speed motor it will be possible to reduce considerably the weight of all the mechanical organs which share in this high speed. Altogether a lighter type of vehicle seems to suggest itself as practicable the moment it is assumed, in accordance with facts which have by this time been abundantly verified, that a motor of the modern light design will resist the wear and tear of the traffic. A vehicle with 20 to 25 seats should probably be the largest size. It should not weigh more than 5,000 kilograms fully loaded. Such a vehicle, in order to scale an incline of 8 degrees at 8 kilometers per hour would require power equal to 14 horsepowers and, figuring with a loss of 50 per cent. in the transmission, it would be safe to specify a motor of 30 horsepowers, which may now be built with cylinders of 85 millimeters (3.4 inches) bore and 40 millimeters (5.6 inches) stroke with a compression of 6 kilograms and a maximum speed reduced by a governor to 1,500 revolutions. Such a motor would not have to work hard except on the inclines, and could be operated with three gear speeds.—From *Technique Automobile*, October 15.

—

FIRE Engine Features—Among the numerous fire engines with centrifugal pumps which are turned out at German automobile factories one made at the Benz-Gaggenau works recently attracted attention at a local exhibition in Dusseldorf and at competitive trials arranged for a convention of fire departments in Rhenish Prussia and Westphalia. The four-cylinder motor gives 52 horsepowers at 800 revolutions per minute, 63 at 1,000 revolutions and 75 at 1,200 and drives a centrifugal pump with four disks made by Ehrhardt & Sehmer. Geared to 1,700 revolutions per minute this pump discharges 2,000 liters (528 gallons) at a manometer pressure of 100 meters, which is taken to indicate that the pump will deliver this quantity at a height of 100 meters if the water is led to this altitude within the hose. At the trials the height of the throw from nozzles of 25 millimeters (1 inch) diameter was 40 to 45 meters with a manometer pressure of 11 atmospheres (110 meters), and with nozzles of 30 millimeters diameter a height of 50 meters was reached by a pressure of 13 atmospheres.—From *Allgemeine Automobil-Zeitung*, September 27.

Recording Cost of Trucks

Why Exact Records Are Required To Utilize Few Trucks on an Efficient Basis

One or Two Simple Forms Help in the Establishment of Standards of Maintenance Cost

WHILE systematic recording of the work done by motor trucks has shown that these vehicles if utilized to their full capacity are always more economical than if the same work were done by horses, the statement is frequently heard from the users of single commercial vehicles that these do not pay. By this latter profound expression the owner means to say that the expense of his motor deliveries is too high in proportion to the work accomplished. It has been shown over and over again. however, that if such cases exist the fault is not with the automobile but with the people handling it. Cost of upkeep is a most elastic figure, and seems to be influenced by these factors:

(a) Direct expense for fuel, oil, tires and repair parts;

(b) Wages of driver, helper and mechanic, where the labor of a skilled man has to be called upon to keep the car tuned up;

(c) Work accomplished, that is weight carried for a number of miles in a number of hours, as compensation for the expenditures incurred.

If the user of a single freight automobile who claims that it does not do more efficient and economical service than horse teams consuming the same amount of money will keep a detailed record of the cost and work of his vehicle, he will in every case be able to locate a cause for the high-priced maintenance of the vehicle, a cause which may be eliminated. It may be that the truck is not running one-third of the time while out on deliveries, which of course greatly reduces its value, or increases its operating cost; or perhaps the driver does not treat the truck as it should be treated, so that waste of fuel, frequent replacement of tires and necessity of repairs of the mechanism result. By keeping a record of the work done by the truck every day and the fuel consumed thereby, two principal factors of upkeep are determined, and by further records repairs, tires and lubricants used may be kept track of. As soon as a sufficient number of records are at hand, the owner should approach the dealer who furnished him with the car, show him his records and invite suggestions as to reduction of upkeep expense. In the majority of cases the dealer, when confronted with the records of 2 or 3 months' operation, will be able to propose a solution of the user's problem within a few minutes or will come to his assistance in some other way, so that finally the standard of expenditure is reduced. This is part of the service the dealer owes to his customers.

A form which is proposed to be used by the user of one or two trucks is shown in Fig. 1. In practice the form, which is to be printed on thin cardboard, may be made as deep as necessary to permit of recording all the deliveries made by a truck in a day. The form is started when the truck leaves the garage or store in the morning, the time of starting being entered together with the number of the trip, in this case, one. Under details the names of the companies or individuals called on by the truck are recorded, and in this way the record may simultaneously be used as a general receipt, if the owner desires to use a blank somewhat wider and accommodating a column for the receiver's signature. When the truck returns to the store, the time of its arrival is marked on the form, and the second trip with its starting time are also recorded, and so on, until the working day is over. The important records of the gasoline consumed by the truck during the day, of the mileage traveled and the running time, giving the hours and minutes the truck was actually moving on the road, are entered on the upper portion of the form and serve as the most valuable part of the records. Under remarks, extraordinary delays, mishaps, etc., find their place. By printing the reverse side of the form with the four columns, like the face side, the space of the blank may be considerably increased, and a greater amount of actual work may be recorded on a blank without enlarging its size.

A similar blank which is not shown here and which serves for summing up all the records made in a month will help the owner to gain a concrete idea of how his truck costs were composed in that space of time. This sheet has spaces for recording the total amounts of gasoline, cylinder oil, transmission and differential grease, tires, and spare parts used, with a possibility of giving a detailed record of the latter item. Furthermore the total number of miles run during the month and the total number of running hours are noted on this sheet, as well as the following facts which are readily calculated from the records: average speed, consumption of fuel and lubricant per mile, total cost of upkeep per mile, and, if possible, fuel and tire cost per ton-mile.

In some cases the dealer may not be able to inform the user of what standards of expenditure may be expected in the maintenance of a truck, and in this case the best thing to do is to address the factory, or nearest selling branch of the manufacturer. It happens very frequently that the owner considers his case absolutely singular and original, and therefore may be inclined to believe that he cannot expect good advice from outsiders. But it is a fact that the cases of trucks which do not pay may be classed under a few types, according to the variables which enter into the cost of truck upkeep, and which are enumerated above. Upon addressing competent experts in truck operation ninety-nine out of 100 owners find that their case is typical and easily to solve.

Foreign Constructions Designs and Practices

Working Conditions Should Be Brought Into Consideration in Testing Steels for Constructional Purposes

High Temperature, Heavy Load and Shock to Be Sustained Often Overlooked by Engineers in Selecting Material

STEEL for automatic construction is not, as a rule, tested under the identical conditions of the use to which it is to be put in subsequent practice.

Testing plants are needed where the test conditions will closely approximate practical running conditions of the car. But these tests have always been difficult to make. Some of the methods take too much time that it is often preferable and productive of more good to proceed by rule-of-thumb and after acquiring the necessary experience follow the beaten path.

If the general importance of testing materials under conditions akin to practical use is sufficiently appreciated, it will suffice here to review some of the processes which appear to be good in view of the facts and the general need. **If steel is to be subjected to temperature changes during service, that the steel should be tested under identical conditions of temperature change is advocated.**

The necessity for adequate testing of materials covers a wide range of activity, especially as engineering work is so close to the unknown that it must be regarded as uncertain. Take, for illustration, a fine specimen of a boiler plate; it is tested cold, at the temperature of the surrounding air, but it is subjected, not only to high temperatures, but a too wide temperature variation in practice. What, but uncertainty, attends the life of the boiler? It is not in temperature change alone that uncertainty rests. It is said that good steel for a bridge structure must have its sulphur and phosphorus constituents down to 0.04 per cent. If the steel is to be used as framework for a building, however, these constituents may be even above 0.06 per cent. In this allowable variation between bridges and buildings, so far as sulphur and phosphorus in steel are concerned due notice is taken of the effects of these constituents on steel, but when it comes to automobiles do we continue to differentiate? No! Why not? It requires absolutely no argument to show that steel is subjected to a far greater difference in shock as between automobile and bridge use than between bridge and building use.

In building work while the load is considered live it is not the same serious live load as the members of a bridge must labor under. In consequence, a lower factor of safety, as it is called, is used in the building structure than in the bridge. It is also the practice to use poorer steel in the building than in the bridge. In a word, while the general physical properties of the two steels may be quite the same, the sulphur and phosphorus contents will differ as stated.

Do engineers make due allowance for the effects of additional shock? No! On the contrary they reduce the factor of safety and demand no better steel than that which is used in bridge construction work so far as sulphur and phosphorus are concerned.

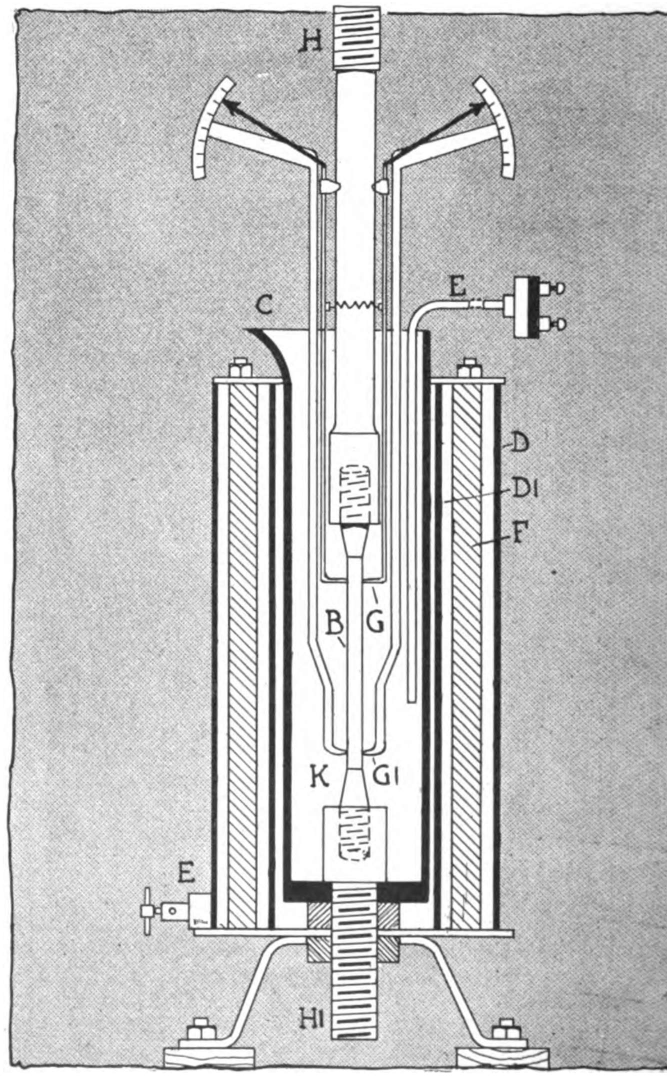

Fig. 1—Section of Steel Testing Machine in the Krupp laboratory at Essen, Germany, employed to test steels at high temperatures

The parts designated are: B, vertical specimen bar to be tested; H, top holder for specimen, and HI, bottom holder for same; G and GI, top and bottom gauges for test specimen; C, crucible for test, and K, salts used in crucible to generate necessary heat; D, is outer shell; DI, inner shell; F, spacer between shells; and E, necessary electrodes.

Fig. 1, a section of a testing machine used in the Krupp plant at Esseu-Ruhr, Germany, for testing steel at high temperatures, proves that steel makers of the first class fully appreciate the need of just such tests. In this example the specimen of **the steel to be tested is adjusted to the holders in the usual way, excepting that a special form of crucible filled with barium or other salts is provided, and an instrument of precision is fitted to the whole in order to observe**

the elastic limit of the steel when the temperature is raised to the desired point.

The temperature is raised due to the melting of the barium or other salts in the crucible, an electric current being used, with electrodes fitted in the crucible for the purpose. In order to keep the molten salts in the crucible, it not only stands vertically, but the bottom holder, which must pass through the bottom of the crucible, is provided with a suitable packing for the joint. **The crucible and its fittings, adjusted and related as indicated, go into a testing machine for the pull to be exerted, but this pull is only sufficient to determine the elastic limit of the steel at the desired temperature.** Boiler plates, for instance, are tested at a dull red heat. Other materials are tested at the temperatures at which they are required to do practical service.

Referring now to shock tests, remembering that it is of no great value to know the conventional physical properties of automobile steel if the shock resistance qualities are not known, it will suffice for the purpose here to show one method which is quick, accurate, and capable of being worked by the regular force of men in any ordinary plant.

The shock test sanctioned and advocated by the German Union for the testing of materials is the one referred to here. The test bar is of rectangular section, 30 by 30 millimeters, with a distance of 120 millimeters between supports. The test bar is notched to the center, Fig. 2.

The Charpy pendulum testing apparatus is used to make the shock test using the test bar of the size mentioned and advocated by the German Union. The head H, Fig. 2, on the free end of the pendulum strikes its blow against the test bar B, fair in the plane of the notch N, with sufficient force to rupture the test bar. It remains merely to note the force in kilogram-meters or foot-pounds required to rupture the test bar. This information is given direct by means of a registering device fitted to the Charby pendulum apparatus.

That there is a great and serious variation in the shock ability of different steels is quickly told by the use of this apparatus. That the conventional physical properties, as they are usually given, is a fair index of the quality of a given steel for a purpose is far from the truth. But this should not be wondered at. It is well understood that both good and bad steel may come from the same chemical composition. It is also understood that good and bad steel may come from the same heat, and it is even possible to get good and bad steel from different sections of the same bar.

The great point, under the circumstances, is to know as much about the steel to be used as possible. It is sound to say that nothing of great value is known unless the shock test is made as well as tests for conventional physical properties as tensile strength, elastic limit, elongation and contraction of area of the test bar. But if there is to be a display of ignorance about steel used in automobile construction, if the user is to accept the steel maker's grading of the fabric, the shock test as here referred to should not be disregarded. A bad piece of steel can never get by in the shock test—its presence will be proclaimed. A good piece of steel will always be known by its shock-resisting qualities.

Then, too, if steel must be heat-treated, the dangers are great when poor steel is used, and these dangers are too great to be ignored even when good steel is used. **But the shock test will find trouble if the heat-treatment given a grade of steel is inadequate for the need, and, since these shock tests may be quickly made, it is easy enough to conduct a few experiments for the purpose of determining the best heat treatment for a given grade of steel.**

In order to show just about the reasonable expectation from the use of steel for automobile purposes taking the Charby shock test as the index of quality, a few tests of Krupp steel are here given, Table A.

In the steels mentioned the shock-resisting qualities vary between 361 foot-pounds per square inch and 1,987 foot-pounds. This wide range of shock values by the Charby test shows in the face of the fact that, in these steels the sulphur and phosphorus constituents range as low as 0.013 and keep below 0.028 per cent. in the poorest of these products.

It will be seen under these circumstances, that shock-resisting qualities in steel, while these qualities depend upon low sulphur and phosphorus for initial results, are variable over a wide range on other counts.

Before stating the reasons for the variations noted, it is necessary to observe that, for dependable results, and, in order to be able to predict the approximations of variation, the sulphur and phosphorus constituents must be suppressed as they are in these steels.

Referring now to the steels reported, the product E. 120 O shows the highest shock-resisting qualities, namely 1,987 foot-pounds per square inch, against 1,245 foot-pounds for E. F. 60 O. This is in the face of the fact that the E. F. 60 O is the finest grade of chrome-nickel steel, whereas the product E. 120 O is a cementing, case-hardening, nickel steel.

It is in the chemical composition of these steels that search must be made for the reason of the difference. The carbon content is 0.10 to 0.15 in the E. 120 O, nickel steel, but the carbon constituent is 0.20 to 0.25 in the E. F. 60 O chrome nickel steel.

The hardening effect of carbon is well understood. It is fair to expect that shock-resisting qualities will decrease as the steel is hardened by addition of carbon. The nickel content happens to be the same in both of these grades of steel. It holds at from 4.40 to 4.50 per cent. The effect of nickel, as such, must be the same in both specimens. If it is not possible to account in any other way for just the difference in shock-resisting qualities observed, it must not be forgotten that the E. F. 60 O steel holds 1.60 per cent. of chromium, whereas the E. 120 O steel is barren of chromium.

Examining the steel F. 48 O., which is higher in carbon and in chromium that E. F. 60 O steel, and devoid of nickel

TABLE A—KRUPP STEEL SHOCK TESTS

Brand	Pounds Per Square Inch, E. L.	Pounds Per Square Inch, T. S.	Per Cent. Elongation In Inches	Per Cent. Reduction of Oven	Shock Test Foot, Pound per Square Inch
E. F. 60 O. highest grade of chrome nickel steel	103,835	119,482	22.7	67	1,245
E. F. 34 O. grade of chrome nickel steel	102,413	127,020	20.7	60	1,006
F. 48 O. finest grade of chrome steel for structural purposes	105,248	132,000	16.7	58	772
E. 120 O. finest grade of nickel steel for case hardening	61,163	84,206	31	70	1,987
A. 7 J. finest grade of carbon steel for structural purposes	51,226	81,788	27.3	65	555
A. 9 J. special grade of carbon steel for use in crankshafts	66,853	105,685	17.7	60	361
C. 46 O. special steel for side frames of automobiles	88,047	113,792	23.5	65	900

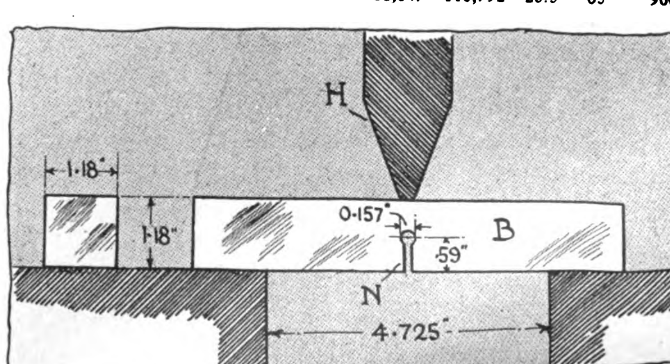

Fig. 2—Diagram showing size of test bar B and conditions surrounding tests of steels in Krupp laboratory for shock-resisting properties using the Charby pendulum apparatus

it will be seen that the shock resisting qualities fall to 772 foot-pounds per square inch. This reduction of shock ability is due first to the increase in carbon, second to the considerable chromium content, and third the absence of nickel, which element is present in the steel used in the comparison.

It might be said that nickel is superior to chromium, that carbon is detrimental and should be suppressed, and that increasing the number of the elements used adds materially to the uncertainties, but the statement if made would only be true from one angle of observation.

The fine grade of carbon steel A. 9. J., which is a steel for crankshafts, hence high in carbon but having no chromium or nickel, has shock-resisting qualities down to 361 foot-pounds per square inch, and in the face of the fact that this is a high value for carbon steel, only to be realized when the metalloids are low and the steel is well fabricated. It is evident that shock-resisting power reaches a low ebb in the absence of chromium or nickel if the carbon content is increased in order to get hardness for bearing purposes and strength to resist torsion, as in this example.

Were it possible to do without hardness for bearing purposes, lowering the carbon, all other things equal, would give the result of A. 7. J., increasing the shock-resisting power of the steel from 361 foot-pounds to 555 foot-pounds. But the addition of about 2.00 of chromium to the higher carbon steel brings the shock resistance up to 772 foot-pounds. Then lowering both carbon and chromium a little and adding 4.40 to 4.50 per cent. of nickel raises the shock-resistance to 1,245 foot-pounds, as the table shows, or, by lowering the carbon to the minimum and eliminating chromium the 4.40 to 4.50 per cent. of nickel in the steel affords almost the extreme of ductility, and, in this case at any rate, the shock-resisting qualities go up accordingly, reaching the high level of 1,987 foot-pounds. **The only way apparent at the moment to get higher shock-resisting qualities lies in the increase in the nickel constituent, but this idea cannot be extended beyond 6 per cent. of nickel, without changing the characteristics of the steel, so that its use for purposes here referred to becomes out of the question.**

There are practical reasons why it may not be desirable to take advantage of the very high shock-resisting qualities of E. 120 O, nickel steel, excepting for certain exacting undertakings resorting to the process of cementation to realize hardness of surface. In the same way, choice may fall upon A 9 J. carbon steel with its relatively low shock-resisting qualities, but it would be fatal to either of these undertakings were a steel substituted, one with an excess of sulphur or phosphorus, for then, instead of the definite values here given for shock-resisting qualities, great uncertainty would creep in, excepting that a much lower shock-resisting power would be assured.

Constructional Features Acquit Driver

The peculiar case of a German automobilist who was acquitted of violation of a local anti-smoke ordinance has been closed recently, and special interest attaches to the case, as the decision in favor of the defendant was brought about by constructional features of the vehicle involved. The driver of the vehicle, on June 13, 1912, passed through the village of Vohwinkel and his car developed intense smoke and an odious smell, and on June 26 he was sentenced to pay a fine of 5 marks ($1.25). The driver appealed against this decision and demanded that the case be taken into court, he having been sentenced by the police authorities. When questioned before the general sessions, the defendant admitted that on the day in question his car had for some time emitted large quantities of smoke and an evil odor; but at the same time he maintained that he could not avert these nuisances, due to the peculiar construction of the machine. On June 13, he said, he drove down a steep hill into Vohwinkel, and it was necessary for him to have the motor clutched to the transmission with the low gear in mesh, to produce the needed braking effect on the hill. As the motor must not give any power impulses, he could not give it any gas, but the automatic lubricating system continued to supply the cylinders with oil which was stored in the combustion chambers. As soon as the truck arrived on level ground, he gave the motor gas and the cylinders, beginning to work, burned the considerable quantities of oil which had accumulated during the travel down-hill, thereby giving rise to smoke and odor production. This statement of the defendant regarding the impossibility to avert the nuisances with which he was charged was corroborated by a technical expert under oath, whereupon the court found that it had been impossible for the driver to prevent his car from producing the smoke and smell. The defendant was then acquitted of the charge and the state was charged with the cost of the proceedings. This course of the events was, to a large extent, due to the skill of the lawyer representing the defendant, who proved very capable in obtaining the material evidence and the corroboration of the expert, upon which the defendant was acquitted.

Double-Disk Truck Wheel

How to make wheels for trucks so well that they will survive the evils of service without using rubber for tires is the problem which is being struggled with abroad. Fig. 3 shows, in part section, a plan that is being considered. The disks of steel look like a cone clutch, so far as shape is concerned, as it is used to transmit power from a motor to gearbox. These clutch faces press against the bevels of the wooden felloe. The steel tire is shrunk over the wood felloe and the steel discs are bolted to flanges of the hub and also held against each other near the felloe by a series of bolts. Resiliency is secured both by the inherent qualities of the metal and by the mounting of the felloe which is wedge-like in form. The wedge formation of the felloe will put a decided tension on the bolts which connect the two steel disks and therefore they are closely spaced as may be seen in the illustration.

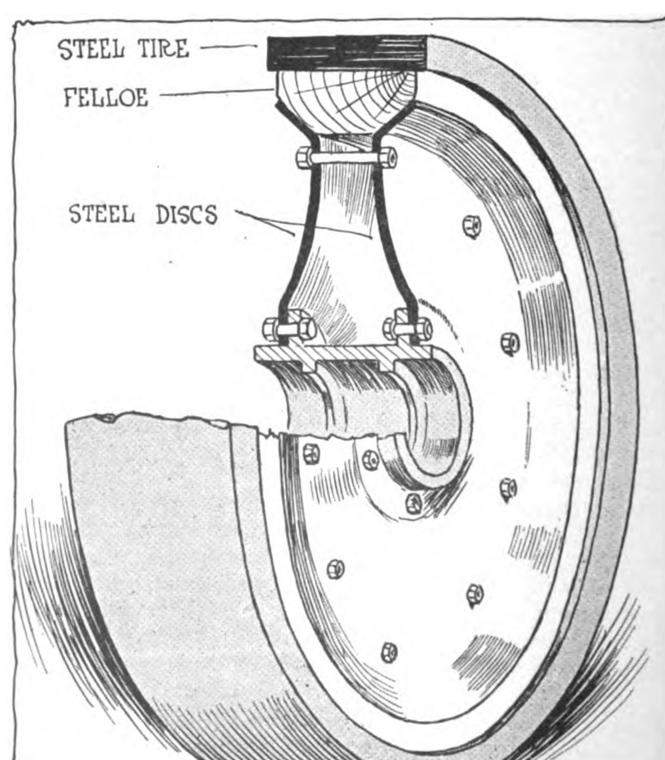

Fig. 3—Sectional view of double-disk truck wheel designed to obviate necessity for rubber truck tires

The Engineers' Forum

Autogenous Welding May Be Made a Boon to the Repairman as Well as to the Manufacturer

M. Keith Dunham Comments on Mr. Tucker's Article in The Automobile *for October 17, on European Welding Practice.*

BOSTON, MASS.—Editor The Automobile:—In the issue of The Automobile for October 17, the article on Welding, European Methods and Uses, by Mr. Tucker, is extremely interesting and Mr. Tucker shows familiarity with his subject. Especially to the manufacturer the article is of more interest than to the repairman. While the English language is supposedly the same, we in Yankee Land certainly do have a different method of expression than our cousin across the water, and a repairman, unless he has studied welding carefully, will find the article by Mr. Tucker shooting over his head.

Autogenous welding is one of the most simple things possible to understand; used in its most common form with oxygen and acetylene there is a heat of approximately 6,300 degrees Fahrenheit concentrated in a fine point. With this heat any of the commercial metals may be united merely by fusing together the edges (which are butted) and filling in the depression made by any butt weld with a stick or a rod of the same material. Ofttimes a repairman, on first seeing the process, confuses this feeding-in rod with solder, inasmuch as the rod flows freely under the flame. There is no comparison, of course, with solder, as the parts are thoroughly fused together and made homogeneous.

Mr. Tucker states in his heading Autogenous Welding System that in practice a proportion of four volumes of acetylene to five of oxygen gives better results than the theoretical two volumes of acetylene to five of oxygen. The best authorities in this country agree that the proportions of oxygen and acetylene are chemically fixed and to produce a neutral welding flame the consumption of gases will be approximately the same in any torch. On a pressure type blowpipe there is no question that the flame is more easily kept neutral than in an injector type. Any intelligent workman, after a 15-minute explanation, can readily adjust a well-made torch so that his proportions of oxygen and acetylene are correct, or, in other words, so that he has a neutral welding flame.

In this section of the country, and to a large extent the same holds true throughout the United States, the trend of the times is toward the use of safety-storage acetylene rather than generators, especially where there is only repair work to be done. In nine repair shops in the city of Boston devoted to repairs and manufacturing by the oxy-acetylene process, eight use safety-storage acetylene.

Every automobilist is familiar with safety-storage acetylene: to him it is commonly known as Prest-O-Lite or Searchlight gas and the ordinary tank for this purpose has 40 cubic feet; larger tanks are made, however, for welding purposes, but they are built upon the same principle and simply contain more gas than the automobile tanks.

Oxygen throughout the country is supplied by the manufacturers in loaned cylinders, so that a repairman wishing to take advantage of a high temperature flame to weld a chassis, for instance, needs the proper reducing valves, torch, horse and connections, and he can connect to an automobile lighting tank and his oxygen cylinder and with the flame weld the break together in position. Figuring the highest possible cost of gases in this section of the country they could not exceed $2 for a job of this character, so that Mr. Tucker's claim that the safety-storage system is expensive will not be admitted by repairmen in this country.

The use of the tank system in England may be impractical, but in the United States the rapid development of the acetylene companies, manufacturing gas and selling it by this system, is conclusive proof that it is thoroughly practical.

Automobile parts, as a rule, are costly enough so that the price of the gas in a repair job is not an item. If the gas costs 50 cents by the generator method to weld an automobile cylinder, the tank system does not prohibit the automobile repairman from using it merely because the gas in this way would cost 75 cents on salvaging an article worth at least $15 and he can well afford to spend $1 on the cost of raw materials and supplies.

The chief thing for the repairman to remember is that with the safety-storage system of acetylene and the use of high pressure oxygen in cylinders there is no care whatever with his apparatus and it is ready for use when he wants it merely by opening a valve and when he closes the valve the gas does not deteriorate and the outfit is ready any time for an emergency. With the generator system considerable care is required and a large investment necessary, which to the ordinary repairman is almost prohibitive.

The garage with a welding outfit as a part of its shop equipment will always find plenty of uses for it, have the reputation of getting its customers out of trouble quickly and thoroughly and will add materially to its income—M. Keith Dunham, general manager Waterhouse Welding Company.

The Use of Mathematics by Engineers

In an editorial article on this subject *Engineering*, of London, recalls some remarks once made by Rankine in accounting for the disrepute in which mathematics had fallen among practical engineers, to the effect that any theory of engineering, to be worthy of the name, must take cognizance of the whole of the facts and factors concerned, and not merely of those which it is possible to put into mathematical form. By sinning against this rule, the mathematics advanced in each case become subject to contempt exactly in the measure as too much is claimed for them. Every practical engineer knows indeed far more than it is possible for him to formulate in equations. Bit by bit, as experience accumulates, certain of these factors become amenable to mathematical methods, but in the initial stages of a novel development good guesswork is almost the only guide on which the practical engineer can rely. There is, however, unquestionably an immense mass of data pigeon-holed uselessly in the archives of manufacturers simply because the mathematical knowledge required for analyzing these records effectively is not possessed or applied by the technical staff. Much would be gained if such data were brought to public notice.

The Interchangeable Body

Used Mainly by Moderately Wealthy, as Very Rich Can Afford Separate Machines--Superfluous for Others

INTERCHANGEABLE bodies for automobiles so that the car can be kept in service the year around are a subject that interests the industry from a variety of angles. Save for the concerns dealing in very small cars handled in New York, every company asserts that a greater or less proportion of its customers use more than one body on a single chassis.

In the case of the Peerless, for instance, the proportion is said to run as high as 50 per cent. In the Cadillac experience it is 40 per cent. In other cases it runs about 15 per cent., according to statements gleaned from sales managers, but the majority is lower and the average of all the estimates would be not more than 10 per cent.

Definite figures are more difficult to obtain than even the sales managers think, for so many factors enter into the proposition that at best the figures given by the companies themselves are little better than guess work.

The business in extra bodies is not increasing, according to the generally expressed opinion along the row. The reason for that conclusion is double-headed, and is as follows: The man who can afford to purchase an expensive car, can also afford to own a supplementary automobile. Thus, the wealthy motorist may own a powerful, costly touring car for use 6 or 8 months in the year and an inclosed car for winter use. The man of moderate means who has an automobile may feel that he can not afford the extra car, but the same reason would lead him away from the idea of using an extra body. With the very wealthy no useful purpose is served and with the man of moderate means no solution to the problem is presented by the extra body.

Thus the use of the interchangeable body is limtied in its scope and extent to a few lines. The limousine is growing in demand for year round service by the class of buyers who use automobiles from the necessities of their station in life. With this class the limousine, having a large carrying capacity and equipped with a motor larger than that used in the average town car, is a favorite. The class referred to has plenty of money, but its members are not rated as very wealthy. The multi-millionaire class is equipped with a variety of automobiles for various seasons and uses. In neither of the above-mentioned classes is there any appreciable call for interchangeable bodies.

The moderately wealthy class is where the interchangeable body has its greatest use. The man who can spend $5,000 a year on the operation of his car is the one who presents the most fertile field for extra bodies. He must have a chauffeur, for the owner who drives hardly fancies running a town car or even a limousine and after deducting the chauffeur's pay, the appropriation of $5,000 would hardly warrant the ownership of two cars.

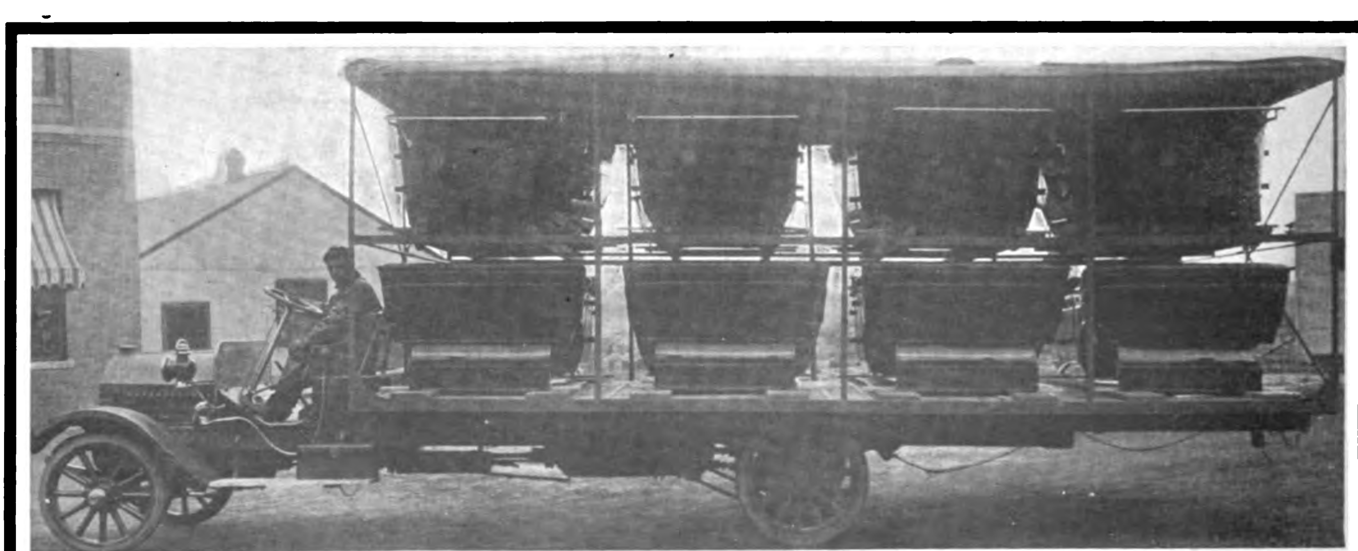
The man of comfortable means who owns a car uses it for pleasure in very large proportion and drives himself. There is only a small market for extra bodies in such cases and practically none at all where the expenses of running the car itself represent all the man can afford to pay for automobiling.

Nevertheless the business constitutes a factor in the automobile industry and there are probably 5,000 automobiles in New York and its immediately contiguous territory which use an extra body. In the great establishments of the body-builders in and about New York there are storage facilities for 2,000 bodies. The remainder are kept in public and private garages, barns and even attics. Fewer customers in proportion to the total number who own extra bodies had the change made from one type to the other in 1911 than they did in 1910. This indicates that they have added to their automobile equipment, rendering the change unnecessary or that they are using the enclosed type more freely in summer than heretofore. Approximate figures show that of the stored bodies about 70 per cent. are for touring cars. Whether this percentage is carried out is uncertain in the absence of a detailed canvass among the thousands of owners.

Novel Way of Transporting Bodies

The R-C-H Corporation, Detroit, Mich., uses a special type of truck for the transportation of bodies between the body factory and the assembling plant. The truck is here illustrated and has a wheelbase of 196 inches and an overall length of 21 feet, the body being 10 feet, 6 inches wide and 8 feet, 10 inches high. This gives space for the superimposed arrangement of two rows of four R-C-H touring car bodies each, or of 11 roadster bodies, each of which is crated in an individual compartment. The peculiar construction of the body which is specially adapted for its purpose, gives the truck a side appearance not unlike the front of an aeroplane. The vehicle makes four or five trips a day, each of which is 16 miles, and travels at a rate of 12 miles an hour.

It is easily seen that the use of this single freight automobile for body transportation greatly facilitates the handling of this part of car equipment.



Special truck used by the R-C-H Corporation, Detroit, Mich., for carrying bodies from the body factory to the assembling plant

Monster Gotham Garage

Remodeled Boarding Stable Has 60,000 Square Feet of Floor Space and Storing Capacity for 300 Automobiles

ONE of the largest garages in New York City, in which at times 300 cars are housed and where automobiles pass the door sometimes at the rate of one a minute, has been developed from a huge boarding stable. This is the Joscelyn garage, 120 West Fifty-second street, which is described below, in order to illustrate the possibilities of creating a modern garage out of a stable.

As the accompanying floor plan shows, the three-story building which is 200 by 100 feet, with the longer side facing the street, is divided into three portions, the last compartment to the right being still used as a boarding stable by the former owner of the building. The garage building proper consists of three sections divided by two fire-walls into a right and left storage place on each floor, while a central space accommodates the elevator, the entrance on the ground floor and the chauffeurs' rooms on the two floors above, while on the top floor this central space is also devoted to the garage work.

Caring for Chauffeurs' Comfort

The floor plan while illustrating the arrangement of elevator and wash rack, which of course is the same for all floors, illustrates the street floor especially, on which the entrance if formed between the two middle fire walls, and the superintendent's office located adjacent to it. The locations of patrons' telephone and checker's office are also shown and attention is called to the fact that the checker is situated in a wooden box some 15 feet above the floor. This arrangement has been illustrated on page 482, THE AUTOMOBILE, of September 5. Next to the telephone booth there is a small stairway which winds up to the chauffeurs' rooms on the two floors above. The floor above the street level contains the chauffeurs' barber shop and billiard room, while on the next floor facilities for reading and writing have been provided.

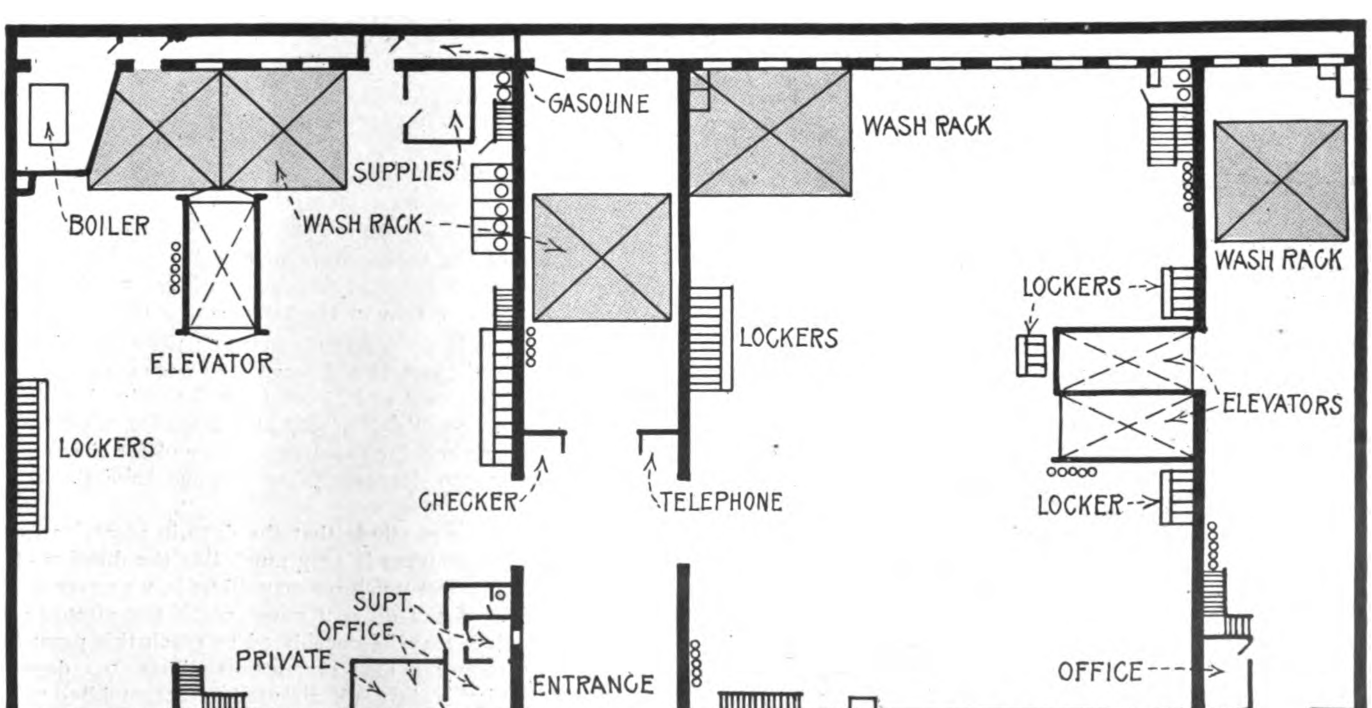
A rigid system of storing cars and accessories has been evolved at this garage. It is controlled by the chauffeurs themselves, and ordinarily, has nothing to do with the garage management. Each chauffeur is given two lockers, one for keeping his spare tires, etc., and one for his clothes. As to the car storage system, the entire garage has been divided into individual spaces of equal size which are capable of accommodating a car of any dimension. Each car always uses the same space. The cars are arranged along the walls, whereby a passageway in the middle portion of each floor compartment is left free. The lockers which are also arranged along the walls, are located as shown in the plan.

To prevent all interference in the system of operating the lockers, each locker is fitted with a single key, this being given to the chauffeur, while a master key is kept in the office of the superintendent. This permits of opening the locker for the chauffeur in case of his losing or misplacing his own key.

While the garage does not operate a repair or supply department, it furnishes its patrons with supplies by means of the following system. If a client is in need of a part or material, the garage undertakes to send an order to the dealer who handles the required goods, and after delivering it to the patron, charges it to him on his monthly bill. A supply room on the ground floor serves for the storage of accessories left by transient clients for a short time.

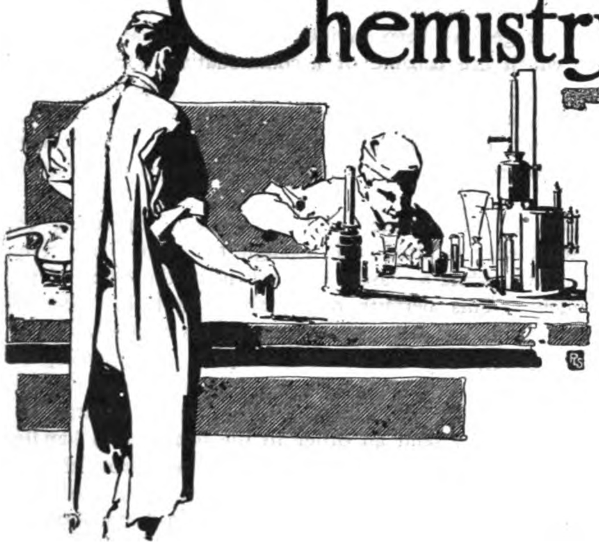
As above stated, the capacity of the garage is 300 cars, but at present only about 190 are kept there, these requiring the services of about 100 men, part of whom work in day time and part in the night. In addition to the facilities named before, there are others that a garage with so large a clientèle cannot do without. An efficient steam-heating system is installed throughout the buildings, the steam being conducted in long, coiled pipes along the walls, which are brick-covered, thereby providing a better heat insulating medium than concrete would. The appliances for fire prevention and protection are in accordance with the orders of the city fire department, and they include sand pails and chemical extinguishers. The illumination, in addition to daylight entering through tall windows, is by incandescent lights, principally drop lights, which so far seem to present the most efficient means for garage lighting.

All the equipment has been designed or rather installed with the special purposes of garage work in view, and it can only be said that the men in charge of the enterprise have solved their problem in an excellent manner.



Floor plan of Joscelyn garage which was constructed by adapting a large boarding stable for the specific requirements of automobiles

The Chemistry of Cylinder Oils



Viscosity of the Oil Does Not Affect the Thoroughness of Engine Cylinder Lubrication

Part II

Being the second of a series of articles on cylinder oils which will appear from week to week. Discussions are invited and the columns of THE AUTOMOBILE *are open to pertinent criticisms.*

By W. Jones

IN the twenty samples of cylinder oils which we have so far tested it is shown that **the viscosity has no relation to the specific gravity, nor does the carbonizable carbon depend upon this in the least.** We therefore consider that **the specific gravity will not have much, if any, value in determining which of a number of oils would be likely to give the best results in practical use in the engine.**

The viscosity, however, is of somewhat more importance, the carbon figure appearing to more nearly follow the viscosity, although it does not do so entirely. We would, therefore, give more consideration to the viscosity on this account, and also to a certain extent for the lubricating value of the oil.

It is generally considered that the viscosity of an oil largely affects its lubricating value. That the thicker the oil is, the better lubricant we have; that such an oil would tend to keep the two wearing surfaces apart better than a thin oil. That that would be the case under some conditions, undoubtedly is true; but it would not necessarily be the case under all conditions. For instance, if we wish to lubricate a very heavy shaft, it is frequently considered to be necessary to use a very heavy or thick oil, so as to help bear up the shaft, and prevent its weight from pressing through the film of oil which keeps the two surfaces apart. Now, if this shaft was moving only slowly, this argument would have some weight. But if the shaft is to revolve rapidly, a much thinner oil could be substituted to advantage, as it would be found that the thinner oil would be carried under the shaft much more easily than the thicker, and would therefore preserve the film more effectively.

Then again, we must consider the effect of heat on the viscosity of the oil, even if it should be found that a thick oil, or high viscosity, would give us the **best effect. We must consider not the oil as it is in the can, but the oil as it is in use, at the temperature of the engine or shafting, as the case may be.**

There does not appear to be any **very good law for the drop in viscosity, except perhaps at the lower temperatures; but when we come to the higher temperatures, such as we have in automobile cylinders, the viscosity of an oil could only be determined by actual test, and tests at such temperatures would be very difficult, if not impossible, to make.** We can, however, make such tests up to **500 degrees Fahrenheit** without much difficulty. In our **list of twenty oils** published in last week's issue we find **that while we have** viscosities from 1.7647 to 18.6071 at 80 **degrees Fahrenheit;** at the temperature of 212 degrees Fa**hrenheit we find that** this difference **has been very much reduced, and that these two extreme cases now stand at 1.1428 and 2, showing that** they not only have both **dropped, but that the higher the viscosity is at the low temperature the more quickly it drops, and this we find to be the case generally throughout the list.**

If we should attempt to formulate a law based on these figures we would find that these oils would all pass the unity mark at temperatures between about 250 degrees Fahrenheit and 400 degrees Fahrenheit. This we do not find to be the case. No. 1867, Table A1, being the lowest viscosity at 80 degrees Fahrenheit, is 1.7647; at 212 degrees Fahrenheit it is 1.1428, and at 350 degrees Fahrenheit we still have a viscosity of 1.0357, while theoretically it should reach unity at about 280 degrees Fahrenheit.

Again in No. 1870, which at 80 degrees Fahrenheit is 6.1764, at 212 is 1.4285, and at 350 degrees Fahrenheit we have the same figure, 1.0357. This oil should pass unity at about 270 degrees Fahrenheit. Now, taking the other extreme in No. 1896e at 80 degrees Fahrenheit we have 18,6071; at 212 degrees Fahrenheit we have 2.; at 350 degrees Fahrenheit we have 1.1071; at 400 degrees Fahrenheit we have 1.0714; and at 500 degrees Fahrenheit we have 1.0357.

If we should attempt to calculate the drop on this oil from the drop between 80 degrees Fahrenheit and 212 degrees Fahrenheit, we might expect it to pass unity at about 250 degrees Fahrenheit. This shows that all the laws on the subject are not of much use.

We notice that in these three oils we have arrived at the same figure, but at different temperatures. In the first two we got there at the temperature of 350 degrees Fahrenheit, while in the last we only got there at 500 degrees Fahrenheit. We also notice here that at the temperature of 350 degrees Fahrenheit there is no difference between the two first oils, while in the third there is a difference of 0.0714, or between 1.0357 for the first two and 1.1071 for the third. Again, we see in the first two oils, No. 1867 and No. 1870, we have at 80 degrees Fahrenheit for the first 1.7647, and for the second 6.1764, while at 350 degrees Fahrenheit we have the same figure, 1.0357.

From all this we conclude that the drop in viscosity from low to high temperatures is very much like the dilution of a solution, that however much we may dilute it, we never reach pure water. That the oil will never reach the viscosity of water, although it may be considered to reach this point for all practical purposes at temperatures above 500 degrees Fahrenheit, and therefore all oils used in automobile engine cylinders have practically the same viscosity in the cylinder when in operation. That it makes little or no difference as far as the viscosity is concerned, if we use No. 1867 with a viscosity of 1.7647, or No. 1870, with a viscosity of 6.1764 The lubrication in the cylinders would be, as far as the viscosity is concerned, the same.

After this consideration of the viscosity bearing on the the lubrication value of the oil, we would naturally look at the list from a different standpoint than before. We now can see why the oil No. 1867, at the top of the list, has given such universal satisfaction. We would now be more likely to select an oil with a low viscosity figure. We should not, however, depend entirely upon this one test, for, as we have already noted, the carbon figure does not entirely follow the viscosity, therefore the carbon figure should always be taken into account.

There are also some other determinations to be considered, such as the acidity and the effect of these acids on the metal of the cylinder. These subjects will be taken up later.

Volatility of Petroleum Distillates

NOTHING leads to more exact knowledge of the indefinite character of petroleum compounds than the information which comes during the process of making flash and fire tests. These hydrocarbon compounds of the methane paraffin series are only indefinite, however, in their proportions of carbon and hydrogen. Confining the discussion to refined hydrocarbon products, **it is a fair inference that the compositions of the products are substantially limited to fractions composed of carbon and hydrogen, with but mere traces of other elements, unless, on occasions, it will be found that a small content of oxygen will be present in the mixtures.**

In conducting flash tests, the flash point depends largely upon the rate of the heating of the liquid. The equipment used for this purpose consists merely of a small pan or dish partly filled with sand, with a royal Berlin porcelain dish about 2.75 inches in diameter and 1 inch deep, resting upon and slightly bedded in the sand, in which the liquid to be tested is placed. Heat is applied to the under side of the protecting pan by means of a gas flame from a Bunsen burner, and a thermometer is so placed that the mercury bulb rests in the center of the porcelain dish, so held in place by any suitable means, as a frame, that the bulb of the thermometer will be submerged in the liquid, but it is not permitted to contact with the bottom of the porcelain dish. **Provision must be made to apply flame to the surface of the liquid to be tested; this may be done by lighting the end of a length of fine string or coarse thread; but a needle flame from a gas burner, with a rubber hose connection, is better.** Flash test apparatus is stock among dealers in laboratory equipment.

In dealing with hydrocarbon liquids, when it is desired to conduct flash tests, a sufficient knowledge of the characteristics of the liquid is usually available to enable the tester to make a surmise of the probability, thus saving a long exploration. But if the heat applied is at a rapid rate the flash point will be found at a relatively low temperature. If the heat is applied at a very gradual rate the flash point will be determined at a relatively high temperature. And these differences will be noted for all of the hydrocarbon liquids.

The reason why the flash test affords different temperatures depending upon the rate of the application of the heat is that the constituent fractions of the liquid are not all of the same volatility. If, for illustration, a sample of 150 degrees Fahrenheit fire test petroleum is taken, even though it proves to be of this quality, the fact remains that the flash point can be developed at a temperature considerably lower than it should be for a 150-degree Fahrenheit fire test petroleum product; it is a mere matter of urging the heat. If the heat is urged, the more volatile constituents will be evaporated fast enough to evolve enough vapor to support a flash. If the heat is applied at a very gradual rate the more volatile constituents will be evolved at such a slow rate that they will float away in the air, never affording a sufficient presence of vapor to make a flashing mixture.

The lower the flash point of the liquid, the greater will be the difficulty of conducting a proper test. This is partly on account of the restriction in the range of the temperature; but, for the most part, it is due to larger proportions of the more volatile fractions of the petroleum in the mixture. Unless the heating is done with care at a slow and gradual rate, if the liquid is of the lighter fractions of the petroleum, the flash point and the burning point will merge. It will be understood, of course, that the only difference between the flash point and the fire point of a liquid lies in the fact that with a mere flash combustion is not supported; the fire point, on the other hand, represents the temperature at which combustion is supported. It is not out of place to infer, from what has already been said, that if the liquid is a close fraction distilled within a narrow range of the temperature the flash point and the fire points will be close together. Heating at a rapid rate, since it produces a considerable volume of the more volatile constituents of the liquid, promotes the merging of the flash point and the fire point, due to the considerable amount of the heat of the subsequent flashing, thereby releasing enough of heat to promote a burning temperature in the body of the liquid. Frequent flashing also has the same effect.

The rate of the heating of the liquid, under the circumstances, must be uniformly maintained for tests of this sort; otherwise the readings, both for the flash and the fire test, will be so variable in their character that the comparison of tests will be for naught. It is the practice in some laboratories to raise the heat at a rate of 15 degrees Fahrenheit per minute; this is for all petroleum products which have a fire test of 300 degrees Fahrenheit or over.

Experiences of an Automobilist in Cold Weather Which Bring Out the Importance of Proper Safety Measures

By Barry NacNutt

Readers of The Automobile *are invited to submit accounts of cold-weather experiences and criticisms of those appearing in these columns.*

SOUTH BETHLEHEM, PA., Nov. 4—In the past 2 or 3 years, the practice of driving automobiles the year around has become more and more general and I think there are now but few owners of cars who lay them up during winter weather. There is no question, however, but that there are difficulties met with in winter which do not obtain during the summer months and the following experiences relate most of the difficulties that I have had in operating my car in cold weather. With the exception of the tire trouble, all of my difficulties may be obviated and I hope that those who drive cars under similar conditions may profit by my experiences.

For 2 or 3 years I have kept my car in a garage which is heated by hot water and therefore have done away with one of the most trying annoyances that the man who takes care of his own car has to encounter. Nothing is more uncomfortable than to work around a car with the thermometer in the garage well under freezing, and never is it more exasperating to attempt to start a cold engine than in the morning when one is in a hurry to get to his office.

But unfortunately I am compelled to leave my car standing outside for 3 or 4 hours, morning and afternoon, in an exposed position and it is this exposure of the car to the cold which has caused most of my difficulties.

With the thermometer below 15 degrees and the engine cold, I find it almost impossible to start the car using the ordinary grade of gasoline, about 65 degrees Baumé. I have flooded the carbureter, injected raw gasoline into the cylinders, etc., but with no result. A friend of mine has compounded a mixture of hydrocarbons of very low boiling point which I have found will start the car satisfactorily at all but extremely low temperatures, it being only necessary to inject about a teaspoonful of the mixture into each cylinder. When the temperature has been in the neighborhood of 10 degrees below zero, I have found that I could only start the car by using gas, either illuminating gas or acetylene gas from the tank, allowing the gas to flow into the intake and running the engine until it had warmed up sufficiently to produce the necessary vaporization of the gasoline.

On one occasion I was unable to obtain any gasoline flow from the tank to the carbureter. The car was hauled to the garage and upon investigation I found that the feed pipe had become clogged with ice. This was explained by the fact that in the earlier part of the day there had been a severe sleet storm. The filler cap on the gasoline tank, which is exposed, had lost its gasket and undoubtedly enough water had leaked into the gasoline tank to cause the trouble.

For some years I have used a solution of denatured alcohol in water in the radiator during the winter weather. This I have found entirely satisfactory, the solution being non-corrosive and inexpensive, 5 gallons of denatured alcohol sufficing for two seasons.

A very peculiar thing happened once during last winter. After starting the engine and running the car for about 15 minutes, I found the engine becoming very hot and soon traced the trouble to lack of circulation of the cooling water. Upon investigation I found that the cooling water had frozen in the form of slush in the pump preventing its action, and yet the solution in the radiator was unfrozen. This was evidently due to the fact that the solution at the pump was weaker in alcohol than that in the radiator, but I am unable to account for this effect. This experience was not repeated during the winter and it would be interesting to know if other automobilists have noticed this phenomenon of a partial separation of the alcohol from the water in one part of the circulating system.

Another difficulty that I have encountered is the lowering of the E. M. F. of the dry cells used for ignition. This lowering of the E. M. F. of the dry cells by reduction of temperature is only serious when three-quarters of the life of a dry cell has been exhausted. Under these conditions, a dry cell which will give a sufficiently high E. M. F. at ordinary temperatures is practically worthless at a temperature around zero. The lowering of the E. M. F. of a storage cell is not so marked as that of a dry cell, but there is danger in the use of storage cells of the electrolyte freezing, the freezing point of the solution of sulphuric acid used in a storage cell being about 10 degrees Centigrade.

I think that few drivers realize the great danger that exists in running an automobile engine in a confined space where there is not a large amount of fresh air to mix with the exhaust gases. I knew, of course, of the danger from inhaling carbon monoxide but did not have brought home to me the very small amount of this gas necessary to produce a toxic effect until I had had the following experience. I was tuning up the carbureter, running the engine with the car in the garage, and had left one of the large entrance doors open about a foot and also had the side door of the garage open. I happened to be standing in such a position that the draft blew the exhaust gases past me. In 5 minutes I began to feel dizzy and, realizing the trouble, hastily left the garage and got into fresh air. But for 3 hours I was very sick with the symptomatic nausea and headache of carbon monoxide poisoning. One may be sure that since then I leave the doors of the garage wide open when it is necessary to run the engine while in the garage.

Carbon Monoxide in the Muffler

Of course, if the carbureter is properly adjusted the amount of carbon monoxide in the exhaust of a gasoline engine is very small, provided the gas does not come in contact with hot carbon which reduces the carbon dioxide to carbon monoxide. As the muffler of an automobile engine is always more or less foul with soot and as this soot becomes highly heated by the exhaust, there is reason to suppose that under these conditions quite a large amount of carbon dioxide is reduced to carbon monoxide and so, even with a well adjusted carbureter, there must be a fairly large production of carbon monoxide in the muffler.

The fact that rubber becomes hard and inelastic at low temperatures is, of course, well known, and I frequently notice an in-elasticity of the horn bulb on very cold days, the bulb taking a long time to regain its normal shape after having been squeezed. It is fortunate that during the coldest weather there is usually a good layer of snow on the ground which covers up the sharp stones in the roads; for one can see that, as the

Among the New Books

Works Which Have Recently Appeared That Should Appeal to Automobilists as Well as Those in the Industry

CARE AND OPERATION OF AUTOMOBILES. By Morris A. Hall, American Society of Mechanical Engineers. Published by the American School of Correspondence, Chicago, Ill. 140 9 1-2 by 6 1-2-inch pages, with 69 illustrations. Cloth, $1.40.

The author has intended this work for the private owner who desires to take care of his own car and thus minimize the expenses of its upkeep. The book is divided into two sections, the first deals with private garages and the repairs which may be safely undertaken by the amateur; the second treats of the automobile itself and includes instructions on the proper management of the car as well as its construction. There is nothing complicated or technical about the style in which the author gives his information, the book being made purposely elementary throughout. The private owner who is not an automobile expert will find much that is useful knowledge in its pages.

GASOLINE ENGINES, THEIR OPERATION, USE AND CARE. By A. Hyatt Verrill. Published by The Norman W. Henley Publishing Company, New York City. 320 5 by 7 1-2-inch pages, with 150 illustrations. Cloth, $1.50.

As a comparative study of the different devices used in the gas engine this work should be of value to the student although in some parts the author has neglected to take into consideration the steps made in recent years. This is notably the case in speaking of automatic intake valves of which mechanical errors we have seen the last. In this connection he states that "several excellent motors utilize this system." A few pages further on, however, he gives an excellent and detailed description of the Knight sleeve valve as well as of some of the more advanced types of rotary valve. The rudimentary principles are carefully studied and while the book may not be recommended for the advanced student or one who has followed the industry from day to day, it should prove a satisfactory text book for the beginner.

ENERGY AND VOLTAGE DIAGRAMS OF LARGE GAS ENGINES; THEIR USE AND LAYOUT. By Paul L. Joslyn. Published by The Gas Engine Publishing Company, Cincinnati, O. 70 pages, with numerous diagrams and tables. Cloth, $2.

The designer of large gas engines has to consider many things which on small engines are often left to be worked out after the engine has been built in its first form. With small engines, it is not so expensive or so difficult to change some points, and it frequently happens that very radical changes in construction are so effected. But with the engine of several thousand horsepower, it is impossible to do this. So far as can be done, everything must be worked out in advance. Castings and machine work run into a large amount of money on engines working on blast furnace gas, and to scrap a cylinder or a bed casting because some change is found necessary may amount to several thousands of dollars in initial expense, manufacturing cost, delays, etc. In this book, the author gives the methods of laying out energy and velocity diagrams for large engines operating on blast furnace, producer or natural gas, with instructions as to their use, etc. The data given is the result of actual designing of this character on some of the largest engines built in America and Europe and will be found of advantage to the designer working on engines of this character.

SCARBOROUGH'S ROAD MAP AND MOTOR GUIDE OF MINNESOTA. Published for and under the auspices of the Minnesota Automobile Association. 872 pages, with complete maps. Heavy paper, $1.00.

More than 550 routes are mapped and outlined in this folder and the automobilist of Minnesota, Iowa, Wisconsin or Missouri should consider one of these route books as part of his necessary equipment if he intends to do any extensive touring about his home or neighboring states.

THE GASOLINE AUTOMOBILE. By Victor Lougheed, member S. A. E., and Morris A. Hall, member American Society of Mechanical Engineers. Published by the American School of Correspondence, Chicago, Ill. 307 6 1-2 by 9 1-2-inch pages, with numerous halftone and zinc engravings. Cloth, $2.50.

Divided into three distinct parts this book forms a complete text or reference book for the study of the modern automobile. As distinguished from the standard work on gas engines it includes a section which is devoted to the explanation of the different types of bodies found on the modern car while the garage question is also thoroughly analyzed both from the standpoint of the public and the private garage. The authors have made a successful attempt to get away from the stereotyped form of automobile book illustrations. Actual sketches and reproductions made from photographs of cars in actual use at the present day are used in place of the oftentimes impossible pen-and-ink sketch. Among the interesting and valuable chapters are those devoted to the driving and the repair of the pleasure automobile.

DAS AUTOMOBIL, SEIN BAU UND SEIN BETRIEB—A handbook for automobile owners by Diploma-Engineer Freiherr von Löw. Second revised edition, 1912, with 363 illustrations. Published by C. W. Kreidel Publishing Co., Wiesbaden, Germany. Price 6 Mark ($1.50).

For those who read German this book is of especial value because the author does not only understand his subject practically and theoretically, but also possesses the gift of picking out the essentials and presenting them in plain and lucid language. He knows all the steps in the evolution of automobile design and the reasons for the changes which have taken place from time to time. The style is very brief and meaty, and even readers well versed in the subject will not fail to find valuable sidelights when looking up matters of special interest to themselves. The illustrations are specially drawn and very clear, each of them serving a definite purpose in the presentation of a fact or an idea. A book of similar qualities in English would be of unusual merit as an aid to teachers in the automobile schools.

FARM GAS ENGINES. By H. R. Brate. Published by The Gas Engine Publishing Company, Cincinnati, Ohio. 195 5 by 7-inch pages, with line cut illustrations. Cloth, $1.00.

There are some excellent points on the carburetion and ignition of gas engines in this work which apply not only to farm engines but to any piece of motor driven apparatus. The remarks on the carburetion of kerosene are especially timely in view of the world-wide protest against the rise in the price of the more volatile petroleum products. In fact the title of this work is far narrower in scope than are the contents and it can be perused with great interest by any one interested in gasoline engines.

---

elasticity of the rubber is greatly reduced by the cold, cuts and subsequent blowouts would be of frequent occurrence.

I have tried various non-skidding devices but have found that chains are the only satisfactory arrangements to prevent slipping on muddy roads or roads covered with snow and ice. Steel studs in casings themselves, or in protective coverings, soon wear down and then become worse than useless. Even when new, the space between the studs becomes filled with snow which melts under the pressure of the wheel and then freezes, producing a slippery coating of ice on the tire which is very dangerous. In slimy mud, this sort of non-skid device is useless.

If one drives his automobile with care, serious skidding need never occur under any conditions; but I have found that in order to produce the necessary traction between the rear wheels and the road, it is imperative to use a non-skid device, and, as above stated, chains are the only satisfactory solution of the problem. If the chains are put on the wheels loosely enough to creep, the extra wear on the tires caused by them is inappreciable.

Drive Pinion Should Mesh Correctly; Fibre Disks Have Long Life; Causes of Transmission Trouble; Ether Costs Too Much for General Use; Cost of Laying Up Car; Use of Anti-Freezing Solutions; Ordering a Definite Spiral Spring

Drive Pinion Meshes Improperly

EDITOR THE AUTOMOBILE:—I am having trouble with noisy differential bevel gears. I have adjusted the small pinion forward but it only prevents gears from humming for a short time. I removed axle housing and found that gears were apparently in perfect condition. Ball bearings on differential are adjustable in either direction. I have been told by good authority to move differential to one side, bringing gears a trifle out of mesh, while another equally good authority tells me to put them into mesh still deeper.

Any advice that you can give me will be appreciated.

Plymouth, Mich. SUBSCRIBER.

—If the gears are in good condition and have not worn away a simple adjustment will cure the noise of which you complain. As may be seen in Fig. 2, there are three ways in which the pinion can mesh with the large differential gear. It can be too far forward or back and it can be in correct mesh. It is evident that the direction in which the pinion is too be moved depends on how it is now in mesh with the large bevel wheel. Should the pinion be too deeply engaged move it back, and vice-versa. You will also find an adjustment on the large wheel which will enable you to move it more closely toward the pinion. When the proper mesh is secured there will be practically no noise so long as the parts are kept lubricated with grease or non-fluid oil.

Fiber Disks Will Stand Wear

Editor THE AUTOMOBILE:—I have a 1908 50-horsepower Rainier which I want to overhaul during the cold weather. As means of quieting valve stem taps I thought of cutting out the screw bolts that lift valve and filling in with fiber when operating fiber would strike valve stem instead of steel. How long would fiber last after first adjustment? If it would stand the tapping or lifting up on valve for 2,000 miles and then need adjustment, I would not object to adjusting the screw bolts then, but if it did not last long it would not be worth while.

2. What can be done to quiet noisy timing gears? Mine are oiled from oiler, three pipes leading to top of timing gears and the oil dropping on them lubricates. Would grease, if used, run into motor through front bearing and cause gumming up of motor?

New York City. GEORGE RUDY.

—1. These fiber disks are used on many cars and the adjustments are not required more frequently than with the metal-to-metal contact, while there is undoubtedly a marked diminution in the amount of noise. They will run 25,000 miles before requiring renewal and will not require adjustment more than every 2,000 miles.

2. The only thing that will quiet noisy timing gears is packing them in grease. This has the drawback that you state: namely, the grease is apt to work its way through into the crankcase of the motor and as a result will gum the latter up in a short time. When timing gears become very noisy it is a sign of wear and a new gear should be inserted.

Transmission Trouble Causes

Editor THE AUTOMOBILE:—I am driving a certain car in which the second gear became worn out after very slight service. A friend has an old model of the same make in which he has transmission trouble frequently. We are wondering if part of this is not owing to the placing of transmission and differential on back axle with inadequate support. Is it not better practice to place transmission further forward on the frame?

Odel, Neb. CHAS. N. HINDS.

—There are so many good cars which have not the slightest trouble that have the gearset mounted in conjunction with the rear axle that it can hardly be stated that this system is not so good as that in which the gearset is mounted amidships. Where the bracing is insufficient, however, to prevent changes in the alignment of the gears the trouble you mention is sure to materialize. In the models of the last few years in all the cars which are mounting the gearset aft of the propeller shaft, there has been a tendency toward stiffening the structure at the rear end of the frame. It is not likely that transmission has suffered because it has been placed near the rear axle, but because the material was softer than it should have been.

Ether As an Aid to Combustion

Editor THE AUTOMOBILE:—The quality of gasoline that I am using is very poor. Ether has been recommended to increase power. Will you kindly inform me through THE AUTOMOBILE the quantity of ether to use to gallon of gasoline?

Sacketts Harbor, N. Y. L. W. DAY.

—It would be highly impractical to attempt to use ether continuously to offset the bad effects of poor gasoline. There are many physcicians who make a practice of priming with ten drops of anaesthetic through each priming cup in very cold weather after the car has been standing. Last winter a certain physician made some experiments in the line of adding ether to the gasoline in the tank and came to the conclusion that he got better results when he added about 1-2 ounce of ether to each 10 gallons of gasoline. Anaesthetic ether is expensive, and hence it is impractical for the motorist to use it continuously. Commercial ether contains a certain percentage of water which would more than likely render it unfit for use in the motor cylinder.

Average Cost of Repairs

Editor THE AUTOMOBILE:—Would you please let me have some information on the following: What is the probable cost of overhauling a four-cylinder motor car? What is a reasonable amount to pay for a set of valves ground; also for timing valves and magneto?

Newark, N. J. A CAR OWNER.

—Overhauling the motor will, of course, include the valve timing, etc., and the cost of this will to a large degree vary with the repairs which are necessary. Many people let their motor go without a general overhauling until it gets in such a condition that it cannot work satisfactorily, while others who are wiser either have this work done or do it themselves once every year if the car is run all year round or once every two seasons if the car is laid up in the winter. Assuming the average case where the motor is overhauled every other year, the cost for the average type of 30-horsepower four-cylinder motor would be about $50, figuring on an average of 66 hours work at a labor charge of 75 cents an hour. If any extra parts are needed this would, of course, be extra and should the bearings be badly worn the time would be longer. To grind the valve and time them and the magneto, would be the work of one day of 10 hours, the cost would be $7.50 ordinarily. In some of the more inaccessible motors the cost would run above this, while in others it would run below. This is about the average charge to be expected.

Denatured Alcohol Evaporates

Editor THE AUTOMOBILE:—Since the use of anti-freezing radiator solutions is now necessary, I would like a little information concerning the use of denatured alcohol for this purpose. I have filled by Overland cooling system with half alcohol and half water, which I understand is safe for temperatures down to minus 25 degrees Fahrenheit, but since alcohol evaporates faster than water, the question is, will I always have half alcohol and half water in the cooling system, provided I use the same solution in replacing that which evaporates, or will such a large portion of the alcohol evaporate that my solution will eventually become nearly all water and thus be unsafe as an anti-freezing liquid?

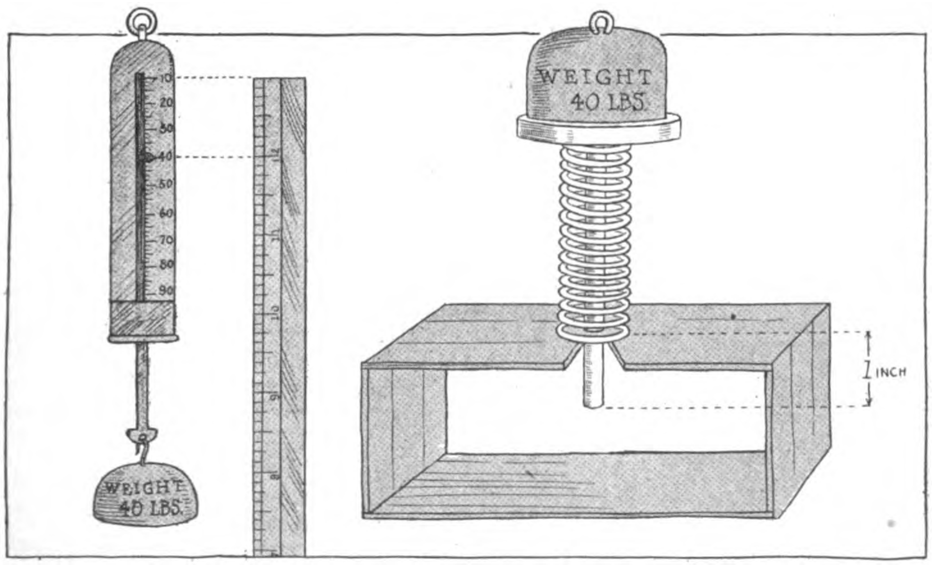

Fig. 1—A 40-pound-to-the-inch spring will compress 1 inch under a 40-pound weight

2. How can I tell what proportion of alcohol and what of water I have in the cooling system?

3. Some time ago one of your correspondents asked some pertinent questions regarding five-cylinder, four-cycle motors with cranks set 72 degrees apart. THE AUTOMOBILE replied that information regarding such an engine was rather scanty and asked its subscribers for a discussion of the subject, but as yet I have not noticed any article throwing light on the matter. I for one would like to know just why such a motor could not be built to operate successfully. The explosions in a five-cylinder motor would overlap each other so as to produce a continuous torque the same as in a six, and since five cylinders would weigh less and require a shorter crankshaft and shorter hood with less complication generally, I fail to understand why such an engine is not manufactured and used instead of the heavy, long, complicated and expensive six-cylinder motors so much in vogue at the present time. I would be pleased to have the opinion of some gas engine designer regarding the above.

East Canaan, Conn. D. C. CANFIELD.

—1. On pages 839 and 840 of the issue of THE AUTOMOBILE for October 24 there is a full discussion of all the non-freezing solutions, which includes an answer to questions 1 and 2. It may be stated, however, that the evaporation will occur and that the condition of the solution in the radiator may be determined by the specific gravity. The specific gravity of the correct solution is noted and the mixture is kept at this specific gravity by the addition of more denatured alcohol every time a marked evaporation is detected. The specific gravity is determined by a hydrometer.

2. This question is answered under above reply.

3. No discussion has developed on the five-cylinder motor for the probable reason that it has not been tried to such an extent that any one knows anything concrete about it. THE AUTOMOBILE, in the issue of September 12, published the opinion of Mr. Herman Dock on this subject. Mr. Dock at one time was manufacturer of such a motor and his views may be taken with full confidence by the investigator and at the same time with the feeling that they are given by one who is an authority on the subject. He said, in part: "I believe the only reason why this type of motor is not being built is because its merits have not been investigated, for, in my judgment, which the performance of a motor of this type will bear out, there is nothing in the line that will equal them unless it be a seven cylinder.

"In one or two instances wherein I tried to interest automobile manufacturers in this engine I was met with the argument 'that the public were satisfied with the four or six, therefore, why the use of improving?'

"In a five-cylinder engine there is nothing to invent, but I did, I believe, build the first one of its class in Philadelphia in 1901. Since then in connection with the concern which had the contract I built the government field searchlight engine and others and wherever they have been put in commission they give satisfaction.

"For automobile use they are much superior to the four or six as the shaft is in constant torque, one cylinder being always in pressure, and the machines in which I have ridden with the five cylinders are the best hill-climbers of any.

"As to balancing, this class of engines was a surprise, for while I was building the first one many interested engineers saw it and the general opinion of all was that it would be so out of balance as to be worthless.

"But, as a matter of fact, it is the quietest, smoothest engine I have found and more flexible by far than its four- or six-cylinder brother.

"Finally it is my belief that whenever some enterprising manu-

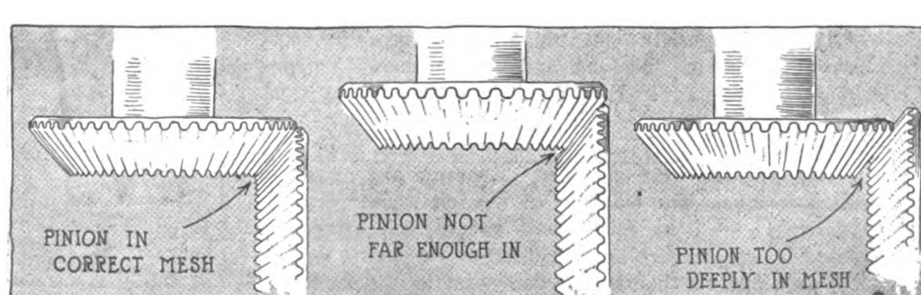

Fig. 2—Diagram showing how pinion can be too deeply or not deeply enough in mesh

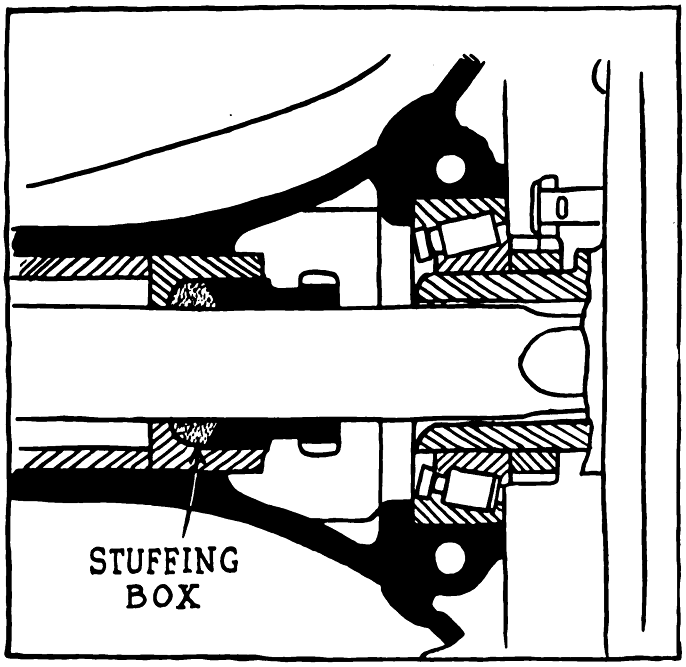

Fig. 3—Installation of felt or hemp packing box at inner end of drive axle

facturer of automobiles take up the five cylinder he will have a walkover and command the field, given that his production is always first class."

This is an interesting topic and one which could be further discussed to advantage. There is a lack of data as regards actual performance on the road and Mr. Dock does not state what cars were ever manufactured that used this motor. THE AUTOMOBILE has no record of any such.

How to Order Spiral Spring

Editor THE AUTOMOBILE:—I desire to order a spring that will compress 1-inch under a 40-pound weight. What must I tell the spring maker? Is a 40-pound spring one that will compress or extend 1 inch under a load of 40 pounds? I have asked several people regarding this and they all seem to disagree on the subject.

Saratoga Springs, N. Y. C. J. WILKINS.

—There is more or less confusion as to what a 40-pound spring would be. That is, whether it would be a spring which had a total capacity of 40 pounds or whether it would compress 40-pounds to the inch. The particulars necessary in ordering the latter would be the diameter of the spring, the length when under no load, the length under a given load and a brief description of the purpose for which the spring is intended.

Keeping Oil from Brake Drums

Editor THE AUTOMOBILE:—In THE AUTOMOBILE for October 10, page 734, you say a thick wadding of felt is placed around the drive axle and acts in the nature of a stuffing box. Would you please tell me as definitely as possible about this. How thick should the felt be? What shape and size are the pieces of felt? What tools are used to put it in with? Is the entire space from bearing to bearing filled up, and how much? How long should it last in miles run? How do you get it out when it becomes worn?

Mongaup, N. Y. GEO. S. BELDING.

The felt is in the form of a ring or washer and about 1-2 inch thick as a rule The diameter of the felt washer depends upon the size of the drive axle. As a general rule more than one of the felt washers are used to close up the space between the drive axle and the housing at one point in the length of the axle. Should there be no provision in your car for these washers it would be suggested to secure four felt rings for each side. The hole through the center of the washer should be ordered 1-16-inch in diameter less than the size of the drive axle, as it is easy to stretch them over the axle and get a tight fit. The outside diameter of the washer should be a trifle greater, say 1-4 inch, than the inside diameter of the axle housing at the point at which it is desired to place the washers. In a floating axle the felt washers would be slipped over the drive axle close together from the differential end and then worked into place by the most convenient means possible. It is impossible to state what sort of a tool would be best without seeing the car and noting the conditions. The entire space from bearing to bearing is not filled. Only 2 or 3 inches is necessary if the felt is a tight fit. The washers should last for at least two seasons' use. It can be removed by taking out the drive axle and poking it out. Almost every car in existence has some means of checking the flow of oil from the differential housing to the brakes and a few of these are shown in Figs. 3, 4 and 5 with an idea of illustrating what makers do to prevent the slipping of the brakes from the gathering of oil on the lining of the shoes.

From these illustrations it will be seen that in most cases the interior of the axle housing has been designed to take the felt washers and hold them in place. A stuffing box is employed by some while the spring shown in Fig. 5, is used by others. Felt washers may be jammed into the space between the axle and the housing, however, should there be no such provision for their installation.

Street Gamins Bother Motorists

Editor THE AUTOMOBILE:—There is a law which requires that cattle must be kept off our public highways, yet there is no law in regard to children being kept from playing in the middle of the streets.

The one great argument always used is that children in the big cities have no other place to play. It is the children in the country that cause more than one-half the trouble. There can be no doubt at all that they have more than sufficient room to run and jump to their heart's content without endangering the lives of motorists as well as their own lives by darting out into the road at any old time regardless of what is coming.

If it were only the young one's carelessness that caused accidents we might be more lenient with them. Children can hardly be supposed to understand the real dangers to be apprehended from automobiles. Very often, in this supposedly educated coun-

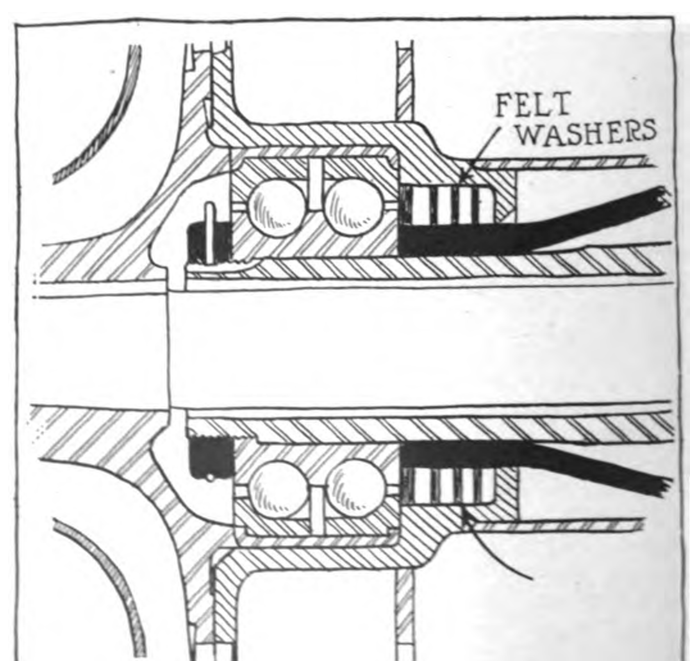

Fig. 4—Some makers put felt packing at the wheel end of the axle to exclude the oil

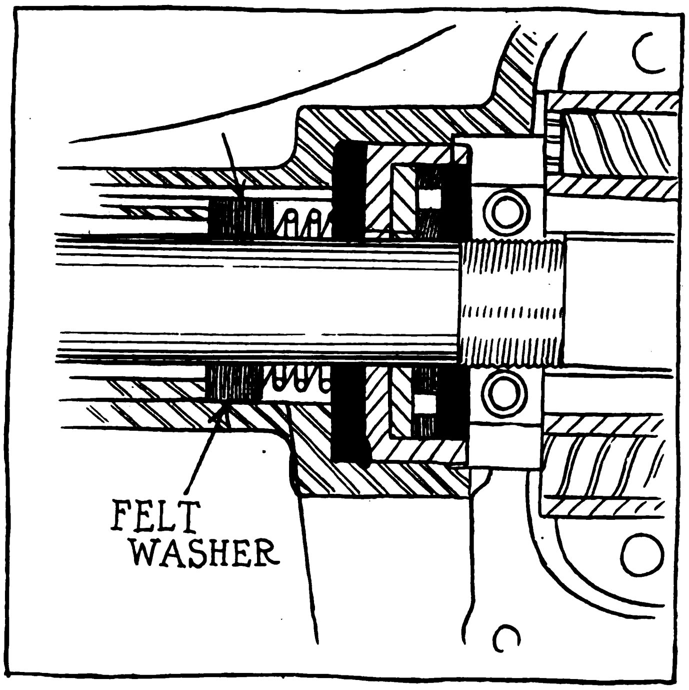

Fig. 5—Easy installation of most cars. Felt washers used with spring

try of ours, children throw dirt and rocks at approaching cars. Either a driver must pass through a country settlement at such speed as to prevent damage to his car by pure deviltry on the part of little children in the street and risk hitting one of them, or else he must drive slowly with a tolerably sure knowledge that he will get a rock thrown at his car or a handful of dirt in his face.

Two weeks ago I was driving my car along a country road in the Berkshire Hills. I was going at a speed of 14 miles per hour and climbing a small hill. Several children saw my machine approaching and ran to the side of the road. I slowed up and passed them, barely moving. One can never tell just what a kid is going to do! As the machine reached a point directly beside the children, one of the smallest ones picked up a handful of sand and pebbles and with a well-directed throw completely blinded me. I held my machine in the center of the road and stopped instantly, but not before one of the other children had darted in front of my mud guard. When I cleared my eyes of dirt the child was lying in the road behind the machine. I gave my number, offered to call a doctor or take the injured one to the Hospital and be of service in any way possible.

Six or eight people witnessed the accident and they all agreed that I was in no way to blame. This did not prevent the police from arresting me and holding me under $2,000 bail. After 2 weeks' fight put up by the best lawyer money could secure I was cleared. It cost me several hundred dollars and caused me great inconvenience. I had to appear three different times in the country court, 5 or 6 hours by the railroad from New York. Everyone would have been thoroughly shocked had I suggested sueing the mother and father of the 3-year-old child who was to blame. The youngster I hit was up and about in 3 days. This is the justice of some of our automobile laws in this glorious free country.

It is hardly possible that the government can control children directly or make them see the danger of playing in the street. It is also hardly possible that the same government can keep the children from becoming a menace to motoring. In fact, they are that already. But cannot the parents of these children teach them the right and wrong in regard to their actions in the street? What mother would see her offspring deliberately break an electric lamp without reprimanding him? What mother would stand by and let her child steal apples from a street vender? Yet parents feel no responsibility at all in regard to automobiles.

The animosity shown toward motor vehicles some years ago was pardonable. The same feeling today is ridiculous—and unpardonable. True, there are many who drive cars that care very little for the rights of those living along the road, but the percentage of careful drivers has doubled itself. The percentage of automobile haters has not cut itself in two.

A short time ago a young child; perhaps 4 or 5 years old; threw a rock the size of an egg at me. It missed my head and dented in the car door, entirely ruining the enamel. Then the offender ran into his house, conveniently near and left me to pay all the damages as usual. If that rock had hit me it would have been all over except the funeral expenses. As it was, it only took $25 out of my pocketbook.

Let the parents of American children wake up! Do you want your youngsters to become known to the automobile world as pests? Do you wish every driver to put on full speed the instant he sights a child? Which is the most dangerous, cars passing your house at the rate of speed far exceeding the limit to avoid your children or 15 miles an hour with the assurance to the motorist that he will not be annoyed. The common people of this country must decide and they must decide now.

New York City. EUGENE JONES.

Wiring Diagram for Mea Magneto

Editor THE AUTOMOBILE:—Will THE AUTOMOBILE kindly tell me how to wire up my Mea magneto for a four-cylinder car? Is it necessary to have a separate coil?

Wichita, Kan. C. SQUIRES.

—Assuming that you want the cylinders to fire 1-4-3-2 the wires would be connected up in the manner shown in Fig. 6. Should it be desired to fire according to any other order all that is necessary is to change the wires leading to the plugs. For instance in firing 1-3-4-2, all that would be required would be to interchange the wires leading to spark-plugs Nos. 3 and 4. No extra coil is required with this magneto as there are both primary and secondary windings on the armature. The low-tension winding ordinarily is short-circuited by a breaker which opens at certain points of each revolution with the result that a high voltage is generated across the high tension winding at the moment of the break, and a spark is produced across the spark gap in the cylinder to which it is connected. In the diagram the primary current is generated in the coarse winding P and serves to induce a current in the secondary winding B which passes through the connecter ring and a brush supported by the brush holder G. The high tension lead C communicates between this brush holder G and the revolving segment of the high tension distributer H. The ground connection of the spark-plugs I is represented by the dashed lines A. The primary circuit is represented by the line B, which shows communication between the circuit breaker E and the armature. The condenser is represented at F.

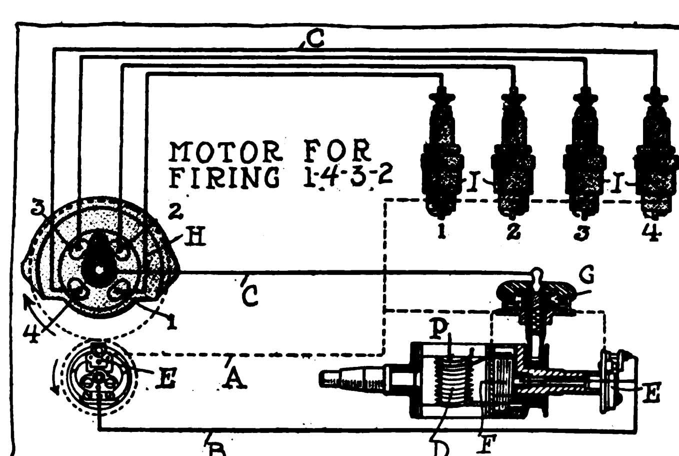

Fig. 6—Wiring diagram for use with a Mea magneto of four-cylinder car.

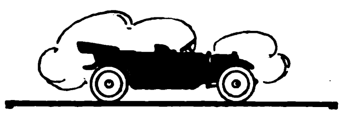
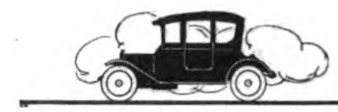
Coupé Design for 1912 Chalmers Chassis





Scale Drawings and Details of Light Four-Passenger Body for Winter Travel

By George G. Mercer

OF the Chalmers models, a 30 touring car chassis has been selected on which to show the third of the closed-body designs. This chassis is a 1912 Chalmers 30 with 115-inch wheelbase and 34 by 4-inch tires. The stock chassis that has been in service during the season should give a good account of itself with the body design here illustrated, as the power, tires and springs are sufficient to take care of this 750-pound body.

The chassis changes required are new rear fenders and gasoline tank, the location of this latter changed from under front seat to the compartment at the rear, Fig. 5. In this position the tank shows a filling plug projecting above the cover of the compartment and it will be necessary to use pressure feed. The old tank can be made to do service either by adding the filling plug, as specified, or by having the cover of the compartment made to raise for filling. This will save on the expense. Another item that will reduce cost is to make use of the stock rear fenders that are used on the runabout, as these are the same shape as those illustrated. No other change is required to the chassis, the locations of the levers, change and brake are right for the closed body and the electric dash lights will be entered as part of the body equipment.

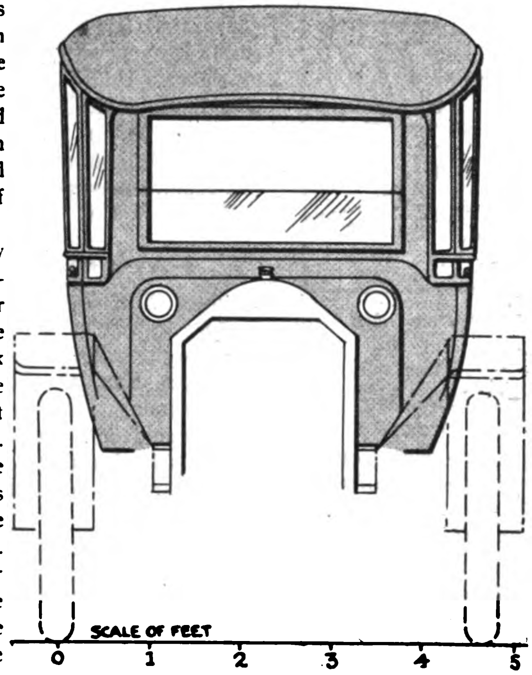


Fig. 1—Front view of Chalmers 30 coupé design

The makers of this car also furnish a model 30 with 104-inch wheelbase and the stock bodies are a runabout and small coupé, generally called a physician's coupé. The object in choosing the 115-inch wheelbase chassis is to furnish a design that does not conflict with the stock body and that is large enough and yet light enough to be used to replace the touring body in the winter season, and in addition it may be said that this design is equally applicable for use on the model 36 and will fit the chassis of either the 30 or the 36-horsepower cars.

The science of getting the article most applicable for one's needs is to examine exhaustively a number of samples, then, after eliminating, make the final selection from the remaining few. Body designs are chosen by the same method and as no one design is all merit or demerit, the final choice is often a combination of the essentials of a number. The design here reproduced is in no sense a substitute for the stock body design, but is one having totally different features; it is intended as the complement to the five-passenger touring body and to alternate with this latter for service during the winter months.

The illustrations show a four-passenger body with the seating arrangements for two on the front seat and two on the rear seat, all facing forward. This design has a true flush-sided effect. The lower side panels at the front are graduated to the dash and blend into the cowl, which is well rounded, Fig. 5. The rear side panels are formed in one piece with the back panel and the rear corner is rounded, Fig. 2. The roof is arched and the corners rounded over. The compartment at the rear is made just large enough to contain the gasoline tank, the size of which is indicated, Fig. 5, and under the rear seat is a lock 7 inches high, 20 inches deep and 40 inches wide.

Inclosed body designs of the coupé type have a fault that has been difficult to overcome, namely, the access to the seats. In some cases the entrance on the right side is entirely blocked by

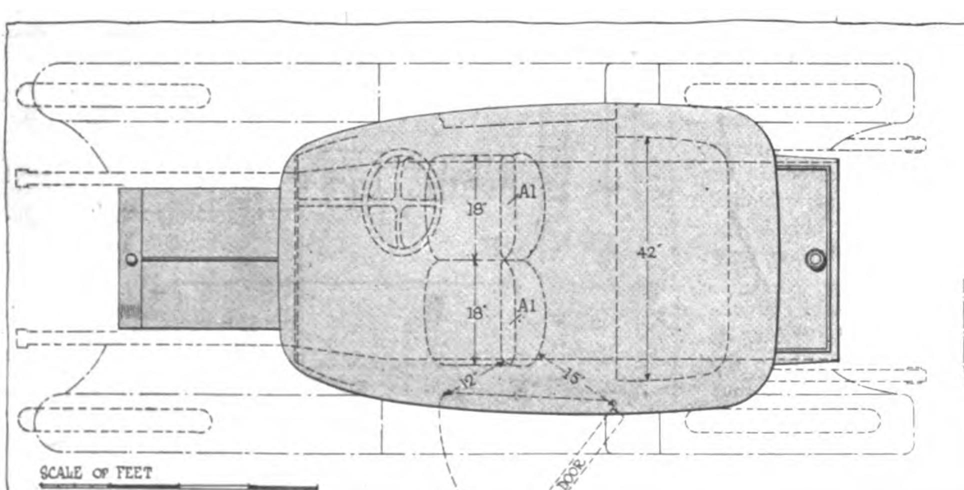

Fig. 2—View from above of suggested Chalmers coupé

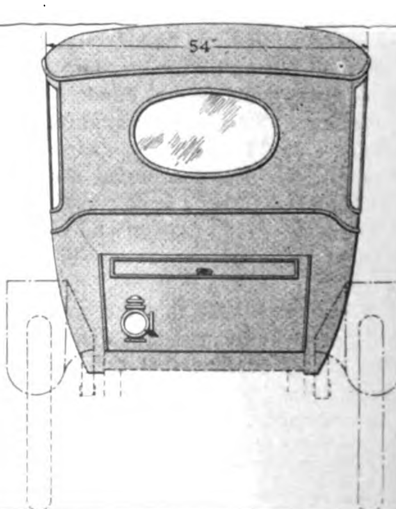

Fig. 3—Rear view of coupé

the levers, and if the body is of the four-passenger type similar to this one, the difficulties are greater than with the two-passenger body. The location of the steering wheel back of the dash only enters into the calculations on a very short wheelbase chassis.

One solution of this difficulty is the offset doors. This was illustrated in the coupé design published in THE AUTOMOBILE October 31, 1912, and another solution is that presented in this design. Fig. 5 shows a door 30 inches wide over the mouldings with the seats indicated in dotted lines. The front seat is made individual and the cushion part is made to tip up. A, Fig. 5, shows the cushion elevated. On Fig. 2 the top view of the cushion is indicated by A1 and the open position of the left door shown by dotted lines. The entrance to front and back seats is marked. To the rear the passage is approximately 15 inches and to the front approximately 12 inches is obtained between the body framing and the bottom of the raised seat. The individual front seat cushions are each 18 inches wide. The rear part of these seats and the backs are built solid to the lower framework of the body, the cushion part is hinged and when dropped to the horizontal is supported by a solid top at the back end, no partition or framework being used under the front of the seat as this would interfere with easy entrance. The rear seat cushion is comfortable both in depth and width for two people and the thickness of the cushion which is 10 inches will insure the maximum of comfort. Ample foot room is allowed by the partial open space under the front seat. The head room over the seat is the maximum for a coupé body.

The general dimensions of the body while affording ample room inside are well within the allowance that will insure a compact and light-weight body. The extreme width is 54 inches over all and the length from front to back of the body is 76 inches.

The windows on the sides of the body are approximately the same width back and front of the doors, these latter being placed about central in the body to carry out this harmonious effect. All windows on the sides and back are made with the frameless glass; the back window is stationary and those on the sides all drop the full length. The front windshield is made with the customary rain visor division, with the part below the cut stationary and that above it hinged at the top and made to swing outward. The supporting rods in the forward position are short arms that slide on perpendicular rods inside the front pillars. The roof extends forward of the pillars 8 inches, Fig. 5, and serves as a partial protection from the down beat of rain and snow. It assists in keeping the glass clean.

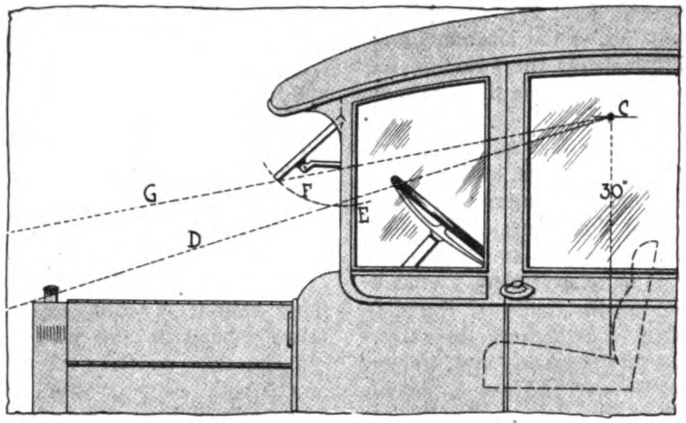

Fig. 4—Diagram showing method of determining the correct position of windshield and swing-visor

Carriers for extra tires are not illustrated as it is not practical to put them on the running board, on account of the very wide door, but provision can be made for them at the rear of the gasoline compartment. It will be necessary to carry the tires in a nearly perpendicular position.

Fig. 4, a section of the front of the body, shows the seat, front windshield and the top of the engine hood. Its purpose is to illustrate a suggestion for determining the proper height up for the cut in the windshield glass, so that when the swing part is forward as a visor the opening is right for the driver to see through. If the cut is too low, the swing part is proportionately longer and the opening will in turn be greater, thereby allowing more cold air and rain to enter.

The point C is located in a perpendicular line from the back of the seat, at a height of 30 inches. This is the height of vision of the average man and is a rule applied by trimmers and top makers. From C a line is carried to the top of the hood at the front and is marked D. The point where line D passes through the glass E is the line of cut through the glass and will be the lower line of the swinging section.

Line D is the line of vision of the average person, seated in

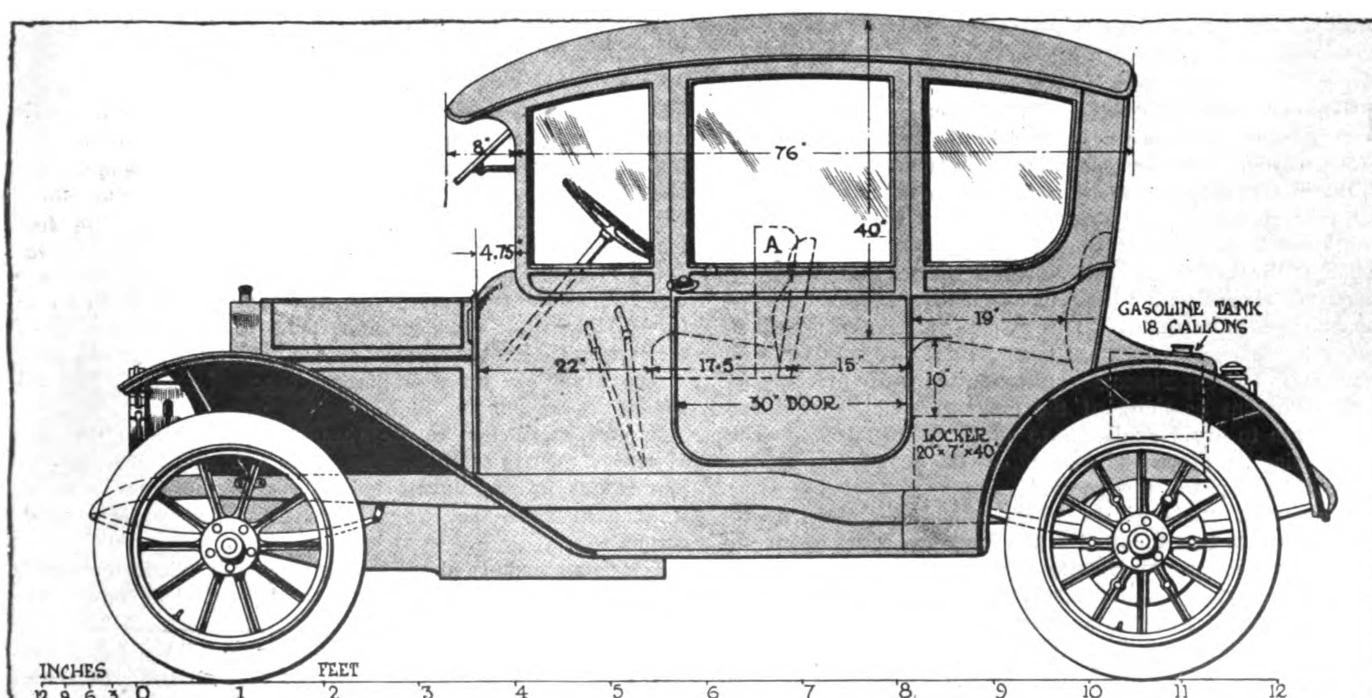

Fig. 5—Side view to scale of suggested coupé design for Chalmers 30 chassis

position to drive the car and allows free sight over the front of the radiator. It can be readily seen that if the location of the cut E is made without the proper calculation the swinging section will be either longer or shorter than will give the maximum of vision with the minimum of opening.

In other words, if, for example, the line E was made 1 inch lower then the line of travel of the swinging section would have a radius 1 inch greater than F and the intersecting point with line G would be further toward the front; consequently the actual open space to obtain the range of vision between the lines D and G will be greater by 1 inch lower than E and by 1 inch further forward than the intersecting point of F and G.

This example shows how important it is to have the correct line of cut that will suit the position of the driving seat, and the rule illustrated is as simple as any in use and can be readily applied by any person.

The construction of the body is aluminum 16-gauge panels with aluminum mouldings and the framing is of good quality ash. The heavy mouldings on the door pillars and those back and front of the door and the front pillar are made of wood and are worked solid on the framework. The rear compartment is made of aluminum panels and wood framing and the lid at the top lifts off when the filling cap of the gasoline tank is removed.

The roof is rounded over on the edges more than ordinarily and is made with the customary laminated wood roof panel, which is glued on the top edge of the side and end top rails, and when set the rounded edge is formed by planing the roof rail and the panel edge sufficiently to get the shape. The top canvas is drawn over the roof and the edges fastened under the drip moulding that extends all round. The bows inside to support the arch are placed 7.5 inches apart. This construction is sensible and any bodybuilder will guarantee his work made according to this specification.

This style of roof is in harmony with the general body design illustrated, and, moreover, it is a design of roof that is meeting with favor when used in connection with a body design having all the exterior lines rounded.

The style, applicableness of the design for the make of chassis and use for which it is intended, as well as the type of construction, have been detailed in a general way, and also the special features, that is, the extra width of the door opening to the seats and the proper method of determining the cut in the front windshield, have been outlined sufficiently. It now remains to consider the finishing up of the job and the cost.

The finishing up of the body, that is, the nice attention to details and making sure that the job is really complete, is a matter that only the reliability of the firm doing the work is a guarantee for. No specifications can insure thoroughness on the part of the mechanic. The best practice, if cheapness is not the one thing desired, is to buy reliability from a firm with an established reputation, and when making the contract, select from samples, cloth and lace for trimming the seats, doors and sides of the body, cloth or satin for lining the roof, carpet for the floor and silk for the curtains. The toilet cases can be selected from samples and will vary according to price; there should be at least one complete toilet case and one card case and one ash or cigar tray to be put on the doors. Corded hat racks are useful and pockets of ample proportions can be placed one on each side at the front of the door opening and two small pockets can be placed at the rear of the front seat back; this will be useful for those seated at the rear. The interior woodwork is walnut to conform to the finish of the dash and two electric dash lamps are placed in the dash with only the rim and the glass projecting. This is illustrated in Figs. 1 and 5. The current for lighting these lamps will also be used for the dome light in the roof.

The listed color specifications for Chalmers closed bodies, 1912, are upper body panels black, lower body panels either Chalmers blue or Brewster green, and chassis, including wheels and hood, black, and these colors are applicable for the design submitted. The trimming will conform in color to the body color selected.

The cost of a special made body of the design illustrated, finish and appointments to be equal to the stock limousine body, will be approximately $1,300 to the retail trade. This is a fair average price and it can be increased or reduced according to the will of the customer, who may want more or less than specified.

Practical Application of Autogenous Welding to Aluminum

From a Paper Read by Dr. F. Carnaveli Before the Institute of Metals, London, Eng., Continued from Last Week.

THE experiments on this group were carried out with two types of metal, one designated by the letter S (see Table V), consisting of pure aluminium containing 99 per cent. of the metal in the form of rods of two different diameters (30 and 12 millimetres respectively) and of flat bars, 6 millimetres thick; the other sample used during the test was in the form of rods, 15 millimetres in diameter, consisting of aluminium alloyed with 3 per cent. of copper (a type of alloy in common use industrially). The welding material consisted of thin rods of metal of identical composition with both types respectively. The experiments were conducted under precisely the same conditions as those of the previous series, special care being taken to avoid oxidation, to which the metal is so easily liable during the process of welding. For this purpose appropriate deoxidising powders were used.

Micrographic study of the several samples, pursued by the same method as that followed in the foregoing series of investigations, enabled one to identify without difficulty the welding zone by its coarsely granular structure. This structure is a consequence of the high temperature attained by the metal in fusion. In the case of a sample 8 millimeters in diameter and 80 millimeters in useful length which was cooled after welding, the weld zone showed thin, dark filaments which are the margins of the big crystals, while within the crystals themselves are seen small, and exceptionally numerous, dark, rounded inclusions—less abundant in the other samples—formed by the oxide which has remained imprisoned in the metal. In this case oxidation was especially active during the process of fusion. This structure, which repeats itself in the various samples of type S, undergoes modifications varying according to the different treatment to which the metal is subjected. Hammering, for instance, tends to approximate the structure of the weld-zone to the original texture of the metal; while reheating tends to make the texture of the entire weld-zone homogeneous, eliminating the interval strains set up within the metal as a consequence of rapid fusion and similar rapid cooling.

In contradistinction to the phenomena observed in the case of copper, the oxy-acetylene autogenous welding of pure aluminium results in an intimate union between the latter and the welding material, the two substances forming an inseparable corpus.

The data accumulated and the observations made in the course of this series of experiments with the oxy-acetylene autogenous welding of aluminium, show—

1. That sudden heating and rapid fusion of the metal subjected to the welding process alter its physical and mechanical properties in a manner analogous to that observed in the case of copper, though in less degree. They set up within the metal

TABLE IV—SHOCK TESTS MADE ON SAMPLES OF BRASS AND BRONZE WITH THE CHARPY APPARATUS

No. of Sample	Initial Dimensions of Sample	Thermal Treatment	Indicated Angle	Breaking Test Kgr. Mm.	Mean Chemical Analysis: Of the Metal. Per Cent.	Mean Chemical Analysis: Of the Welded Zone. Per Cent.	Remarks
A1	Rods, diameter= 40 millimetres.	Rough fusion.	128°	4.646	Cu=94.2 Sn=5.7	....	Not welded.
A2	Rods, diameter= 40 millimetres.	Reheated.	119°	6.698	....	....	Not welded.
A3	Rods, diameter= 40 millimetres.	Cooled in air after welding.	141°	2.112	....	Cu=94.89	Welded; medium-grained fracture, with small vacuoles.
A4	Rods, diameter= 40 millimetres.	Reheated after welding.	132°	3.807	....	....	Welded; medium-grained fracture, with vacuoles.
B1	Rods, diameter= 40 millimetres.	Reheated.	134°	3.407	Cu=87.9 Sn=11.01 Zn=1.03	....	Not welded.
B2	Rods, diameter= 40 millimetres.	Cooled in air after welding.	140°	2.286	....	Cu=90.2 Sn=9.01 Zn=0.8	Welded; finely granular fracture, with numerous vacuoles.
B3	Rods, diameter= 40 millimetres.	Reheated after welding.	139°	2.464	....	....	Welded; finely granular fracture, with numerous vacuoles.
C1	Rods, diameter= 40 millimetres.	Reheated.	136°	3.019	Cu=87.1 Sn=9.3 Pb=3.48	Cu=89.7 Pd=2.9	Not welded.
C2	Rods, diameter= 40 millimetres.	Cooled in air after welding.	145°	1.457	....	....	Welded; finely granular fracture, with numerous vacuoles.
C3	Rods, diameter= 40 millimetres.	Reheated after welding	139°	2.464	....	....	Welded; finely granular fracture, with numerous vacuoles.

latent internal strains, and modify its structure detrimentally.

2. That the structural modifications, induced by excessively rapid heating during the process of welding, take the form of coarse crystallization of the metal.

3. That, so long as all the necessary precautions are observed in the process of welding, the changes in the mechanical properties of pure aluminium, such as breaking strain, ductility, hardness of the weld-zone, are not very profound, although a notable increase in brittleness is observable, as is shown by the results of shock tests. The presence of copper, however, modifies profoundly in a detrimental sense the mechanical properties of aluminium.

4. That, in consequence of the feasibility of achieving with pure aluminium a perfect and homogeneous weld of the metal, both mechanical (hammering) and thermal (reheating to 450 degree to 500 degree C.) treatment is extremely efficacious, in that it sets up greater homogeneity in the weld-zone, and eliminates the effect of the excessively rapid heating undergone in process of welding, ameliorating consequently the quality of the metal.

5. That whenever aluminium contains small quantities of other elements easily oxidizable at high temperatures (as(for example, copper), the oxidation of the metal in fusion is facilitated, also the inclusion within it of granules of oxide detrimental to the mechanical properties of the weld-zone.

6. That, taking into account the results obtained, as also the foregoing conclusions, we may assert that the oxy-acetylene autogenous welding of aluminium, when carried out with the necessary precautions, is capable of extensive application in practice, especially for the autogenous welding of small parts.

In connection with Table IV it is interesting to note that considerable variations occur in the composition of bronzes and brasses according to the number of constituents of the alloy and in proportion to their affinity for oxygen and to the volatility of the oxides formed therefrom. Thus, in the bronzes of type B, Table IV, in the welded zone, there is an average diminution of 19 per cent. in the proportion of tin; while the loss of zinc, a more easily oxidized metal than tin, amounts to 22.3 per cent. (the original proportion present being smaller than that of tin). In brasses, wherein the percentage of zinc is much higher, its decrease in the welded zone is 28.7 per cent.

TABLE V—SHOCK TESTS WITH THE CHARPY APPARATUS

Number of Sample	Initial Dimensions of Sample.	Thermal and Mechanical Treatment	Indicated Angle	Breaking Test. Kgs. Mm.	Brinell Hardness (average), 50C Kgs.	Remarks
S1	Rods, 20 mm. in diameter.	....	117°	7.181	......	Not welded.
S2	Rods, 20 mm. in diameter.	Reheated.	110°	8.936	27.2	Not welded.
S3	Rods, 20 mm. in diameter.	Cooled in air after welding.	141°	2.112	......	Welded; medium grained fracture; small vacuoles.
S4	Rods, 20 mm. in diameter.	Reheated after welding.	119°	6.698	25.9 in the weld.	Same as above, but no vacuoles.
S5	Rods, 20 mm. in diameter.	Hammered and reheated after welding.	128°	4.646	27.2	Same as above, but no vacuoles.

Harking Back a Decade

FROM *The Automobile and Motor Review*, November 1, 1902:

The Massachusetts Automobile Club, of Boston, although but a babe in years, has already attained to the proportions and vigor of a full grown organization. It occupies a club house expressly built for it. The club was formed in 1900 and now has a membership of 160. Col. James Taylor Soutter is president. Charles J. Glidden is an enthusiastic member.

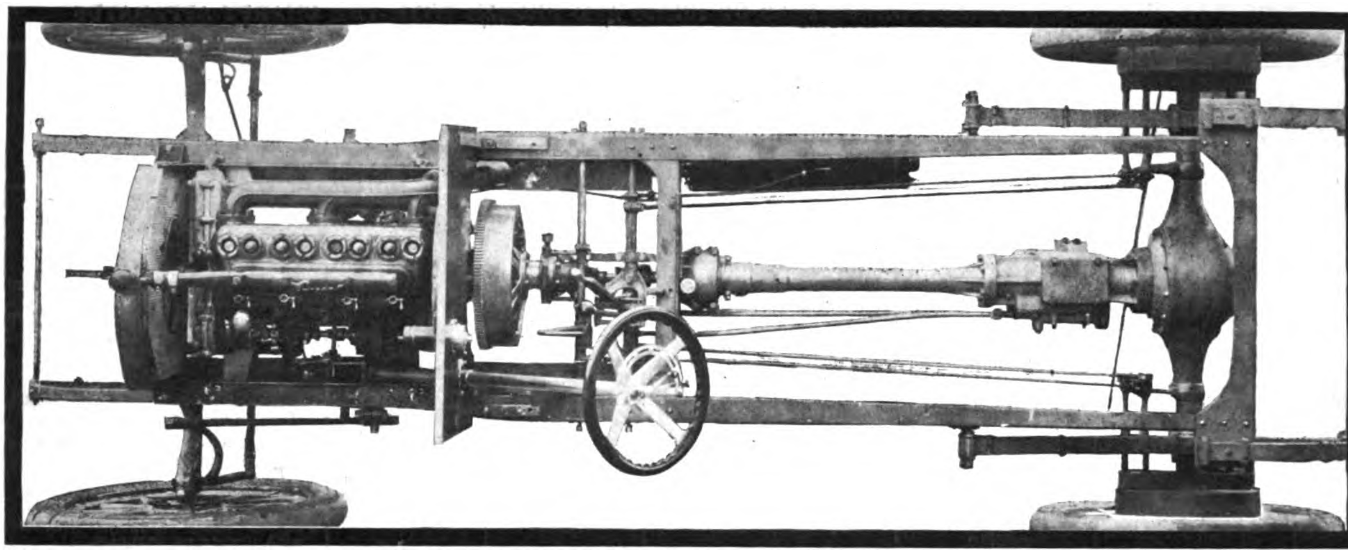
The license clerk at Cleveland, O., has announced that 414 automobiles have been registered by him since the new law went into effect last summer.

The Massachusetts State Highway Commission is at present making an inspection of the main highways of the Bay State, using a Locomobile surrey for the purpose. They will visit 350 towns and will traverse the state from end to end. It is expected that a considerable appropriation will be made to improve the roads in the Berkshires.

J. A. Seitz, of Syracuse, who recently completed a tour through Ontario, reports that the people in the rural districts were almost as badly frightened by the appearance of his automobile as were the horses.

The plan put forward by the Standard Welding Company, of Cleveland, for standardizing automobile rims as to the number of lug holes and spoke holes is attracting much attention. In the 26 and 28-inch rims, there are five lug holes and in the 30-inch size and larger, the number is eight.

The entry list for the fifth exposition of the automobile at Paris closed October 10. The show will open December 10 and remain in session until Christmas.



Chassis of the four-cylinder 1913 Lenox, showing position of the gearbox at the rear of the propeller shaft

Lenox Adds a Six

Motor Develops 61.5 Horsepower on the Block—Four Cylinder Model Will Be Continued

FOR 1913 the Lenox Motor Car Company, Boston, Mass., offers a new six-cylinder car beside the four-cylinder machine. Aside from the difference in the wheelbase length and in the motors, the two are practically the same in constructional features, although the six-cylinder is made somewhat heavier than the four and the parts whose length depends upon the wheelbase are necessarily different in the two models. The wheelbase of the six-cylinder is 130 inches, while that of the four is 118 inches.

The four-cylinder model is practically the same as for 1912, except that a number of mechanical refinements have been introduced, none of which, however, is radical. The aims in making these changes were simplification of construction, greater accessibility, economy of time and attention of maintenance, and the minimization of running expense.

The four-cylinder motor is of the vertical L-head type with the cylinders cast en bloc with the valves at the right side. The S. A. E. rating is 29.8 horsepower, but the engine will develop 45 brake horsepower. The six-cylinder motor is of the T-head type and is larger and more powerful, having a rating of 38.4 by the S. A. E. formula and developing 61.5 horsepower on block tests. It has a bore of 4 inches and a stroke of 5 inches, the exhaust valves being at the left and the intake at the right.

Upper—Four-cylinder Lenox touring car for 1913
Lower—Six-cylinder—note cowl on both models

The cylinders are cast of gray iron and 20 per cent. steel with integral waterjackets so designed that the water circulates entirely around each cylinder. The cylinder blocks are open above the combustion chamber heads and this renders complete cleaning of the waterjackets possible and insures perfect flow of the cooling water. The flange base is wide and with side webs forms recesses beneath the valve pockets covered for the protection of the valve mechanism. The cylinder block is machined rough bored, reamed, aged and finished by grinding, this process eliminating all casting strains.

Pistons Carry Oil Grooves

The pistons are carefully turned and ground, being fitted above the wristpins for four compression rings of the diagonal split eccentric type, ground to size on the edges and peripheries. There are two oil grooves at the bottom of each piston.

The upper half of the aluminum alloy engine base casting carries the main and camshaft bearings, and a central transverse web carries the center main bearings, the lower section being divided by a horizontal web containing the oil pools for the splash lubrication. Below this is the oil reservoir.

The crankshaft is a nickel steel drop forging, the crankpins being 2 inches in diameter and the main bearings 2 inches in diameter forward and 2.125 inches diameter at the center and rear. These being respectively 3.625 and 4.5 inches long, give a total of 11.125 inches bearing length.

The bearings are of nickel babbitt in bronze journals. The camshaft is of nickel steel drop forging 1.125 inches in diameter, with integral cams. The camshaft has three bearings, each 2 inches in diameter and 2 inches long. The camshaft bearings are of phosphor bronze. The shafts are hardened, heat-treated and ground to size. The camshaft is forged with a forward flange to which the timing gear is bolted.

The connecting-rods are I-section drop forged heat-treated steel and carry bronze journals lined with nickel babbitt. The large ends of the connecting-rods carry oil scoops. The wristpins are of hardened steel and are secured in the piston bosses by set-screws.

The valves have nickel heads and carbon steel stems and the ports are 2.25 inches in diameter. The valve tappets are of the mushroom type with set-screws and lock-nuts for adjusting for wear. The stems, tappets and springs are inclosed.

Lubrication is by a spring-returned plunger pump driven by an eccentric off the camshaft. This pump forces the oil to the bearings. The camshafts, crankpins, wristpins, valve tappets and the pistons and cylinder walls are lubricated by splash.

The cooling system consists in a centrifugal pump forcing the water up to the waterjackets to the large radiator, which is 2 inches deeper on the four than on the six. Auxilliary cooling means consist in a large belt-driven fan.

Ignition is by a Mea high-tension magneto driven by a flexible coupling to the water-pump shaft.

The carbureter is of the automatic float-feed two-jet type with a long waterjacket and auxiliary valve controlling the high-speed intake. This has a strangling tube which prevents any accumulation of gasoline at the seat of the auxiliary valve and insures against choking of the motor when accelerated after running slow.

A Gray & Davis electric starter, consisting of a motor and battery, is used. A 6-volt, 90-ampere-hour storage battery furnishes the current for driving the dynamo for starting and lighting.

A cone clutch is employed, faced with leather, beneath which five helical springs being installed in bosses for adjusting the tension. Behind the clutch is a Hartford universal joint. The shaft is coupled to the rear section of the shaft by a squared sleeve in which the sections slip. The rear end is connected in the large globe end of the torsion tube containing the propeller shaft.

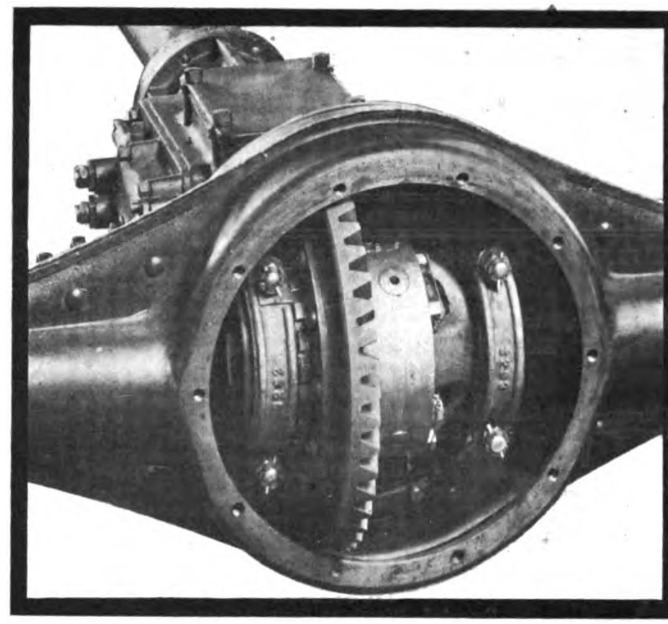
Interlock Provided in Gearset

The gearset is of the selective sliding gear type with three speeds forward and reverse, the driving pinion being on the transmission shaft. There is an interlock between the shafts so that only one of them may be operated at a time. A bronze cage with annular ball bearings carries the differential gear mounting and the bearings may be adjusted at either side to the pinion gear.

The rear axle housing is of pressed steel, the axle being three-quarters floating, of the single-bearing type, with the wheels mounted on annular ball bearings. The driving shafts are 1.5 inches in diameter and the wheels are secured with tapered nuts and keys. The gearset case may be opened at the top or the left side for examination and the differential by removing the cover plate.

The front axle is an I-section drop steel forging 1.75 inches wide and 2.625 inches deep, dropped in the center. The bearings for the pivots are in the yoke instead of in the pivots and the pivot pins are carried in hardened steel bushings. The pivots carry ball thrust bearings at the top and the wheel spindles are fitted with annular bearings.

The springs are of Krupp silico-manganese steel, the front springs being semi-elliptic, 36.5 inches long and 1.75 inches wide, and the rear three-quarters elliptic, 43.5 inches long and 2 inches wide.



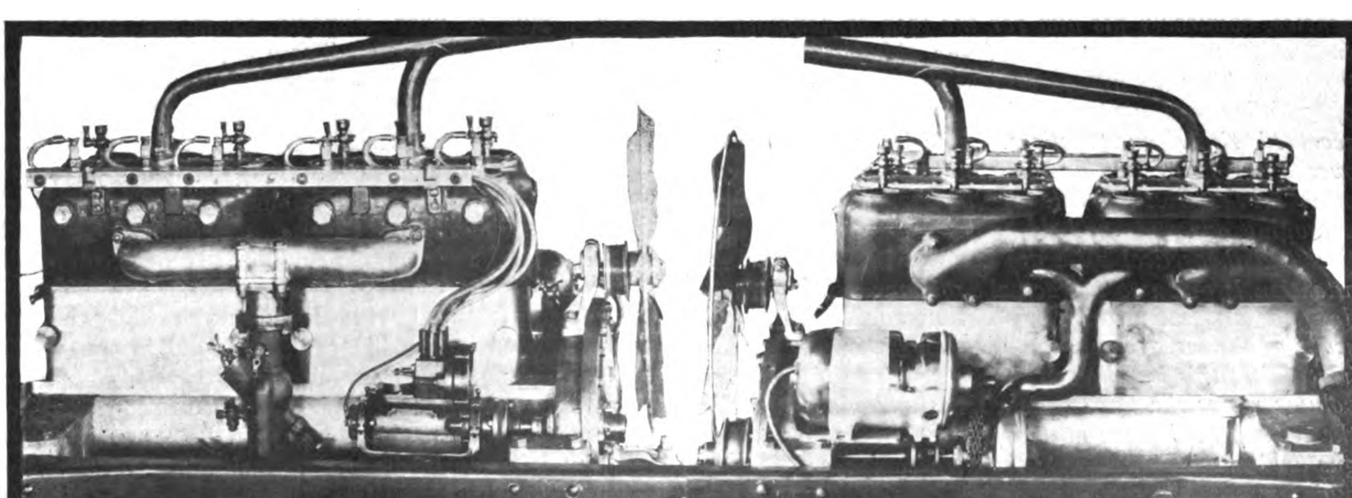
Rear construction, showing accessibility of bevel gear and differential

The wheels are of the artillery type of second growth hickory, 36 inches in diameter and having twelve spokes 1.75 inches wide. The tires are 36 by 4 inches all around.

The frame is a pressed steel channel section 3 inches wide and 4 inches deep, dropped 3.5 inches forward of the upper half of the rear springs. The heavy rear cross-member is carried beyond the side-members and the ends, supported by brackets, form the upper supports for the springs. The frame is stiffened by the clutch rocker shaft and the control lever shaft.

Lenox cars are furnished in four to seven-passenger touring or inclosed types, as well as in roadsters of two, three, four or five-passenger capacity. All types have a cast aluminum cowl. The 17-gallon gasoline tank is installed beneath the front seat.

All cars are fully equipped, having besides the Gray & Davis starting and lighting system mohair tops, lamps finished in black enamel and nickel, quick detachable demountable rims, foot rail, robe rail, tools, tire holders, bulb horn, adjustable windshield and speedometer. Storage space is provided under the rear seats of the touring cars and the rear decks of the roadsters..



Left—Intake side of the six-cylinder Lenox motor, showing the way in which the valves are inclosed. Right—Exhaust side of the motor with Gray & Davis lighting and starting dynamo

Announcement

NEXT week THE AUTOMOBILE *begins the publication of a series of articles on Carburetion by Robert W. A. Brewer, one of the leading European authorities on the subject. The selection of Mr. Brewer hinged on the fact that during the last year he has traveled extensively in America familiarizing himself with the American carbureter field, which fact, coupled with his comprehensive knowledge of the European carbureter tendencies, admirably fits him for the task of handling the subject from the viewpoint of the old world and also the new. This fits him to present the European theories of gasoline and air regulation, as compared with the accepted American practices. The series will extend over a period of two or three months, appearing every other week. Each article of the series will be short, averaging one and one-half pages in length. The practical and theoretical sides are handled in the series, and attention is given to the actual problems with which the designer and manufacturer are concerned. Within the scope of the series comes the question of temperature and heat units; this is followed by the problem of surface to volume ratio; the third article takes under consideration the jet and its design; in the fourth the value of exhaust gas analyses is considered; the fifth compares American and European design in so far as moving parts are concerned, and the succeeding articles treat with other aspects of carburetion.*

Exit the Small Car

The 1913 European Tendencies

EUROPE has ostracized the single-cylinder car. After faithfully nurturing it for over a decade, after developing it to a high stage of perfection, after carrying it to the zenith in the racing field, it has gone down to immediate and inglorious oblivion. Scarcely a relic of it will be found in the offering of France, Germany and England for next year. It has all gone as an avalanche. The single-cylinder type has exited, the small four has occupied the stage. The demand for flexibility has made the change, coupled with the demand for low horsepower rating and low gasoline consumption.

The new four of France, as announced by nearly a score of its prominent manufacturers, has ratings from 8 to 12 horsepower, on a rating which gives the same results as the S. A. E. equation in use in this country and the R. A. C. rating in Europe. True, such a motor is a tiny tot, with its four cylinders in a block casting and often just 2.1 inches in bore and with a stroke of twice that measurement. In millimeters the measurements are 55 x 120, there being very few makers who exceed the 120-millimeter stroke, and with them the bore ranges between 55 and 75 millimeters.

By manufacturing motors of these proportions the efficiency is high and high crankshaft speeds are obtained, in fact, imperative. With such a motor the gear ratio on direct is from 4 to 1 to 6 to 1. With all of them the four-speed gearbox is essential, as it permits of keeping the motor speed up in the efficiency range no matter whether on the level road, on the hill, or on the rough surface. With such motors the fuel economy is from 35 to 45 miles per gallon of gasoline, another essential in continental countries.

European makers are exhibiting much more good judgment in these little cars than merely that of motor economy and flexibility, namely, that weight is being reduced in the general make-up of these cars. A few American makers were early to recognize the merit of weight reduction, but too many of them are still adding more horsepower, adding more weight and cutting the price. This is poor economy to maker and poorer economy to the operator. There is plenty of bore, there is plenty of stroke, and there is plenty of body, but efficiency is lacking all along the line. Refinement and more accurate workmanship are the needs of the hour.

The European small car differs quite radically from the average American small car in that its parts are as finely finished as in the most expensive machines. If shock-absorbers are stock equipment they are in keeping with the gears of the four-speed set, which are of the finest metal manufactured with the highest skill. The ball-bearings used in the big car are found in the smaller one. The same accuracy characterizes every detail of the small creation. Originally the European small car is a more expensive product than the American small car, but it is much cheaper to maintain. Its fuel consumption is very much less; its tire expense is less, and its general maintenance is less because of the materials and workmanship it incorporates.

Trading New Cars for Old Is Bad Salesmanship

President H. O. Smith of the Premier Motor Manufacturing Company Outlines the Standpoint of the Salesman and the Manufacturer and Explains How the Second-Hand Car Problem Will Take Care of Itself

THE automobile is a very live subject. The automobile industry has attracted a tremendous number of very live men—and I can assure you that Indianapolis feels complimented that those men who are gathered here should have spent the time and money that they have in coming to this convention. And may I add that I believe that the selling problem is the big problem, not only with the automobile industry, but with every other line of industry. We soon get to the point where it is not so great a difficulty to produce an article? It may be difficult to produce an article on a basis to properly compete; but the proper distribution of the article, to be able to produce the article could have been made, irrespective of its merits, and then properly distribute it as a problem, and may I say that with the motor car as with all other articles of merchandise nearly, and confining it to the motor car, I believe that a good dealer can hold up a poor car a little while, but a poor dealer cannot hold up a good car very long. Therefore, you see that I place the greatest stress today with the great development of the motor car on the distributor. The development of the motor car and the demand are very natural. It is strictly in line with the times. It is based on the transportation problem, and every agency which has had to do with the transporting of thought, merchandise, or human beings in a more practical and economical way than has been done by other agencies previously employed have invariably met with endorsement and have gone forward.

Prospectives Generally Users

Take the salesman of today: The average salesman that is employed—is it not true that when he first comes to us he presents a list of prospective buyers? Now, follow down this list and what do you find? You find that his list almost invariably includes or is confined to those who today own motor cars, who are already converts to the use of motor cars; but he has conceived the idea that if we pay that man enough money and buy his old car at an attractive enough price to the other fellow, he can possibly place another new car with him. But I want to ask you as practical dealers, have you broadened the influence and scope of the automobile one particle until you have placed that traded-in car, provided it is of any use, if there is any use left in it? I say, No! Of course, we cannot entirely get away from this trading problem, and it is one of the big problems we are all confronted with and wrestling with; but I believe this—as soon as we get to the point where we do not pay any more for the second hand car than the second hand car is really worth or will sell for, that the second hand car problem will to a very great degree take care of itself.

I want all of you dealers to take this as absolutely sincere, and I believe that I am expressing the real feeling of all automobile manufacturers, and I know it is true of the manufacturers of Indianapolis—that they realize and appreciate that the interests of the manufacturer and the interests of the dealer are identical. Every dealer is interested in knowing that the concern with which he is affiliated is prosperous. Every manufacturer on the other hand is interested in knowing his dealer is prosperous.

The manufacturer has two problems—producing and selling. In the selling department every broad gauge distributor must recognize that the dealer associated with his interests is a part ot his selling organization, and why should any dealer join with any distributor that is going to be careless as to the welfare of any part of his selling organization?

We have only scratched the possible surface of the demand for the motor car. The big problem with us today is not—can this country absorb 200,000, 300,000, 400,000 or 500,000 automobiles in a given period? As I see it, the question with us today is—will we develop the uttermost buying power as soon as those cars are delivered?

I could name you one city in the United States which last fall, according to the record, had one automobile, I believe, to every nineteen men, women and children, and yet that city proved to be one of the best markets of the past season. This only gives you a suggestion of the great possibilities that are before us.

Looking at the commercial side of the proposition, the huckster who today is within only 5 or 6 miles of the city and compelled to do his work on land valued at $100 to $1,000 per acre, with good roads and the motor propelled vehicle, instead of being located in or very near to the city limits, will be operating 5, 10 and 15 miles from the city on $150 to $200 an acre land. This is also true of many suburban residents now concentrated about the railroad station when there are hundreds of acres of more desirable land further removed. The tendency of population is away from the city and the suburbanite needs an automobile.

So that, gentlemen, we may all figure without a question on the permanence of the motor car. Why? Because it is a practical proposition. Its demand is on a practical basis. You need not fear anyone who has once kept it, the use of the motor car reverting to the old methods if it is possible for him to continue to have an automobile. It would be just as reasonable for us to think of us turning back to the prairie schooner or the horse-drawn street car as to go back to the old methods of transportation.

The dealer today in many instances when he approaches the manufacturer first asks, not for "Let us see what the details of your product are," but "What is your discount?"

All Are Entitled to Profits

I think there is one of the specific things we might all think about very seriously. The manufacturer is entitled to a fair, legitimate profit. The dealer is entitled to fair, legitimate profit. But there is a limit to what represents a fair, legitimate profit, and the profitable business at the end of the year is not always traced to the largest discount. You must remember that low basic cash list prices and long discounts cannot run together. It ought to be true that the straight cash buyer gets the best price. It is not always so. We very often forget that so much cash and so much allowed for a car do not always represent the net cash return; so that I think it is fair to the manufacturer, and it is to the dealer's interest, to consider the product first that is offered, and the discount second. There is not a dealer in this house but what will say, "I will take a modest but fair discount if I have a product that can sell for the full amount, rather than take an abnormal discount which might carry with it a less profit; a lower price, which does not command cash returns in the majority of instances.

European Patents

ALERT in mind, though dwelling on limited areas when measured with American standards, inventors and engineers of central and western Europe, including the United Kingdom, are ever at work to improve on past practice, especially in the youngest of professions, the automobile industry. Though their efforts attack problems of many classes, a few great tasks seem uppermost in most minds now, these referring to the construction of sensitive carbureters and highly efficient valve mechanisms. At the same time, other details are also being improved, both as regards engine operation and increased comfort of the passengers of the automobile, and some very clever devices proposed to solve the wheel-and-tire problem have been introduced in European patent offices. In this review THE AUTOMOBILE gives abstracts of the most interesting automobile patents which were granted by the British Patent Office during the month of August.

Manufacture of Tires—Describing a new type of mold in which casings are formed.

This patent has reference to a machine for the molding of sectional tires, these being shaped on cores C of elliptical cross-section. While these cores give the inside surface of the casings its shape, the outside is formed by a mold either composed of two parts which are clamped together, or, as in Fig. 1, of packing material P. This is made up from layers of metal or rubber and fabric which are held in position by a wrapper W. The convex portions of the outer mold which serve for the shaping of the casing beads are reinforced by thin metal strips M.

No. 9,321 British—to Margetts International Sectional Tire Company, London, England. Granted August 8, 1912; filed April 15, 1912.

Gasolene Engine Carbureter—Operating on the principle of surface radiation for the evaporation of the fuel.

As Fig. 2 shows, the carbureter referred to in this patent is formed as a chamber C jacketed at J and containing a number of foraminous screens S, onto which fuel is sprayed from a nozzle N which is controlled by a needle valve V. The air drawn in by the engine enters through the carbureter valve V1 mounted eccentrically upon a shaft V2. The opening L in this valve represents a low-speed air passage which remains open even at the minimum motor speed. The air supply which is swept along the curved wall of the chamber C is thereby given a whirling motion and is heated by contact with the jacketed walls, while the starting air is heated by the following device: A cylindrical screen S1 containing concavo-convex screens S2 and inclosed with them in a casing C1, is heated by removing the casing, pouring gasoline over the screens and igniting it, after which the casing C1 is replaced, while air enters through the ports A. The throttle valve T serves to regulate the amount of mixture drawn into the motor, the air used for this purpose being so directed by the valve V1 that it strikes the screens S, whose large surface assists in the evaporation of the fuel sprayed upon them by the nozzle N.

No. 9,504 British—to W. P. Thompson, Liverpool, Eng. Granted August 8, 1912; filed April 19, 1912.

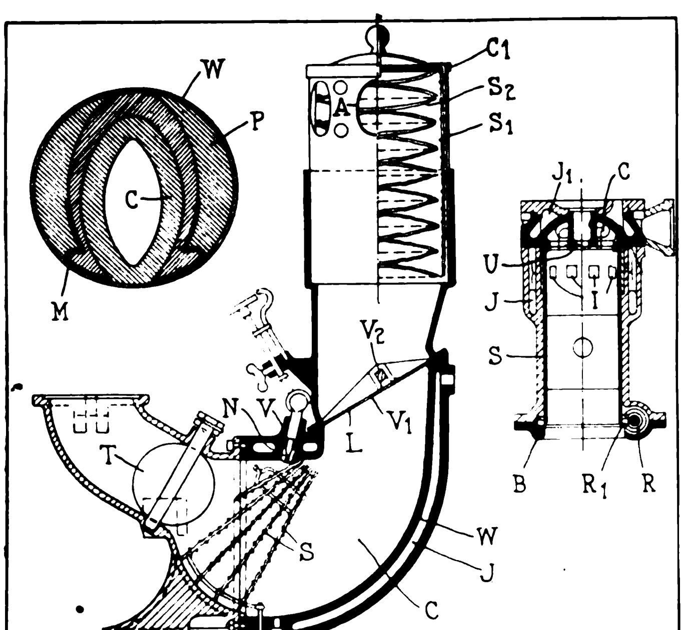

Fig. 1—Margetts tire-making mold. Fig. 2—Thompson screen carbureter. Fig. 3—Gerhardt sleeve-valve motor

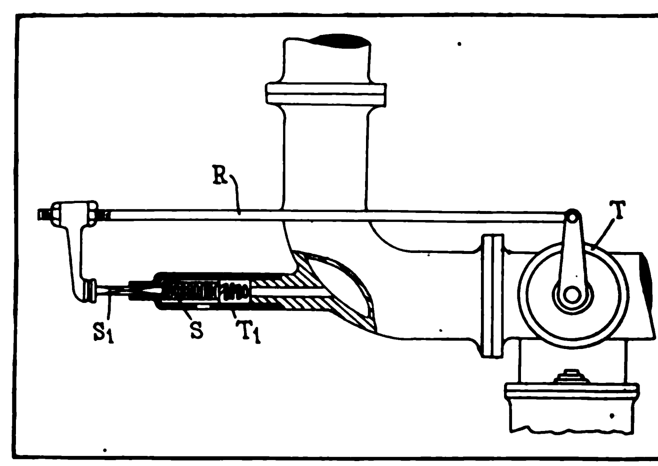

Fig. 4—Webb positive-acting auxiliary air supply for gasoline engine carbureters

Sleeve Valve and Its Cooling—Being a cylindrical valve which is intermittently rotated by a grooved roller.

The sleeve valve S, Fig. 3, is contained inside the cylinder of an internal combustion motor, being closed in the same and having its upper end U fit tightly against the lower surface of the cylinder head, in which an exhaust chamber C is formed. Exhaust ports provide communication between combustion and exhaust chambers when the sleeve is in certain positions, while the admission of fresh gas is governed by a series of intake ports in the wall of the sleeve which are arranged slightly below the level of the horizontal exhaust ports. The fresh mixture before entering the cylinder passes through the jacket surrounding its walls, thereby cooling it, while the same end is obtained in the case of the cylinder head by water circulated through its jackets. The rotation of the sleeve valve S, which is stationary during the compression and explosion strokes, is had by the use of a grooved roller R engaging a series of rollers R1 mounted upon the lower periphery of the valve.

No. 9,741 British—to P. Gerhardt, Wilmersdorf, Berlin, Germany. Granted August 8, 1912; filed April 21, 1912.

Internal-Combustion Motor Carbureter—In which the auxiliary air valve is operatively connected to the throttle shaft and positively operated.

Positive action of the auxiliary air valve of the carbureter referred to in this patent is obtained by using a valve in the form of a spring-loaded sleeve S which has a port in its wall and slides in a tubular support T1. To prevent rotation of the valve, its spindle is squared, and, as Fig. 4 shows, the valve is connected by a link and the rod R to the throttle T so that when the latter is opened to a predetermined extent the sleeve is moved in its support, admitting air through a port in the cylindrical wall of the same.

No. 11,180 British—to G. Webb, Monmouth, Eng. Granted August 28, 1912; filed May 9, 1912.

Pneumatic-Tire Tread Band—Composed of studded fabric or leather which may be bolted to a suitably shaped tread surface.

The subject-matter of this patent are the tire and tire cover shown in Fig. 5. This tire comprises a fabric layer F around which is arranged a leather layer L built in two parts. These

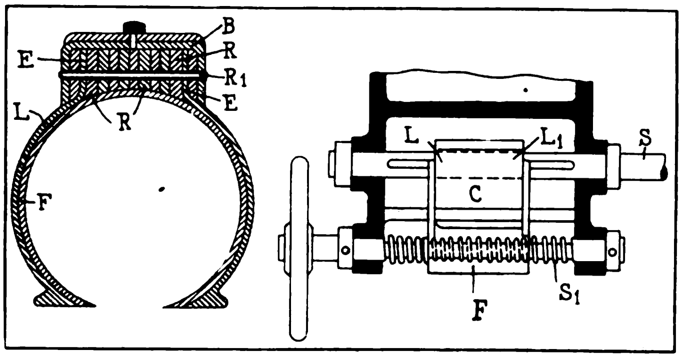

Fig. 5—Withy pneumatic tire tread. Fig. 6—Baird two-cycle motor intake valve

parts have upstanding edges E, between which rings R, made of leather, compressed fabric or any other suitable dense material are secured by tubular rivets R1. The layer L may be covered by a studded rubber or fabric tread band B which is punched and may be secured to the layer by bolts or laces passed through the rivets. It is not necessary to use the tread band with the tire.

No. 11,449 British—to R. Withy, North Camberwell, London, Eng. Granted August 28, 1912; filed May 11, 1912.

Intake Valve Mechanism—In which part of the charge is returned to the compression chamber.

The admission valve, Fig. 6, is designed for the use with two-

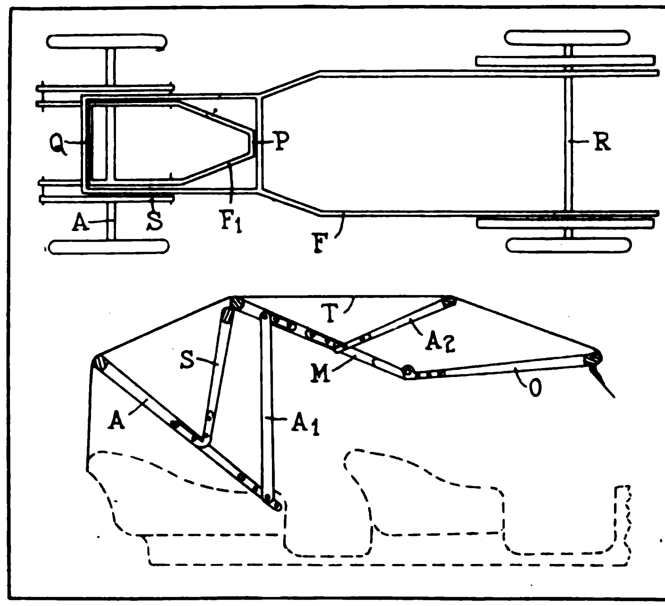

Fig. 7—Cleaver frame and subsidiary frame construction. Fig. 8—Hennessy automobile top construction

cycle motors returning part of their charge to the crankcase or whatever compression space takes the place of the same. The valve is actuated by a cam C mounted on a spindle S and adjusted axially by a fork F which engages a screw S1. The cam has surfaces of different lengths. L and L1, which determine the period during which the admission valve remains open.

No. 11,340 British—to J. O. Baird, North Shields, Eng. Granted August 28, 1912; filed May 10, 1912.

Motor Vehicle Design—Comprising a secondary frame upon which the front portion of the vehicle is carried.

This patent refers to the construction of an automobile, as shown in Fig. 7, in which the main frame F is carried by the rear axle and resiliently supported on it. At two points, P and Q, a subsidiary frame F1 is pivotally connected to frame F in a substantially longitudinal, horizontal axis. The subsidiary frame is also given a resilient support by spring S which rests upon the front axle.

No. 9,444 British—to H. C. Cleaver, London. Granted August 8, 1912; filed April 18, 1912.

Automobile Top Construction—In which the top is attached to the body at two points only.

This patent refers to a top construction, Fig. 8, in which, on

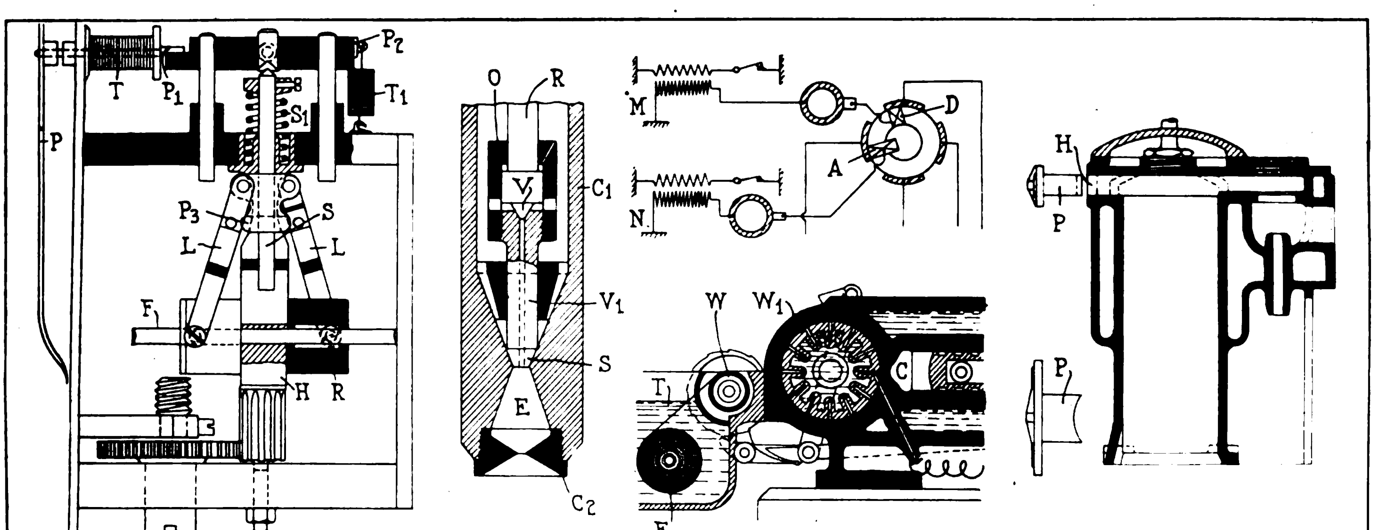

Fig. 9—Robinson centrifugal speedometer. Fig. 10—Breuer fuel admission device. Fig. 11—Bosch two-magneto ignition. Fig. 12—Thorn explosive motor. Fig. 13—Wingfield cylinder-cleaning design

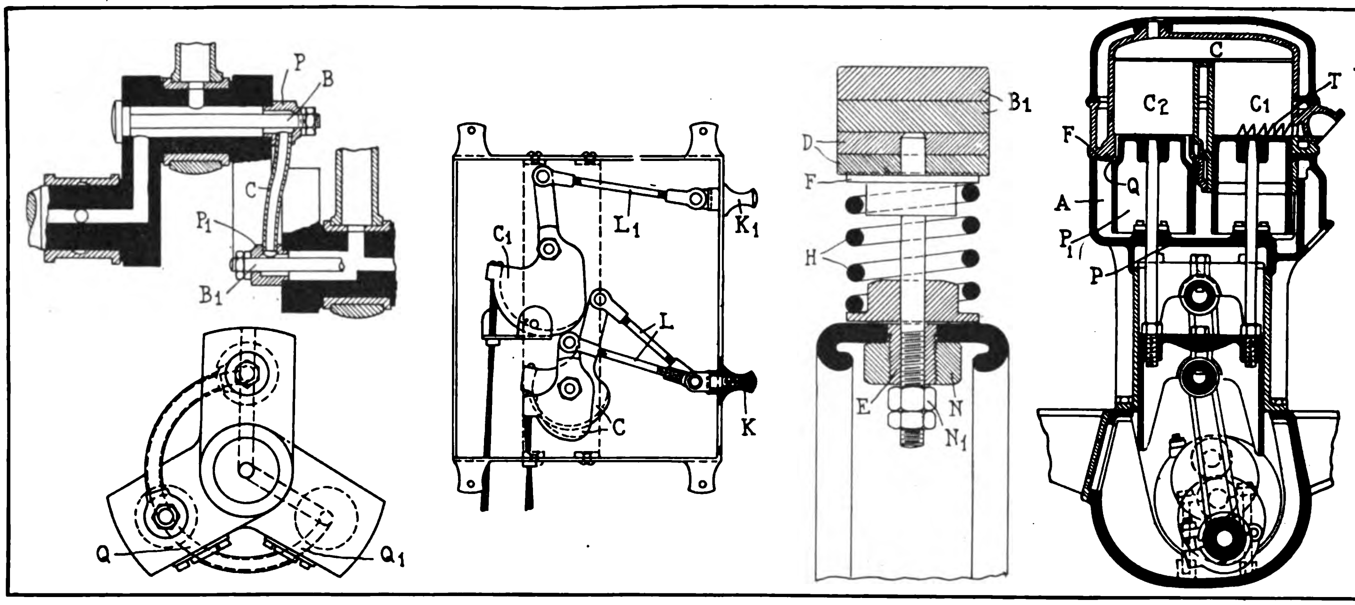

Fig. 14—Delaunay-Belleville crankshaft lubrication. Fig. 15—Bowden control mechanism. Fig. 16—Sutcliffe coiled-spring automobile tire. Fig. 17—Giles twin-cylinder automobile engine

each side of the top, an arm A is hinged to the body of the vehicle at V, at the rear of the entrance doors. The arm A is connected to the arm M by the hinged rod A1 and the short arm S. An outrigger arm O extends over the driver's seat, and an auxiliary arm A2 supports the top material T.

No. 9,334 British—to A. Hennessy, Liverpool, Eng. Granted August 8, 1912; filed April 26, 1912.

Centrifugal-Force Speedometer—In which weights move radially on a transverse rod.

This patent refers to a centrifugal speedometer, Fig. 9, construction in which the indicator is moved by a spring control. The rotating masses R which serve as a governor are carried by a hollow central spindle H, they being free to move radially on the transverse rod T. As they move, they lower through links L the spindle S which is axially positioned in the spindle H and movable independently of the same. The depression of the spindle S acts against the resistance of a spring S1 which is followed by a plate P2 pressed down by the springs T and T1. The latter spring tends to rotate the indicator P so that its movement is arrested by the abutments of the eccentric pin P1 against a cutaway portion of the plate P2.

No 9,929 British—to J. W. Robinson, London. Granted August 14, 1912; filed April 24, 1912.

Internal-Combustion Engine—Describing a fuel admission device for a type of engine in which liquid fuel and air are admitted to the engine cylinders.

The subject-matter of this patent, a fuel admission device, is seen in Fig. 10. It consists of a conical valve V seated in the throat of a Venturi tube. When fuel is admitted to the interior of the casing C1 it passes to the top of the valve seat S, and, when the valve rod R lifts, lost motion between valve V and its cap causes the valve V to be opened first. As the rod R is lifted further, the valve V1 is unseated and fuel is admitted into the expansion chamber E where air is mixed with it and whence it is passed through an orifice in the removable cap C2.

No. 10,365 British—to A. B. Breuer, Manchester, Eng. Granted August 21, 1912; filed April 28, 1912.

Magneto Ignition for Automobile Motors—Comprising two current sources independent of one another and operable on the same set of spark-plugs.

The invention to which this patent relates consists in the use of two distinct sources of ignition current, one of which is used for starting and the other during the continued running of the motor. Confusion of the currents is prevented by the use of a distributer in the secondary circuits. The diagram, Fig. 11, shows the arrangement of this ignition system for a four-cylinder motor. The distributer arm D is connected to the magneto M serving for normal running of the motor, while the arm A is connected to the starting magneto N, which latter may be driven by hand or by a spring wound by the driver or the engine. The angular distance of the arms D and A corresponds to the difference in timing for starting and normal runninng.

No. 9,840 British—to Robert Bosch, Stuttgart, Germany. Granted August 14, 1912; filed April 22, 1912.

Explosion Motor Proper—Utilizing as fuel an explosive which is decomposed when submitted to an electric or other kind of shock.

An engine which is driven by the use of an explosive instead of a fuel burning in the presence of oxygen is shown in Fig. 12. The explosive E, in the shape of one or more bands, is kept in a water tank T on a wheel submerged in water, whence it is fed to a drying wheel W and to chambered wheel W1. The latter cuts off pieces of the explosive band or bands, the size of these pieces being capable of regulation. In a cylinder C the explosive is exploded by an electric spark.

No. 10,011 British—to M. Thorn, Hamburg, Germany. Granted August 14, 1912; filed April 25, 1912.

Cylinder Cleaning Opening—Which is provided in the upper portion of the wall and is ordinarily closed by a plug.

A cylinder may be cleaned upon removing a plug P which fits into a hole H formed in its wall, Fig. 13. The most advantageous position is opposite the valves, or, at any rate, such that the valves and spark-plug will not be interfered with upon cleaning the interior of the cylinder.

No. 9,994 British—to W. Wingfield, Norbury, Surrey. Granted August 14, 1912; filed April 25, 1912.

Method of Lubricating Crankshafts—In which the influence of centrifugal force is overcome.

The lubricating systems for bored crankshafts illustrated in Fig. 14 is applicable to engines whose shafts have at least three crankshaft throws between each two bearings. The lubricant flows through circular tubes C, which are either secured to connecting pieces P, P1 fastened to the crankpins by bolts B, B1 or to flanged pieces registering with passages Q, Q1. In either case the use of passages C avoids the deterring effect of centrifugal force upon the lubricant passing from end crankpins to the middle of the shaft.

No. 10,629 British—to Soc. Anoyme des Automobiles Delaunay-Belleville, St. Denis, Seine, France. Granted August 21, 1912; filed May 2, 1912.

Driver's Control Mechanism—Comprising a group of Bowden wires.

This patent has reference to a control system as seen in Fig. 15. Bowden wires are used to provide connections between the mechanisms to be governed and knobs K and K_1, which are fastened to the dash and in reach of the driver. Each wire is operated through a cam C, C_1 and a link L, L_1, in turn actuated by the knobs mentioned. The latter are forced to move in a straight path by the shape of their bearings.

No. 10,661 British—to Bowden Brake Company, Birmingham, Eng. Granted August 21, 1912; filed May 2, 1912.

Mechanical Automobile Wheels—In which helical springs are used to insure resiliency and leather to form the tread surface.

In this wheel, Fig. 16, a series of studs are used which are formed, near their outer ends, with collars having flanges F. The inner ends of the studs are screw-threaded and pass through flange blocks D. The latter are held in place inside the rim by screwed extensions E and nuts N. Between the flanges helical springs H are in position which provide resiliency. The flexible portion of each wheel is made up by a rubber or leather-band tread B and non-stretchable belting D. Lateral movement of the tire is averted by the engagement of the extremity of the stud and a circumferential slot. The tire is put in place on the wheel felloe by drawing in the studs, this being done by means of the nuts N_1.

No. 10,722 British—to E. Sutcliffe, Brighouse, Yorkshire, Eng. Granted August 21, 1912; filed May 3, 1912.

Internal-Combustion Engine—In which a pair of cylinders is formed with a common combustion space.

The engine described in this patent and shown in Fig. 17 has a pair of cylinders having a combustion space C in common. The front ends of the cylinders open into a single compression chamber separated by a partition P from an inclosed crankcase. Through the port X a combustible mixture is allowed to enter the pump space A, passing thence to the cylinder C_2 through inclined ports Q in the piston P_1. The exhaust leaves through triangular ports T. A flange F supports the cylinders on the top portion of the basechamber.

No. 10,563 British—to J. A. Giles, Derby, Conn., U. S. A. Granted August 21, 1912; filed May 1, 1912.

Internal-Combustion Motor Valve—Being of the rotary distributer type.

The rotary valve V, Fig. 18, serving inlet and exhaust controls a port P covered by the piston when at its upper center and has passages E_1 and E_2 leading to the inlet and exhaust manifolds, respectively. These passages are so inclined as to have their axes intersect near the port P. The valve body has recesses in which sliding pieces are contained, being pressed away from the cylinder by springs. Thus, during compression and power stroke, tight fits are obtained between the valve body and the inlet and exhaust passages. The manifolds F_1 and F_2, for inlet and exhaust, have removable covers G_1 and G_2, so that, when the valve is withdrawn, access may be had to the port P.

No. 11,300 British—to H. V. J. Jouffret, Paris, France. Granted August 28, 1912; filed May 10, 1912.

Automobile Carbureter—In which the proportions of hot and cold air may be regulated.

The subject of this invention is seen in Fig. 19, showing a hollow tube T with a perforated conical end E located above the mixture tube M of the carbureter. Tube M is surrounded by a chamber C containing a helical rib H and heat-absorbing packing. Exhaust gases passing through C heat the rib H. For starting the tube T, through which the hot-air supply enters, is heated by wires W_1 connected with a battery, while cold air may be admitted through valve V. The valve W controls the mixture produced by the air entering through holes H_1 and fuel from the nozzle N.

No. 10,988 British—C. T. B. Sangster and W. Evands, Birmingham, Eng. Granted August 28, 1912; filed May 6, 1912.

Intake Valve Gear—Referring to motors to be operated by compressed air when ignition system fails.

This patent relates to a type of internal-combustion motor which is now principally used for marine purposes, and in which compressed air is used for starting as well as in case of failure of the ignition system. The compressed air is admitted to the cylinder by way of a mechanically actuated valve V, Fig. 20, and an automatic one V_1, which is so constructed that pressure and duration of air supply is automatically regulated, to prevent the admission of air when the engine operates on the ignition system and under reduced loads. The valve V has a double stroke and during part of the explosion stroke it is opened by forward or reverse cams C, which are tapered and axially adjustable. The control is by a lever connected to the throttle and a pressure-reducing valve in the compressed-air passage.

No. 11,230 British—to C. H. T. Alston, London. Granted August 28, 1912; filed May 9, 1912.

Multi-Jet Carbureter—In which the fuel jets are formed by grooves in the carbureter casing.

In this carbureter, Fig. 21, gasoline enters through the float-chamber F cast integral with the carbureter casing C, whereby a space F_1 is formed which serves as a hot-air jacket. The fuel passes from F to a series of jets P_3 which are formed as grooves in the conical surfaces of the casing C and a liner L and are arranged over one-fourth of the inner circumference of C. The suction-actuated piston P regulates both the hot-air and fuel supply through P_1 and the auxiliary-air supply entering by way of P_2. It has a triangular port Q with apex uppermost to control the number of jets in action. To keep constant the length of the port portion of P_1 open to incoming air, a triangular port is placed adjacent to Q. Air ports P_2 are controlled by ports Q_1 in P, registering with them and thereby providing passages. The baffle B on the piston P is designed to facilitate the mixing of air and fuel.

No. 11,167 British—to H. Lindblom, Liverpool, Eng. Granted August 28, 1912; filed May 9, 1912.

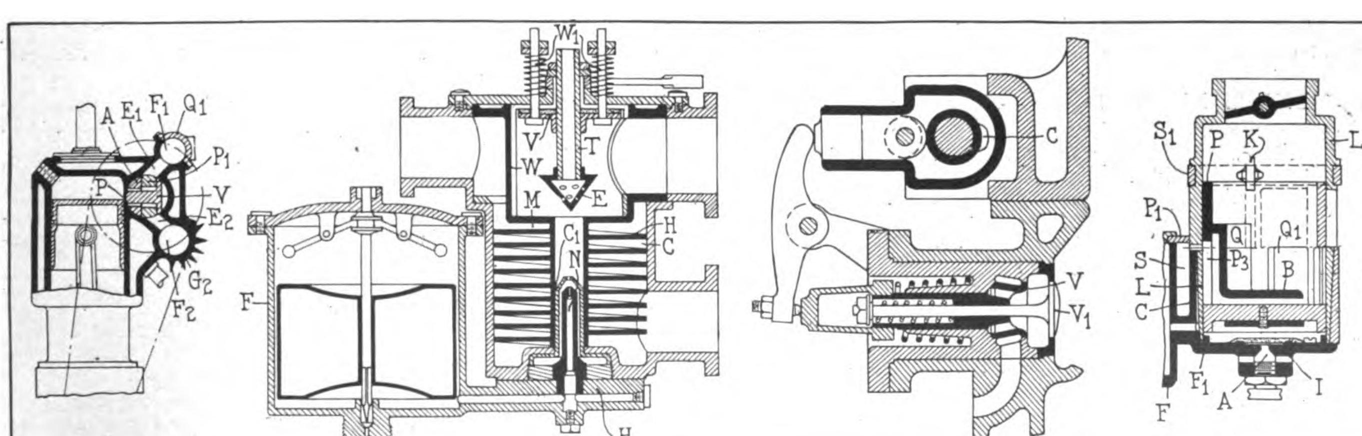

Fig. 18—Jouffret rotary valve automobile motor. Fig. 19—Sangster-Evands carbureter adjustable for hot-and-cold air ratio. Fig. 20—Alston intake valve gear. Fig. 21—Lindblom carbureter.

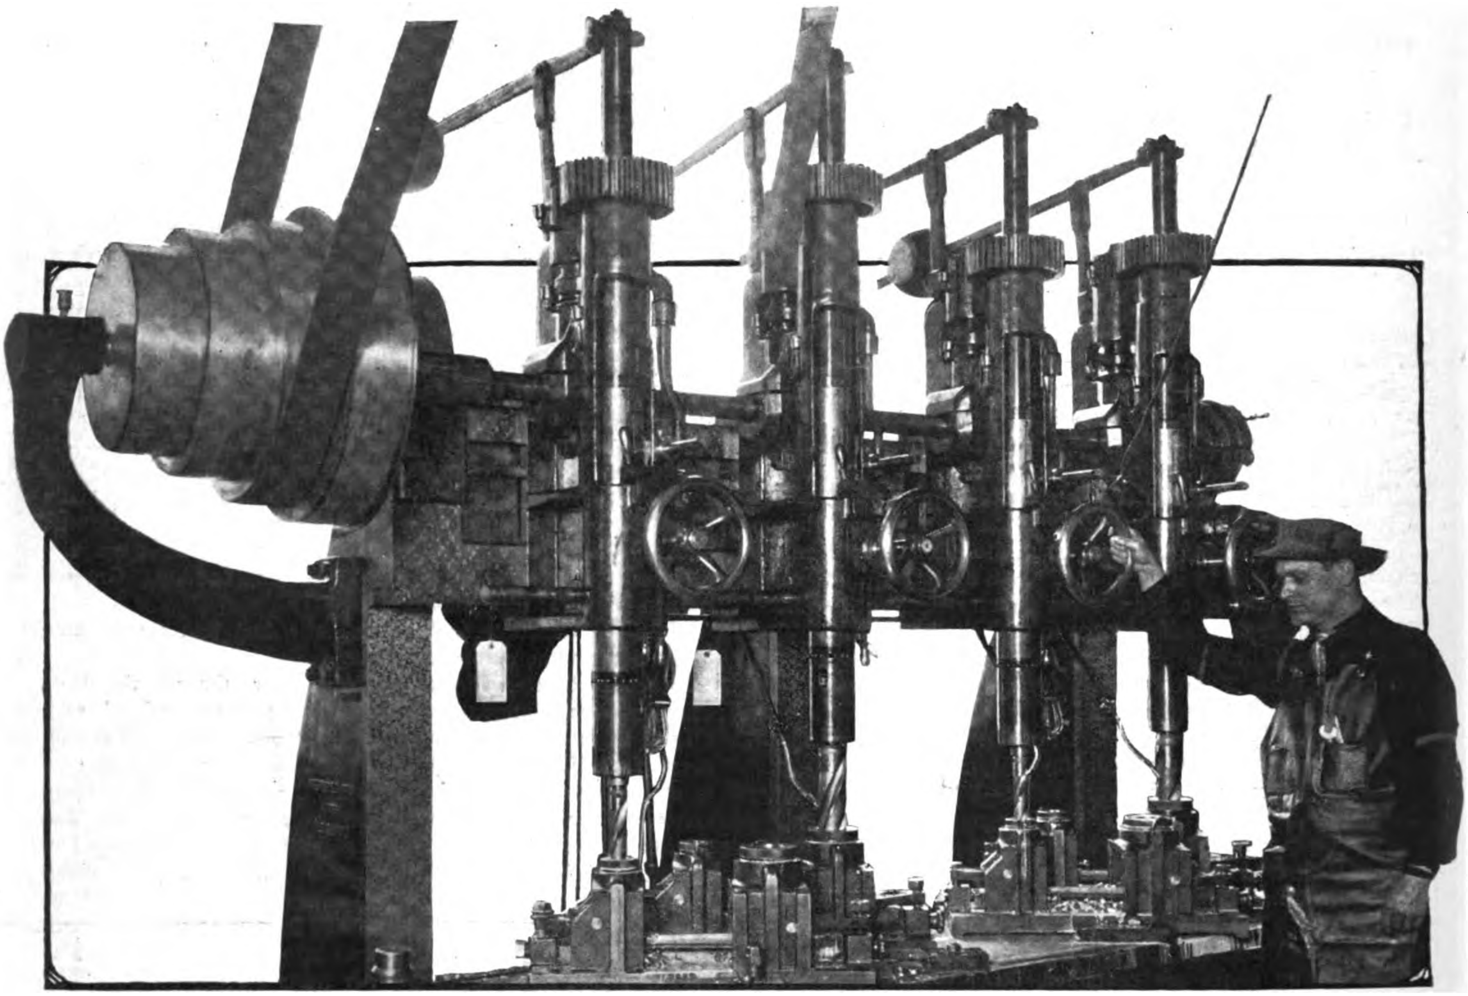
Factory Miscellany



Connecting-rod boring machine used by the Chalmers Motor Car Company, Detroit, Mich. It turns out 300 rods per day

Chalmers connecting rods are made in quantities. In the above illustration is shown a machine that is a true time-saver. This machine has been used extensively in locomotive building and has proved its merit in the shops of the Baldwin Locomotive Works. It has been taken over by only two automobile concerns for use in the manufacture of connecting-rods, the Chalmers company being one of them. This machine can turn out a completely bored connecting-rod in 3 minutes. It takes an operator and a helper to work it and by its use they can turn out approximately 300 finished connecting-rods in one day. Before the installation of this big machine the work was done on three small machines, each requiring a man to run it and the combined capacity was seventeen connecting-rods. The machine has been rebuilt from its original form and now has three spindles, allowing many parts of the work to overlap each other when the operator and his helper are working together. The saving of time and money has been considerable but what is of equal importance is the saving in total floor-space required per part produced. In other words, the output has been increased while the required space per part has been decreased, thus securing a highly desirable point in the increase of factory efficiency.

KLINE'S Richmond Plant—Twenty employees of the Kline Motor Car Corporation, York, Pa., including a number of mechanics and other workmen, left recently for Richmond, Va., in order to install the machinery and complete the other preliminaries for the opening of the company's new plant in that city. The factory is built in two parallel wings, connected at one end by a shorter wing, in front of which and connected with it is a two-and-one-half-story office building. The material is brick and the trimmings are of white stone. The structure stands on a concrete foundation and the floors of the factory are cement. The accompanying illustration shows the factory.

Electric Company Incorporated—The Electric Motor Sales and Repair Company is the name of a new plant recently incorporated to do business in Winnipeg, Man.

Cadillac's Addition—The Cadillac Motor Car Company, Detroit, Mich., has taken out a building permit covering the erection of an addition to its plant, to cost $29,000.

Goodyear Building—The Goodyear Tire & Rubber Company, Akron, O., is having plans prepared for two large additional factory buildings, the erection of which will be started early next spring.

Purchase Findlay Property—A group of Toledo, O., and Lima capitalists have formed a syndicate with a view to purchasing the property of the Findlay Motor Company, Findlay, O. If the deal is consummated the plant will be operated at Findlay.

Knight Builds Addition—The Knight Tire & Rubber Company, of Canton, O., which recently increased its authorized capital stock from $331,500 to $1,500,000, will erect a large addition to its plant. When the new structure is completed the capacity of the plant will be largely increased.

Hart Company in Canada—The Hart Accumulator Company, of London, Eng., manufacturer of storage batteries, will establish a factory in western Canada. E. J. Clarke, managing director of the company, will recommend that a large plant be built at either Winnipeg or Fort Williams, Ont.

Only Temporary Quarters—The Lavigne Gear Company, formerly of Corliss, Wis., and now located at Racine, Wis., is temporarily occupying part of the old Racine-Sattley Company's plant, and the recent move was in line with its plans to establish a permanent home of its own in Racine. The Lavigne company during last week occupied factory No. 17 of the Racine-Sattley works, affording 48,000 square feet of floor space. Two hundred men are now employed, and the output is being considerably enlarged. As soon as the officers have selected a site for permanent location, ground will be broken for a large and modern fireproof factory.

Rebuild Forge Shops—The Studebaker Corporation is preparing to rebuild the forge shops at Clark street, Detroit, Mich.

Chalmers to Build—The Chalmers Motor Car Company, Detroit, Mich., has given construction contracts for a plant addition.

Hudson Plans Addition—The Hudson Motor Car Company, Detroit, Mich., plans to build an addition to its plant at Oakland, Cal.

Crose Truck's Factory—The Crose Auto Truck Company is taking bids for a two-story truck factory, 80 feet by 140 feet, to cost $30,000.

Jackson's Factory Plans—The Jackson Motor Car Company, Jackson, Mich., contemplates a branch factory, to cost approximately $200,000.

Kelly Awards Contract—The Kelly Motor Truck Company, Springfield, O., has awarded the contract for the erection of its proposed factory addition.

Eclipse Enlarges—Contracts have been let by the Eclipse Machine Company, Elmira, N. Y., for an addition, 125 feet by 60 feet, to their factory building.

Federal Building—The Federal Motor Company, Indianapolis, Ind., has given a contract for a factory addition, one-story high, and to cover 50,000 square feet.

Truck Company Builds—The Hydraulic Auto Truck Company is planning the erection of a plant at Los Angeles, Cal., for the manufacture of hydraulic trucks. W. E. Barnes is president, and D. L. Whitford is general manager.

New Birmingham Company—Automobile tops, cushions and covers are being manufactured in Birmingham, Ala., by the recently organized Birmingham Auto Top Company. This is the only plant of its kind in the South. The company is capitalized at $60,000, which was subscribed locally. C. R. Christopher and C. G. Ryan organized the company and are at the head of its management.

Calendar of Coming Automobile Events

Shows, Conventions, Etc.

Nov. 16-23........Atlanta, Ga., Annual Show, Auditorium-Armory, Atlanta Automobile and Accessory Association.
Jan. 2-10..........New York City, Importers' Salon, Hotel Astor, Importers' Automobile Alliance.
Jan. 4-11..........Cleveland, O., Annual Automobile Show.

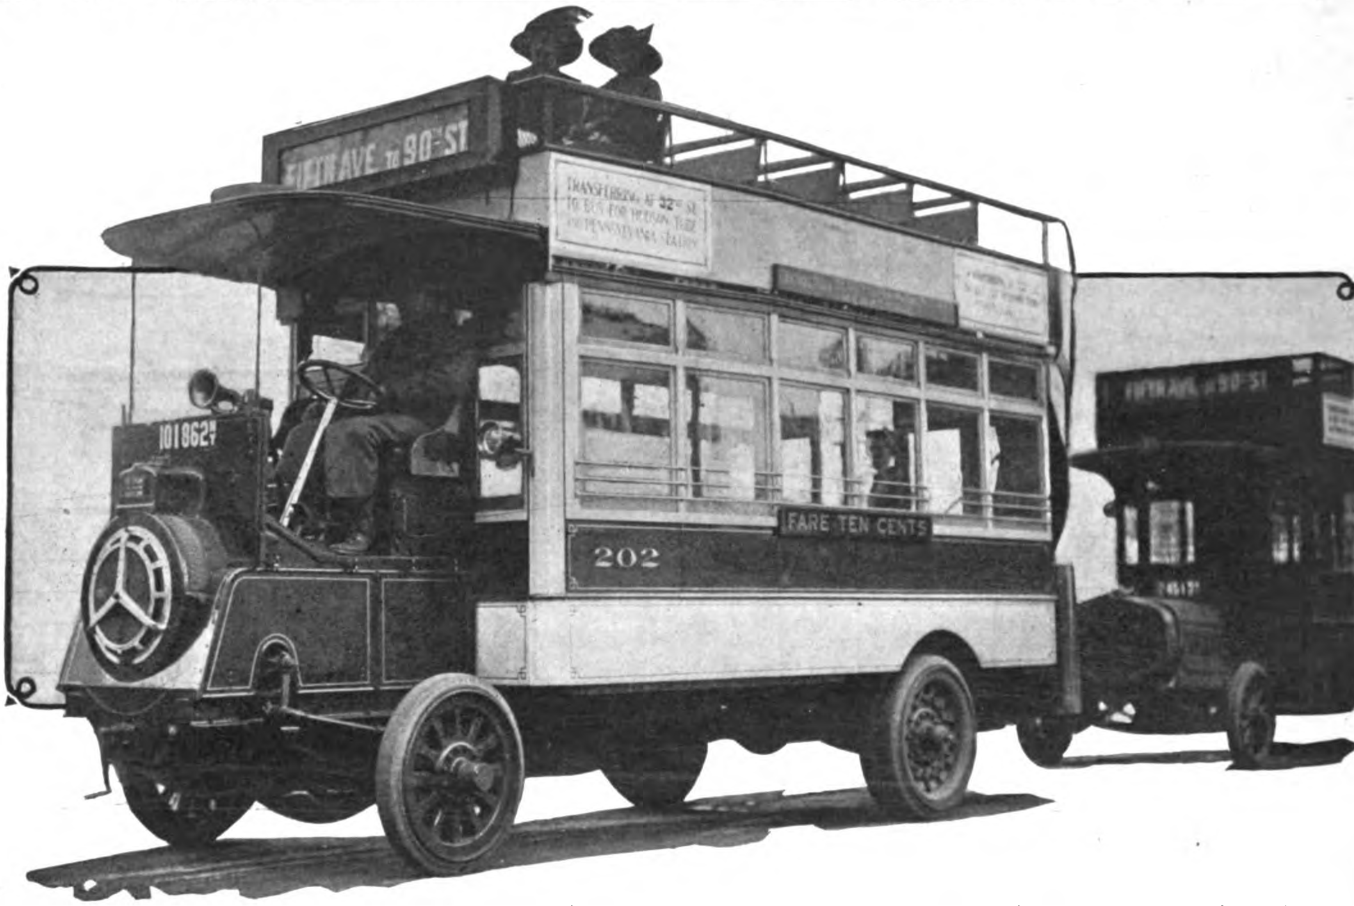
New factory of the Kline Motor Car Corporation at Richmond, Va., to which the company is now moving its machinery and equipment



New type of De Dion bus adopted by the Fifth Avenue Transportat ion Company, New York City. Old type is shown in the background

NEW De Dion Bus—The Fifth Avenue Bus Company, Æolian Building, New York City, recently purchased a De Dion bus. Its horsepower is 36, bore 110 millimeters, stroke 130 millimeters; the wheelbase is 13 feet, and the weight 10,000 pounds. Its inside carrying capacity is 25 and the outside is 22. It has three speeds forward and one reverse. The above photograph gives a comparison of the old style of bus and the new.

National Moves in Boston—W. H. Stevens, who has the National agency in Boston, Mass., has moved from the Autocar building on Beacon street to 1920 Boylston street near Massachusetts avenue.

Limric as a Lecturer—Howard B. Limric, manager of the New England branch of the Goodrich Rubber Company recently delivered a lecture illustrated with lantern slides to the students of the Boston Y. M. C. A. automobile school.

Lowe Makes a Change—L. H. P. Lowe, formerly connected with the Charles T. Jeffery Company, of Boston, Mass., handling the Rambler line, has resigned to accept a position as sales manager of the Dodge Motor Vehicle Company in that city.

Ford Removes—The Ford Motor Company, Philadelphia, Pa., has removed to 257-259 North Broad street. The past week also witnessed the opening of the Ford company's new service and assembly building at South Sixteenth street and Washington avenue.

Bay State A. A. Plans Banquet—The officials of the Bay State A. A. of Boston, Mass., are planning to hold the annual banquet of the association in Boston on December 8 and some of the prominent manufacturers will be invited to address the members.

Shouse Sales Manager—E. A. Shouse has been appointed sales manager of the C. & F. Motor Car Company, San Francisco, Cal.

Large Contract Given—The Jackson-Church-Wilcox Company, Saginaw, Mich., has closed contracts for a volume of steering gears for 1913 cars between 75,000 and 85,000.

Premier's Fall Display—The Premier Motor Sales Company, Indianapolis, Ind., is holding its annual fall display and opening in its salesrooms in North Delaware street. The rooms are attractively decorated in autumn leaves and the complete Premier line is on display.

Roberts Resigns—Thomas R. Roberts has resigned the sales managership of the United Motor Philadelphia Company and formed a co-partnership with Charles M. Reeves, to take over the local agency of the Marion. Under the firm name of Roberts & Reeves headquarters have been established at 1336 Race street.

Minnesota's Road Improvement—Contracts for construction of 2,700 miles of highway in Minnesota next summer will be authorized by the state highway commission. Seven hundred miles will be absolutely new road in the northern part of the state. Surveying, stumping and sand hauling will be done in the winter. The mileage will be completed by fall.

De Tamble's Troubles—E. N. Hill, Thomas De La Hunt and Frank F. Taylor have been appointed by H. C. Sheridan, referee in bankruptcy, to take an appraisement and inventory of the property of the De Tamble Motors Company at Anderson, Ind. When the appraisement and inventory is completed, the property will be offered for sale. J. C. Teegarden was recently appointed trustee to represent about $75,000 worth of unsecured claims against the company.

New Agencies Established During the Week

PLEASURE CARS

Place	Car	Agent
Albany, N. Y.	Franklin	Clarence G. Heck.
Aledo, Ill.	Moon	E. B. Miller.
Anaheim, Cal.	Henderson	P. J. Weisel & Co.
Baltimore, Md.	Stutz	Stutz Sales Co.
Buffalo, N. Y.	Wagenhals	Edgar C. Messersmith.
Butte, Mont.	Packard	Montana A. Gar. Co.
Calvert, Tex.	Henderson	G. T. Bergeson.
Cambridge, Md.	Marathon	E. J. Brannock.
Canton, O.	Moon	Auto Service Co.
Cincinnati, O.	Havers	Western Motor Car Co.

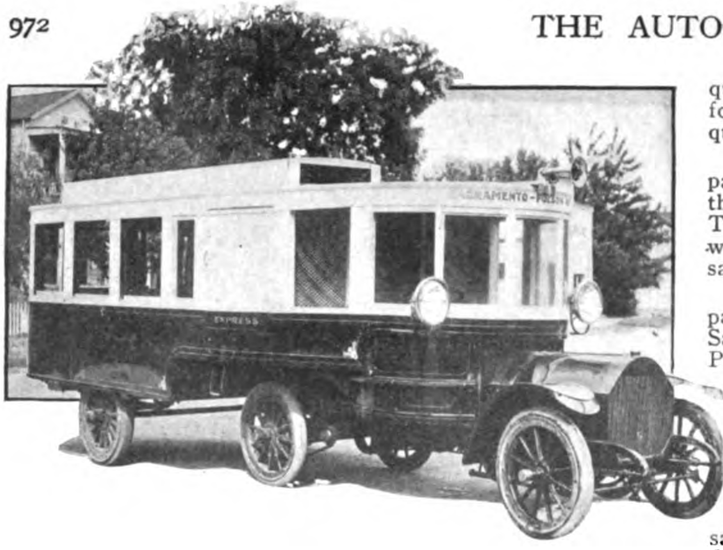
In the oil fields it is getting to be quite a common occurrence to see the shooter drive up to a well on his motor-driven shooting wagon. The trucks used by the American Glycerin Company have a carrying capacity of 720 quarts of nitro-glycerin in addition to the shells used for lowering the explosive into the well. From records kept on the operation of these trucks, it is found that about two-thirds more work can be accomplished than was formerly taken care of by horses. These trucks are from the factory of the Adams Brothers Company, Findlay, Ohio, and outside of specially built bodies the balance of the car is the Adams stock chassis



Novel Locomobile stage coach in service between Sacramento and Folsom, Cal. It makes two trips a day, averaging 90 miles

Bendel Supplants Bremer—M. D. Bendel has succeeded F. G. Bremer as manager of the Twitchell-Gauge Company, Chicago, Ill.

Elmer Leaves Grant—H. H. Elmer, general manager of the Grant Motor Car Company, Cleveland, O., has severed his connection with that concern.

Automobile Value Placed—The basis of valuation of an automobile has been placed at $600 for Oshkosh, Wis., cars and $300 for those owned in the country districts.

Schwartz Resigns—A. E. Schwartz has resigned as general manager and treasurer of the Bergdoll Motor Car Company, New York City. His resignation takes effect on November 7.

Baker Increases Space—Additional show room quarters for the Baker electric, Philadelphia, Pa., have been established at 1927 Market street by the Carroll A. Haines Company.

Goes to Olympia Show—R. M. Lockwood, manager of the foreign department of the Regal Motor Car Company, Detroit, Mich., has gone to England to attend the Olympia Show in London.

Moline Self-Starter Equipped—The Moline Automobile Company, East Moline, Ill., will equip its 1913 car with an electric self-starter and lighting system, each operating independently of the other.

Alco Moves—The Longstreth Motor Car Company, Philadelphia, Pa., dealers in the Alco line, will about November 15 remove to the company's new sales and service building, 2126-28-30 Market street.

Smith-Milwaukee Delivery—The A. O. Smith Company, of Milwaukee, Wis., has just made delivery of a squadron of four Smith-Milwaukee worm-drive trucks to The Texas Company at its Chicago, Ill., branch.

Buick Show a Success—The second annual show inaugurated by the Boston branch of the Buick Motor Company closed last week and it proved a success. Other dealers are thinking of doing the same thing during the fall season.

Lee Tire in West—The Lee Tire & Rubber Company, Conshohocken, Pa., will be represented in the West by Chanslor & Lyon, whose branches are at San Francisco, Cal.; Los Angeles, Fresno, Portland, Ore.; Seattle and Spokane, Wash.

Kliesrath Visits Europe—V. W. Kliesrath, chief engineer of the Bosch Magneto Company, New York City, will sail for Europe November 7. He will make the rounds of the automobile factories and incidentally visit both the London and the Paris shows.

L. A. Austin Resigns—L. A. Austin has resigned his position as sales manager and advertising manager of the Rutenber Motor Company, Marion, Ind., to take effect November 1. He will be connected in the future with the Mais Motor Truck Company, Indianapolis, Ind.

Chief Instructor Engineering—Mr. Julian Chatel, the general manager of the Rochet-Schneider car agency of Canada, has been apointed chief instructor of automobile engineering and mechanics in connection with the Montreal Technical High School.

Stewart District Managers—The Stewart Motor Corporation, Buffalo, N. Y., has appointed E. E. Dennison district manager for Illinois, eastern Iowa and Missouri, with headquarters at Chicago, Ill., and W. T. Butler, district manager for New York state and northern Pennsylvania, with headquarters at Buffalo.

Lozier Acquires Property—The Lozier Automobile Company, Philadelphia, Pa., has acquired by a long term lease the stable property, 66 feet by 184 feet, at the corner of Twenty-first and Ludlow streets. Approximately $40,000 will be expended to reconstruct the building for automobile sales purposes.

Piggins Factory Branch—The Piggins Motor Truck Company, of Racine, Wis., has established a factory branch in San Francisco, Cal., to take care of the entire Pacific coast. President E. N. McNab, now in that city, has appointed J. I. McLaughlin manager. Arrangements are now being made for the erection of a permanent building on Golden Gate avenue.

Johnson Sales Manager—W. C. Durant, vice-president of the Republic Motor Company, Detroit, Mich., has appointed Ted Johnson as general sales manager, with headquarters at Detroit. He will have entire charge of sales for the Chevrolet Motor Company and Little Motor Car Company and for all of the subsidiary companies of the Republic Motor Company.

New Frisco Insurance Company—The American Automobile Insurance Company has entered the San Francisco, Cal., field to make a strong bid for the automobile insurance business, the major portion of which has long rested with the Fireman's Fund Insurance Company, a California corporation. The American Company has appointed J. W. Francis manager here.

Locomobile's Stage Coach—Unique in appearance is the Locomobile stage coach in service between Sacramento and Folsom, Cal. This stage, known as the Sacramento-Falsom Air Line, is in daily use between these two points, making two trips a day, averaging about 90 miles. The total weight of the conveyance is 6,000 pounds and the extreme length 24 feet. The accompanying illustration shows the car.

Automobile Incorporations

AUTOMOBILES AND PARTS

ACTON, O.—Davis King Company; capital, $200,000; to deal in automobiles. Incorporators: A. W. Davis, Hobart E. Mead, B. A. King.

AKRON, O.—Akron Welding Company; capital, $10,000; to manufacture and deal in automobiles. Incorporators: Milton N. Smith, George D. Stiver, Edward H. Boylan, David H. Morgan, Lucile H. Smith.

BOSTON, MASS.—Ultra Motor Car Company; capital, $100,000; to deal in automobiles. Incorporators: R. H. Randall, Elisha A. Bragg, C. A. Parker.

BUFFALO, N. Y.—Lafayette Motor Sales Company; capital, $10,000; to sell automobiles. Incorporators: Frank J. Batt, Annie E. Groh.

CAMDEN, N. J.—Hendricks Manufacturing Company; capital, $250,000; to deal in automobiles and accessories. Incorporators: F. R. Hansell, John A. MacPeak, F. S. German.

CLEVELAND, O.—Perrine Manufacturing Company; capital, $10,000; to manufacture and deal in automobiles. Incorporators: R. A. Wilbur, Charles S. Wather, H. H. Burton, Benjamin A. Gage, A. S. Dole.

DETROIT, MICH.—Sprung Carbureter & Clutch Company; capital, $45,000 to engage in the manufacture of automobile parts. Incorporators: William Healy, J. S. Kennary.

DETROIT, MICH.—Tyro Manufacturing Company; capital, $5,000; to manufacture automobiles. Incorporators: Roy I. Wellington, William C. Stuart, F. J. B. Gerald.

HATTIESBURG, MISS.—Hattiesburg Automobile Company; capital, $10,000; to deal in automobiles. Incorporators: M. D. Fohey, H. S. Buscher, Charles Ehlers.

LOUISVILLE, KY.—Highland Motor Transfer Company; capital, $5,000; to deal in automobiles. Incorporators: John Rommel, C. P. Schillinger, Conrad H. Gutermuth.

LOUISVILLE, KY.—Southern Motors Company; capital, $100,000; to deal in autumobiles. Incorporators: A. T. Hart, Richard V. Look, Graeme G. Bolts, Raynale Whitehand, A. L. McCormick.

MADISON, N. J.—Michigan Motor Sales Company; capital, $10,000; to deal in motor vehicles. Incorporators: Elmer L. Reynolds, Alvah L. Reynolds, Clara Reynolds.

MEMPHIS, TENN.—P. R. Flanigan Automobile Company; capital, $10,000; to deal in automobiles. Incorporators: P. R. Flanigan, J. J. Carrigan, T. M. Scruggs.

MENOMINEE, MICH.—D. F. Poyer Company; capital, $75,000; to manufacture motor trucks. Incorporator: D. F. Poyer.

MT. EATON, O.—Mt. Eaton Supply Company; capital, $60,000; to deal in automobiles, implements, etc. Incorporators: J. A. Yohn, F. B. Schlafly, Charles L. Schaffer, Robert Kenwell, Albert Pfister, Ira C. Wellbaum.

NEW YORK CITY, N. Y.—A. M. A. Company, Inc.; capital, $5,000; to deal in motors, engines, etc. Incorporators: N. Pohly Myers, Walter C. Allen, Harry N. Allen.

PETROLIA, ONT.—Petrolia Motor Car Company, Ltd.; capital, $300,000; to manufacture automobiles. Incorporators: William English, Charles H. Metcalf, John A. McKenzie.

ST. LOUIS, MO.—Brashear Truck Company; capital, $5,000; to deal in motor trucks. Incorporators: Boyle O. Rides, Lewis S. Haslam.

WASHINGTON, D. C.—Croton Motor Car Company; capital, $300,000; to manufacture automobiles. Incorporators: J. P. Stoltz, A. M. Linn, J. D. Bigger, J. I. Brownson, J. H. Donnan, H. C. Warne, C. S. Caldwell, G. W. Dudderar, R. M. Paxton.

Bretz Off to Europe—J. S. Bretz has sailed for Germany, where he will visit the F. & S. bearing factory at Schweinfurt.

Leech Manager Oakland—E. K. Leech has been made manager of the new Oakland branch in Philadelphia, Pa.

Essenkay's Houston Office—The Essenkay Sales Company has established a Houston, Tex., office at 217 Carter Building with H. H. Hassel as manager.

Increasing Repair Facilities—The E. W. Clark Motor Company, of Fond du Lac, Wis., is planning to considerably increase its storage and repair facilities.

Gotshall in St. Louis—N. S. Gotshall has been shifted from traveling representative for the Lozier interests to manager of the St. Louis company, St. Louis, Mo.

Establish Louisville Office—Wilcox Brothers, who have secured the agency for Fisk tires in Louisville, Ky., have established an office and salesroom at 941 1-2 South Third avenue.

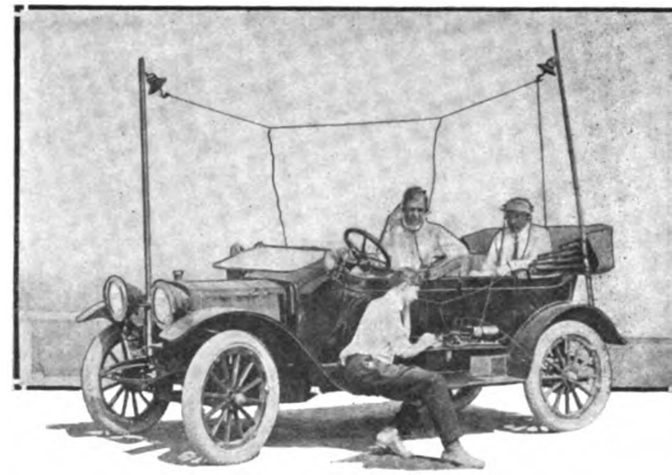
Anderson Heads Ford Branch—W. C. Anderson is to have charge of the Ford branch which opened October 1 in Minneapolis, Minn. He will have charge also of the St. Paul subbranch.

Averill Resigns—H. R. Averill, who has been connected with the Pullman Motor Car Company, of York, Pa., for 6 years as general sales manager, has resigned, resignation taking effect November 1.

Automobile at Dairy Show—A number of enterprising Milwaukee, Wis., dealers are making automobile exhibits at the International Dairy Show which is being given in the Auditorium from October 22 to October 31, inclusive.

Phipps Electric Organized—The Phipps Electric Automobile Company has been organized in Detroit, Mich., by Joel G. Phipps for the purpose of manufacturing electric automobiles. Mr. Phipps was formerly general manager of the Grinnell Electric Car Company.

Hay Leaves Ford—Thomas J. Hay, who for 7 years was manager of the Chicago branch of the Ford Motor Company, recently created a sensation among the local trade by retiring from his position. Dayton Keith, who has been Indianapolis manager of the Ford company, has been named as his successor.



R. C. H. car used by E. C. Hanson, of Los Angeles, in recent wireless telephony experiments between Lookout Mountain and Long Beach

Puncturine Company Incorporated—The Detroit Puncturine Company was recently incorporated in Detroit, Mich. The officers of the concern are: M. H. Chamberlain, L. N. Taylor and K. R. Montgomery. The concern manufactures a tire compound which is intended to heal punctures and cuts in the envelope.

Will Silence Critics—The permanent improvement plan of Milwaukee county, Wis., is elaborate and will silence critics, who declare that Milwaukee county's highways are not only the worst in America, but there seems to be no inclination to improve them. The 12 miles of concrete road built this year will be increased to 52.

Paducah Automobile Service—A daily automobile service has been established between Paducah and Roaring Springs, 40 miles. The Quanah, Acme & Pacific Railroad is now being extended from that place to Roaring Springs and the automobile service will be operated between the two points until the railroad is finished.

Birmingham Cars Tour—Eighteen cars from Birmingham, Ala., took part in the second Birmingham-Meridian tour. The visitors were met at Livingston, Ala., by twenty-five Meridian cars who escorted the guests into the city. All the whistles in the city were tied down and a rousing welcome accorded the Birmingham people.

Lacroix Exclusive Agent—Paul Lacroix has signed a contract whereby he becomes exclusive agent in the United States for the Mercedes car. The contract extends to 1920. The headquarters of the new concern, the Mercedes Distributing & Importing Company, of which Mr. Lacroix is president, are at 1770 Broadway, New York City.

Completes Route Marking—The Lake-to-River Road Association, organized recently by Milwaukee, Wis., and other state interests affected by the planning of a good highway across the state of Wisconsin, from Lake Michigan to the Mississippi River, reports that it has completed the marking of the route by means of banding telephone posts, as in Iowa. The distinguishing mark is a white band on each post, a red X being placed in the center.

Hupmobile Wins Award—The final award in the Studebaker-Hupmobile controversy resulting from disqualification of the former car in the annual reliability run of the Minnesota State Automobile Association for leaving the course at Foxhome, Minn., has been made by the contest board of the A. A. A. to the R. W. Munzer & Sons Company, for the Hupmobile. Protest was originally made by the Studebaker corporation. The award carries the Minneapolis Daily News cup for light car class with it.

Shanks Goes East—Charles B. Shanks, who has been appointed general sales manager of the Kelly-Springfield Motor Truck Company, of Springfield, Ill., will leave San Francisco, Cal., for the East to assume the duties of his new position. Shanks is well known in American automobile circles as the former sales manager of the Winton Motor Carriage Company and the F. B. Stearns Company, of Cleveland. Shanks has turned the management of the Kelly motor truck branch in San Francisco over to Frank G. Miner, who has been his assistant.

Automobile Incorporations

White Plains, N. Y.—General Rim Company; capital, $150,000; to deal in automobiles and parts. Incorporators: Robert W. Ashley, Frank Oberkirch, William Kaul.

GARAGES AND ACCESSORIES

Albany, N. Y.—Albany Motor Racing Association; capital, $1,000; to carry on automobile racing. Incorporators: J. D. Keeler, R. P. Keeler, S. H. Shaw.

Albany, N. Y.—Carbone Company, Inc.; capital, $200,000; to deal in all kinds of rubber tires, etc. Incorporators: W. E. Greene, G. C. Leonard, W. G. Van Loon.

Buffalo, N. Y.—Frontier Garage & Livery Corporation; capital, $25,000; to conduct a general garage business. Incorporators: Francis L. Hoff, Giles G. Meinell, George P. Mitchell.

Chicago, Ill.—Auto Combination Lock Company; capital, $50,000; to manufacture automobile supplies. Incorporators: H. M. Snow, H. L. Mason, F. W. Robinson.

Chicago, Ill.—M. R. L. Resilient Tire Company; capital, $25,000; to manufacture automobile supplies. Incorporators: L. M. R. Labee, M. O. Lundholm, R. W. Moore.

Detroit, Mich.—Baid Sales Company; capital, $10,000; to manufacture and deal in automobile accessories. Incorporators: W. C. Chapman, R. P. Baubie, G. A. Breeze.

Mount Vernon, N. Y.—Mount Vernon Auto Express Company; capital, $1.500; to carry on an automobile express business. Incorporators: Luci Jacobsen, Elizabeth Jacobsen, Fred Cardillo.

New York City, N. Y.—Cathedral Park Garage, Incorporated; capital, $1,000; to carry on a general garage business. Incorporators: Morris Klein, Samuel Klein.

New York City, N. Y.—Columbia Taxicab Company; capital, $5,000; to conduct a general taxicab business. Incorporators: John Graham, James Pathe, Patrick Garrity.

New York City, N. Y.—Globe Tire Company; capital, $500; to manufacture tires. Incorporators: Ralph W. Morrison, R. D. Placak, F. F. Nichols.

New York City, N. Y.—Hallett Point Garage, Inc.; capital, $5,000; to conduct a general garage business. Incorporators: August Kiel, Jr., Thomas D. Tompkins, Gustave Rees.

Paducah, Ky.—Henry Brothers Taxicab Company; capital, $200; to conduct a taxicab business. Incorporators: Finis Henry, Toy Henry, E. E. Henry.

Toronto, Can.—Auto Top & Buggy Company, Ltd.; capital, $200,000; to manufacture automobile tops, etc. Incorporators: James E. Day, John M. Ferguson, Edward V. O'Sullivan.

CHANGES OF NAME AND CAPITAL

Canton, O.—Knight Tire & Rubber Company; increase of capital from $500,000 to $1,500,000.

Louisville, Ky.—Kentucky Automobile Company; increase of capital from $65,000 to $100,000.

Port Huron, Mich.—Havers Motor Car Company; increase of capital from $115,000 to $175,000.

Toledo, O.—McNaull Automobile Tire Company; increase of capital from $50,000 to $75,000.

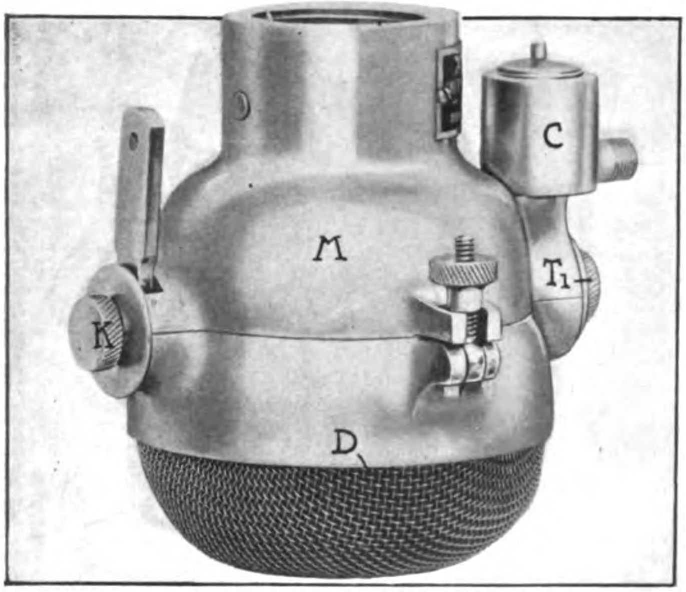


Fig. 4—Side view of fully assembled A. B. C. carbureter

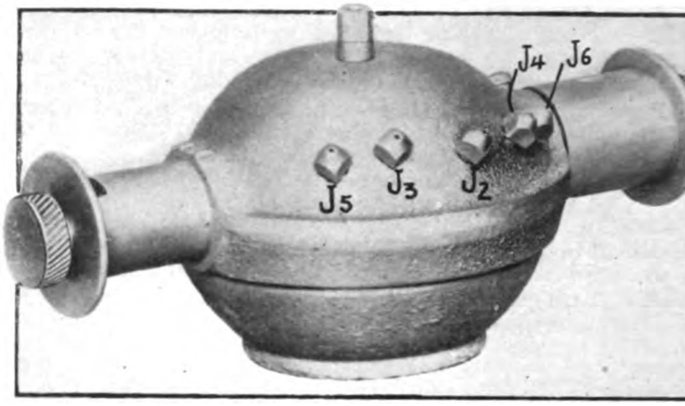

Fig. 1—Float chamber of the A. B. C. automatic carbureter

A. B. C. Carbureter Has No Adjustments

Constant Ratio of Mixture Is Obtained By the Use of Co-operating Float Chamber and Throttle

Multiple-Jet Design Is Claimed to Be Proof Against Leakage, Fire, Theft and Clogging Up of Nozzles

AS the result of 2 years' experiments, the International Accessories Company, 115 Broadway, New York City, announces its multiple-jet, adjustmentless, automatic carbureter. This carbureter is, in a large measure, what is ordinarily termed fool-proof; besides it is leakage-proof and backfire-proof. It is composed of three elements, namely, the upper half of the carbureter casing formed in unit with the needle valve casing, the float chamber and the lower half of the carbureter casing which is formed with a double wire screen separating the air space which surrounds the float chamber from the exterior atmosphere.

The construction of these elements is illustrated in the accompanying cross sections, Figs. 2 and 3. The upper casing M is of a conventional concentric-float design and its throat contains a butterfly type of throttle valve. A lateral portion of the part M is bored to receive the vertical downward extension of the needle-valve casing C which contains a weighted needle valve for regulating the admission of gasoline to the float chamber. Gasoline flowing from the tank to the carbureter enters the device at G, passes the needle valve N and then flows down through the passage P formed in the downward extension of the casing C. In this passage a connecting stem S is in place, the upper end of which is secured to the weight resting on the needle valve, while its lower end rests upon that of the float lever. The gasoline coming down through P enters the float chamber F through the circular bore B, into which the extension of the valve casing fits.

The float chamber is journaled in lateral, horizontal extensions of the casing, which are cut along the contact line of the upper and lower carbureter-casing halves. To insure tightness between the passage P and the bore B of the float chamber, the sleeve S1 formed with a knurled screw head is used as a bearing for this end of the float chamber axis. Fig. 2 shows that this end of the float chamber is made open, but is closed in practice by a plug formed on S1. The float F1 is made up of laminated cork which, according to the company's tests, has not absorbed any gasoline through 18 months of continued service, this being the greatest endurance test made with the A. B. C. carbureter. The float is held concentric with respect to the vertical axis of the chamber by a rod R which is bored down from its upper end to the depth of about 1 inch. The single float lever is securely fastened to the float and is fulcrumed at F2, so that its free end is always under the weighted stem of the needle valve. By this expedient the stem is made to follow at all times the end of the lever, so that when the fuel has reached the proper level in F the float is lifted, the end of the float lever depressed and the needle valve closed due to the weight of the needle N and the stem S.

The proper level of fuel in the float chamber is that of the highest spraying jet in action for a given position of the throttle. Reference to Fig. 2 brings out the fact that the operating lever O which fits into the right equatorial extension of the float chamber at the same time tilts that chamber and the throttle T, Fig. 3, which is connected to it through the hooked rod H fitting in the bore of rod R. At the approximate level of the bore B the float chamber carries six small plugs formed in its surface, which are bored for minute passages varying in diameter from .014 to .022 inch, in case of a 1.25-inch carbureter. Five of these bored plugs or nozzles are disposed on one side of the float chamber and the sixth on the other. All these nozzles act as outlets for the fuel jets; but the nozzle which is on one side, is distinguished by its double office of low-speed and compensating jet. This nozzle is fitted, inside the chamber, with a thin pipe extending down to the level L1, whereas the other five nozzles are not continued inside the float chamber.

Air Enters Through Double Screen

Before taking up the manner of operation of the several jets, it should be noted that the air passing through the carbureter enters through the double screen D, Fig. 2, which is made of one layer each of fine and coarse wire. All this air passes around the equatorial belt of the float chamber before going through the throttle; and as the float chamber and the throttle are tilted at the same time and by the same means, it has been possible to so dimension these parts that the horizontal cross section of the throttle opening is at all times equal to that formed between the float chamber and the carbureter casing. In this way, unlike other types of carbureters, the A. B. C. device is of adjustable size, being, for various throttle openings, a .125, .25, .5, .875 or 1-inch carbureter. The capacity of the air intake is always equal to that of the throttle.

When the opening of the throttle is a minimum, only the low-speed nozzle comes into action, resulting on the use of a single jet. The gasoline evaporated at the mouth of this nozzle is sucked up by the vacuum effect of the suction strokes of the motor, and is atomized by this suction only, as it is forced out through the minute bore of the nozzle. A thickening of the float chamber casing just below the slow-speed nozzle protects the latter from direct contact with the air sucked into the motor, the gasoline leaving it only on account of the pressure in the throttle passage, which is below atmospheric. As soon as the float chamber is tilted further, however, not only are the throttle and carbureter openings increased, but the nozzles for the higher speeds jets, J2, J3, J4, J5 and J6, Fig. 1, are lowered and immerged in the fuel in the order of the jets named. The air passing them sucks out and atomizes the fuel supplied by them. These five nozzles are of different bore and consequently capacity, so that they provide the various correct gasoline-air ratios necessary to give efficient combustion at the various motor speeds. After J6 has been brought into action, if the throttle is opened further, the opening around the float chamber becomes wide enough that a considerable air current rushes past the slow-speed nozzle and increases the fuel delivered from it, by adding its jet-blower effect to the pure vacuum effect of motor suction exerted before.

A peculiar feature of this float chamber construction is that, due to the location of all nozzles well above the bottom of the chamber, no water or sand is able to clog up the jets. The makers state that this has been borne out by numerous tests, and that as much as a teaspoonful of sand and a tablespoonful of water did not in the least alter the behavior of the carbureter. In addition to this feature it should be noted that the removal of foreign matter from the float chamber is an extremely simple undertaking. As the bore B has as much capacity for outgoing matter as for incoming, water and sand are easily passed out through it after the float chamber has been taken out of the carbureter casing.

That this is a simple matter and the work of but a few seconds, will be shown at once. A pair of eyebolts fitted with thumbnuts and attached at diametrically opposite points of the lower half of the carbureter casing are fastened to the upper casing half as shown in Fig. 4. By loosening both thumbnuts and tilting down the eyebolts, the lower half carrying the screen may be taken off and the float chamber including sleeve S1, the lever O, and the screw K, Fig. 2, removed, after disconnecting the hook H from the eye of the throttle lever L, Fig. 3. It is now easy to spill the contents of the float chamber through the above-mentioned bore.

A nice feature which ought to appeal to tourists deserves to be mentioned in this connection. As the float chamber is removed, the needle and its stem drop, thereby shutting off the gasoline supply. This has not only the advantage, that it becomes unnecessary to turn off the gasoline cock, but presents a possibility of leaving the car alone on the road, if necessary, it being impossible to start the motor except by replacing the float chamber or the whole carbureter.

Another point of interest lies in the fact that no impurities may enter the carbureter except by way of the gasoline line. All air is passed through the double screen D, Fig. 2, one layer of which is of 16-mesh and the other of 50 mesh. The main purpose of this screen, however, is to prevent the spreading of a flame entering the carbureter as a backfire from the motor. The principle applied is the same as used in the miners' lamp, and as tests have demonstrated is equally efficient in both cases.

Excepting the steel wire screens and the cork float, almost all the parts of the A. B. C. carbureter are made of brass. An exception is the needle valve; this part is made at present of German silver as well as of Monel metal, an alloy closely related to the one first named. The company has not yet decided which metal will finally be adopted for the manufacture of all needle valves.

Carbureter Is Flexible and Efficient

The perfect automatic working and the absence of adjustments having been elucidated above, it remains to state that numerous tests have created what must be called a favorable impression with those present at such tests. The carbureter proved both flexible and efficient. Its weight is small, being, for example, 4 pounds for the 1.5-inch size. The A. B. C. is made in the following sizes: 1 inch, 1.25, 1.5, 1.75 and 2 inches.

The method of installing this carbureter is slightly different from the ordinary process, due to the different shaping of the throttle portion of the casing. As the latter is not formed with an integral flange, as is the case with most other designs, it is necessary to use a flanged connection attaching to the manifold, which fits around the threaded neck of the throttle extension of the casing. If the carbureter is specially made for any given make of car, it may, of course, be furnished with a flange if it is so desired, or the manifold throat may be so designed as to directly take in the throttle portion of the carbureter.

The few parts of which the carbureter is made are manufactured standard and in large quantities, so that they may be replaced if necessary. Tests made to examine the interchangeability of parts and its effect on engine operation, and these have developed the fact that the changes made did not produce any appreciable change in the operation of the engines tested.

Moore Automobile Jack; Continental Electric Horn; Novel Rim-Removing Tool; Grossman Connectors and Windshield Cleaner; Tyre-Tonic; New Wrenches and Pliers; Endura Packing; Sealo Puncture Preventative

Moore Tire-Saving Jack

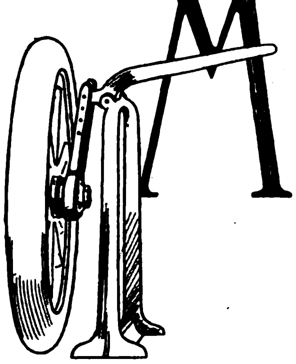

Fig. 1—Moore tire-saving Jack

MEANS for rapidly and easily jacking up automobiles are ever increasing and as the latest production in that line, the Moore tire-saving jack is being announced. This accessory, made by J. C. Moore & Company, Racine, Wis., is distinguished by its simple construction and the possibility of quick application. It consists of a steel support cast integral with a horizontal base, Fig. 1, and extending about 3 feet above the same. On top of the vertical supports the jack mechanism, consisting of a pawl-and-ratchet controlled lever, is attached. The short end of the lever is formed with a depending steel noose, which in using the jack is placed under the hub cap, so that by depressing the long end of the lever the axle is elevated and the jack is locked in this position by the action of a pawl dropping into a ratchet carried on the pivot which serves as fulcrum for the lever.

Continental Vibrator Signal

The Motor Car Equipment Company, 55 Warren street, New York, has just brought out a vibrator-operated electric horn, which, as may be seen in Fig. 2, is of extremely simple design. There are no square portions in either the horn casing or the sound intensifier, which gives the signal of peculiar appearance. The overall length of the horn is 10.5 inches and the diameter of the intensifier 5.5 inches. In the view of the vibrator mechanism the simple construction of this part of the horn is evidenced; the mechanism consists of a small electro-magnet mounted on a case baseplate B and fitted with an armature A, which is carried on a vibratory steel sheet S. The latter is in metallic contact both with the horizontal part H of the base casing and with the angle A1 insulated from H by rubber washers. A1 is fitted with a screw S1 contacting with S normally. Current is admitted to the horn by means of the two contacts C and C1; a wire leads from C to the contact screw on the baseplate, which is insulated from the latter. Both vibrator coils are connected in parallel, thereby producing a strong magnetic field, when the circuit is closed by pressing a button. The path of the current is from C to the contact screw, through both coils and a wire up to A1, through S1 to A, S, H and B, whence it grounds back to C1. As soon, however, as the coil is magnetized by the current passing through it, the armature A is attracted, and the current being interrupted at the former point of contact between S and S1 permits of the armature being returned through the spring action of the steel sheet S. Every time the armature is attracted by the magnet it strikes the rod R, which is fastened to the diaphragm, thereby producing an impact.

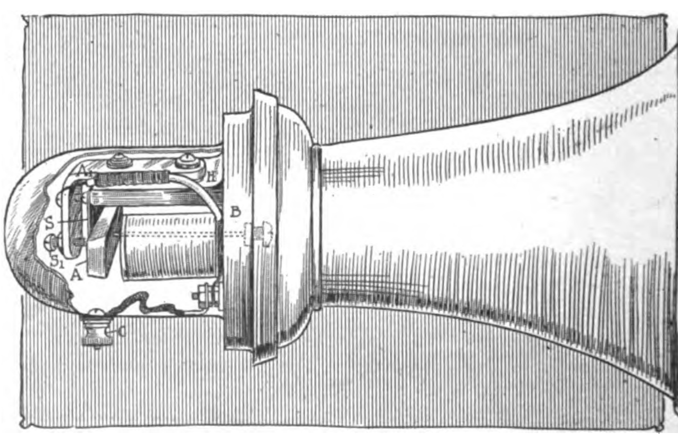
Perfection Rim Remover

The Perfection Manufacturing Company, New Martinsville, W. Va., has designed a tool for the removal of a rim in a quick and easy manner. This tool is made of one piece of steel pressed at both ends with heads and beaks like bird heads. The beak portions permit of wedging the tool under the ends of the locking ring as well as for lifting up the tire so that the valve comes clear out of the hole. The tool and its application are so simple that its use is clear from the illustrations, Figs. 6 and 7.

Grossman Novel Accessories

The Emil Grossman Company, 250 West Fifty-fourth street, New York City, have added several new accessories to their line, and among these the special ignition assembly and the Security windshield cleaner, Figs. 5 and 6, are of such nature as to command especial interest. The former accessory represents a new and handy method of providing connections between distributer posts and of averting short circuits in the line, while the latter insures a clear windshield in rainy weather.

As Fig. 5 of the Red-Rib Ignition Wire Assembly shows, this outfit is composed of as many heavily insulated wire leads as there are spark-plugs used in the power plant. The length of each individual lead may be varied depending on the position of the magneto distributer with relation to the engine, and the wires extending from there to the cylinders are held together by rubberized fabric, as far as possible, separating only where a lead branches off to its spark-plug. Under the rubberized binder each



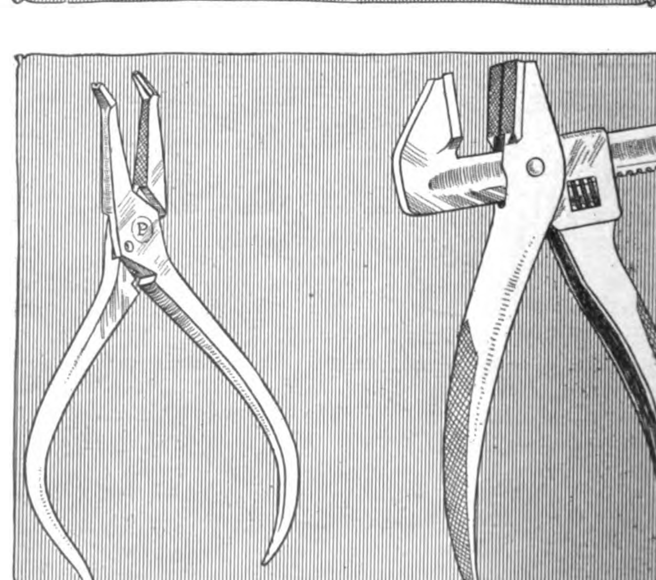


Fig. 2—Continental electric vibrator horn for automobiles
Fig. 3—Mesnard cotter pin pliers. Fig. 4—Starrett tool

wire is surrounded by a substantial rubber coating, and on both ends is fitted with connectors or terminals; two types of terminals are used, one fitting on the binding posts of the distributer and the other of the terminals of the spark-plugs. These respective connectors are also shown in Fig. 5. The assembly may be produced to fit any make of car and any position of the magneto on a car.

The security windshield cleaner consists of a guide, which slides on the horizontal top member of the windshield frame and of a metal rod which is bent, roughly speaking, as a U and attached to the guide. The short leg of the U carried on its end a socket in which a small, spring-urged plug is contained which, when the cleaner is in place in the windshield, bears against the rear side of the pin. It thereby presses the pan against the rubber strip carried in a slotted clamp which is attached to the other leg of the U-member, and which may be moved along the front side of the windshield, cleaning off whatever moisture is there as a consequence of rain. The cleaner may be installed in less than a minute's time, as it merely slips over the top member of the frame and is in no way secured thereto.

Tyre-Tonic Solution

The Sturdy Manufacturing Company, 2637 Michigan avenue, Chicago, Ill., now manufactures a compound which is applied to the face of tires for the double purpose of improving their appearance and filling up small cuts in the tread so that water finds no way into the fabric layers. In this way a repeated treatment with the solution, which comes in cans of various sizes, prolongs the life of a tire, as the fabric is protected from the attacks of mildew, the latter being known as one of the principal reasons of shortened tire life. The compound consists of a carrier solution, which contains rubber and a paint body in suspension, and must be stirred thoroughly before application. The liquid which contains the rubber and paint is inflammable and therefore it is necessary to use caution in handling the solution. The Sturdy company furnishes it in both white and battleship gray.

Turner Improved Pump Cap

The Turner Brass Works, Sycamore, Ill., has made an additional improvement on its line of blowtorches, which facilitates the reinserting of the pump washer after oiling the same. Ordinarily some difficulty is experienced in this work, as the leather washers show a tendency to buckle when reinserted in the pump cylinder after oiling. At present, the pump cap and former, as the new accessory is named, is applied to the leather washer after it has been oiled and within a few seconds the washer is given its exact original shape, so that it may be returned into the pump cylinder without any trouble. Of course the use of this device is not confined to the line of blowtorches, but it should prove equally serviceable to the owners of furnaces.

Mesnard Cotter Pin Pliers

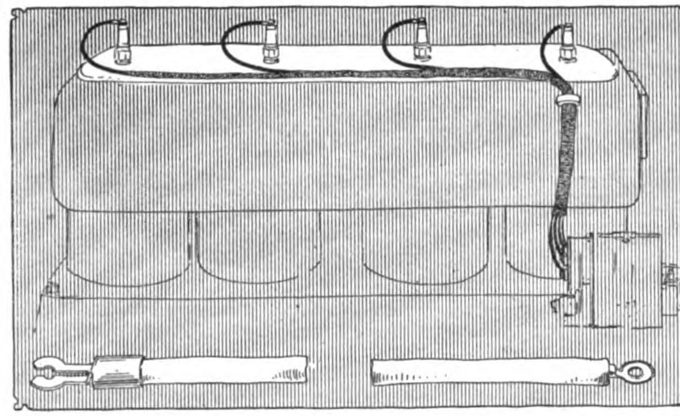
Pliers especially adapted for the inserting and bending of cotter pins have been designed by the Modern Sales Bureau, 1712 Michigan avenue, Chicago, Ill. Under the name of Mesnard's cotter pin pliers this concern markets the small and handy tool shown in Fig. 3, which is tongue-shaped and differs from an ordinary tongue but by the special shaping of its short lever ends. The faces of these short levers are knurled and the extreme ends bent in an angle and formed with a slot for taking in the cotter pin ends. Both pieces—the tool consists of two parts—are held together by a pin P driven through a stout portion formed between the long and short lever ends.

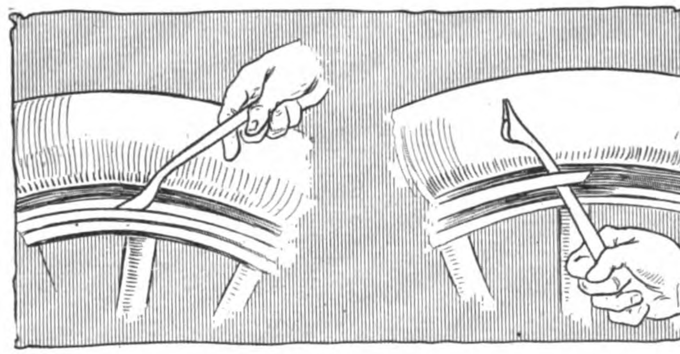
Endura Sheet Packing Material

A departure from packing materials is the new product of the Endura Manufacturing Company, Sixty-third street and Eastwick avenue, Philadelphia, Pa. This packing material comes in sheets of varying thickness, ranging from .015625, to .125 inch, the square yards of sheets having these two thicknesses weighing .75 pound and 6 pounds respectively. Endura is a dark gray material made of vegetable fiber which has been impregnated with inorganic materials; the effect of this treatment being that while the packing is combustible it offers considerable resistance to the heat and does not easily catch fire. It contains neither asbestos nor rubber, is claimed to make an absolutely tight joint and to calk perfectly under the action of water. Due to this property it should not be used in intense dry heat.

Starrett Wrench and Pliers

A clever combination tool, which may be used with equal efficacy as a wrench or as a pair of pliers is shown in Fig. 9, it being the product of the L. S. Starrett Company, Athol, Mass. It is made of hard, nickel-plated steel and consists of three relatively movable portions, the right-angled wrench-and-plier jaw, the straight jaw, which is fitted with a 6-inch handle and a





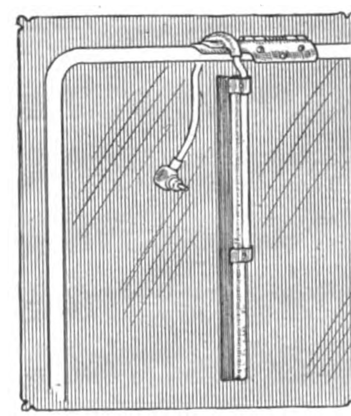


Fig. 5—Red-Rib wire assembly for neat and short-circuit proof conducting of the ignition current to the motor cylinders. Figs. 6 and 7—Two views showing the application of the Perfection tool, in removing the locking ring off a quick-detachable type of rim. The tool may be also used to advantage in taking the tire off and getting the valve out of the rim hole. Fig. 8—Appearance of the Security windshield cleaner for clearing a shield in rainy weather, in place on a windshield of standard design

second handle of the same length, the end of which is formed to be fitted over the extension of the right-angled piece and contains a worm engaging the transverse rack on the underside of the above-mentioned extension. The straight jaw is pivoted through the end of the other handle, so that its angle against the face of the right-angled jaw may be changed, depending on whether the tool is to be used as a wrench or plier. The handles are nicely knurled to give the tool a high-class appearance, and while this aim has been realized throughout, the strength of the device is fully up to the requirements of any work to which its size permits it to be put.

Sealo Pneumatic Tire Treatment

To prevent puncture troubles, the Sealo Tire Company, 1409 Michigan avenue, Chicago, Ill., has compounded Sealo, a liquid which is injected into the inner tube to prevent the air from escaping therefrom, even should the rubber wall be pricked by a pointy object. Sealo is injected into the tube, through the valve stem and by means of a special gun, and when in the tire covers the entire inner surface of the tube, while it retains at all times its liquid state. When the tube is punctured, the outward pressure of the compressed air forces Sealo into the wound, thereby plugging up the same and preventing the air from leaving the tube.

Claudel Carbureter Handled Here

In The Automobile of October 31, the address of the Claudel Carbureter Company in Paris was stated. This carbureter is handled in this country by D. McRa Livingston, 1784 Broadway, New York City.

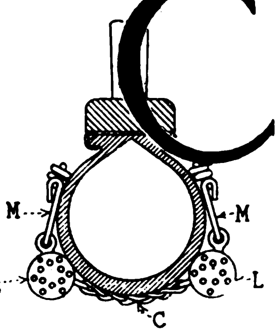

Fig. 1—Simmons anti-skid device

COMPENSATING Carbureter Construction—In which increases of fuel and air are regulated by a connecting mechanism.

The subject matter of this patent, a carbureter, Fig. 2, comprises a fuel chamber C and an atomizing chamber C2 which extends diametrically across C, a nozzle N projecting from C into C2. A throttle T is located in one end of the atomizing chamber and a mechanism M is provided, which operates T and N at the same time, thereby maintaining at all speeds an adjusted ratio between fuel and air admitted to the motor. In the end of C2 opposite to the throttle means for admitting an air current and directing it into the center of C2 are provided; these means are adjustable and vary proportionately with the throttle opening.

No. 1,042,982—to Leonard Sliger, Indianapolis, Ind. Granted October 29, 1912; filed May 31, 1911.

Anti-Skidding Device—Comprising rubber-covered ball-links which are held tightly against the lateral surfaces of the tire tread.

This patent describes an anti-skidding apparatus consisting of a pair of side links L, Fig. 1, on which flexible balls are formed, the latter being in contact with the side surfaces of the tire tread. The links L are supported on the tire by means M, which in turn are connected by members C extending across the tire, holding opposite links together.

No. 1,042,722—to Turner W. Simmons, Bridgeport, Conn. Granted October 29, 1912; filed November 24, 1911.

Rotary Cylinder Valve—Comprising a valve plug worked out in a number of semi-cylindrical shells, forming communications between motor and manifolds.

This patent refers to a so-called valveless motor, in which the poppet valve is supplanted by a rotary plug valve positioned above the combustion chambers of the motor cylinders, Fig. 3. The valve plug P1 is contained in a casing C provided with ports P communicating with the cylinders and with inlet and exhaust passages. The valve plug is composed of as many pairs of semi-cylindrical shells as there are cylinders in the engine. There is an inlet and an exhaust shell for each cylinder and they are constructed with openings affording communication with the inlet and exhaust manifolds when they register with the cylinder openings.

No. 1,042,712—to Albert E. Moorhead, assignor to American Rotary Valve Company, Chicago, Ill. Granted October 29, 1912; filed July 28, 1911.

Internal-Combustion Engine—Two-cycle design in which a valve mechanism carried by the crankshaft regulates the passage of mixture from the crankcase to the combustion chamber.

The engine referred to in this patent has a crankcase C, Fig. 4, formed with a cylindrical interior which has a port opening into its cylindrical surface. A working cylinder C1 is arranged on the crankcase with a piston P in it. In the crankcase a crankshaft S with a crank C2 is inclosed, being connected to the piston by a rod and carrying a valve structure disposed 180 degrees away from C2. A semi-annular shoe S1 is mounted on the valve structure and governs the port through which a fuel mixture enters the crankcase, whence it is passed to the working cylinder.

No. 1,042,970—to William H. Richman, Philadelphia, Pa. Granted October 29, 1912; filed August 25, 1908.

Demountable Rim—Which is carried on the beveled portions of two interlocking felloe rings.

The rim this patent relates to is seen in Fig. 5, being carried on a felloe constructed of a fixed ring R with an annular recess on one side into which fits a removable ring R1. Screws projects through R1 into R; R1 has notches formed in it. Pins P in the notches of the fixed ring guide the movable ring into place. Each rim is beveled on one side from its outer to its inner edge, so that a depressed, annular bed is formed between the rings for a rim.

No. 1,042,478—to Albert D. Reid, West Chester, Pa. Granted October 29, 1912; filed May 22, 1912.

Windshield for Automobiles—A V-shaped design which may be tilted forward.

Fig. 6 shows the subject matter of this patent, a V-shaped windshield which is independent of the motor bonnet, above which it is secured. The shield S swings about a rear horizontal axis A and is fitted with a rigid arm F extending forward to a fixed portion of the motor bonnet, to which it may be attached.

No. 1,042,925—to John L. Kennedy, Washington, D. C. Granted October 29, 1912; filed October 6, 1910.

The AUTOMOBILE

English Car Tendencies for 1913

First Report of Annual Olympia Exhibition Which Opened in London, November 8—Fewer Car Models—Silent Chain Drive Universal—Wire Wheels Gain—Fewer Sixes

1913 Models Show Numerous Refinements in Lubrication, Suspension, Gearboxes, Clutches and Other Features—Statistics of British Car Industry for Present Season

By J. S. Critchley

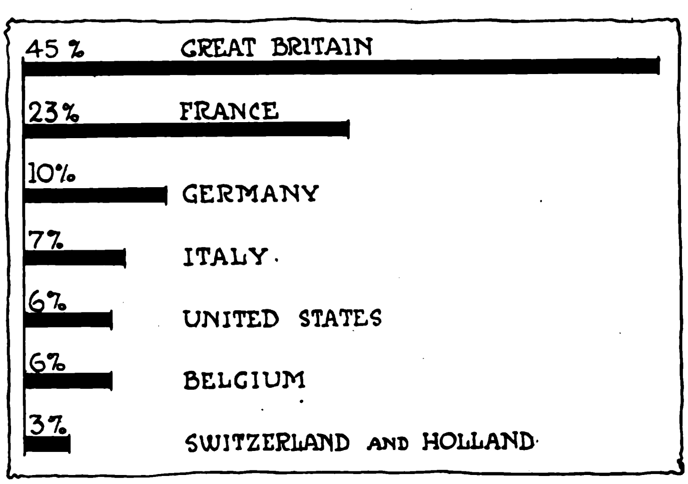

Diagram illustrating the percentage of the exhibitors representing the various countries whose manufacturers are displaying their products at the Olympia show in London. United States is fifth

LONDON, Nov. 2—*Special Correspondence* — One week from today the annual Olympia show will have opened its doors disclosing one of the greatest motor exhibitions which Europe has had an opportunity of witnessing. In all, 353 exhibitors are installed, this constituting a new record. There are 119 exhibitors in the complete car section; thirty-five body-builder exhibits; 150 accessories; eight press, and two associations.

Of these exhibits Great Britain has 45 per cent.; France, 23 per cent.; Germany, 10; Italy, 7; Belgium, 6; United States 6; Switzerland and Holland, 3, as may be seen in the accompanying diagram.

Although the English manufacturers have been slower than usual in announcing their new models, it has nevertheless been possible to obtain an accurate estimate of the improvements that have been made by the different companies. All of them have had their new products out for months, but in not a few instances have kept the details as quiet as possible.

In a word, 1913 will not be a startling year. There is nothing radical offered. Contrasted with the shows of 2 and 3 years ago there is little in the way of sensations. Rather there has been a perceptible decrease in the use of certain constructions, which the experience of a year or two has tested; and, on the other hand, there is an equally perceptible tendency towards other constructions which have been well tried out during this period. Then, again, many of the standard constructions remain practically as they were during this season.

The six-cylinder motor has lost somewhat as compared with 1912. For next year there are twenty-two distinct six-cylinder models, whereas for 1912 there were twenty-six. The list shows one or two concerns that have discontinued six-cylinder construction, notably Adams, two Standard models, Crowdy, etc. The horsepower of the sixes listed for next year range from 23 in the small Star to 59.9 in the Napier. The popular rating is between 23 and 30.

There is a slight reduction in the total number of models of all motor types for next year, showing that several of the concerns have reduced the number of models they are marketing, there being only one English company, namely, Vauxhall, which has increased its number of models.

The stroke-bore ratio leans slightly to an increase. This is particularly so in the new models. The maximum stroke, 160 millimeters, or 6.4 inches, is not found in many models, one being the 20.1-horsepower Sunbeam, with measurements 90 by 160; a stroke of 150 millimeters is used in four models with bores under 100 millimeters, namely, Sunbeam, 80 by 150; Calthorp, 80 by 150; Star, 90 by 150; and Vulcan, 80 by 150. A recent test of long-stroke efficiency was that of the Sunbeam, 80 by 150, on Brooklands, when in a 10-lap standing start an

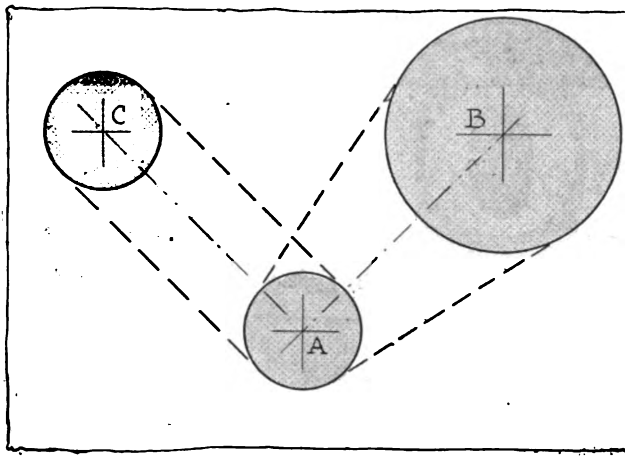

Fig. 1—Silent chain-drive scheme for camshafts where distance A-C does not exceed 7 inches

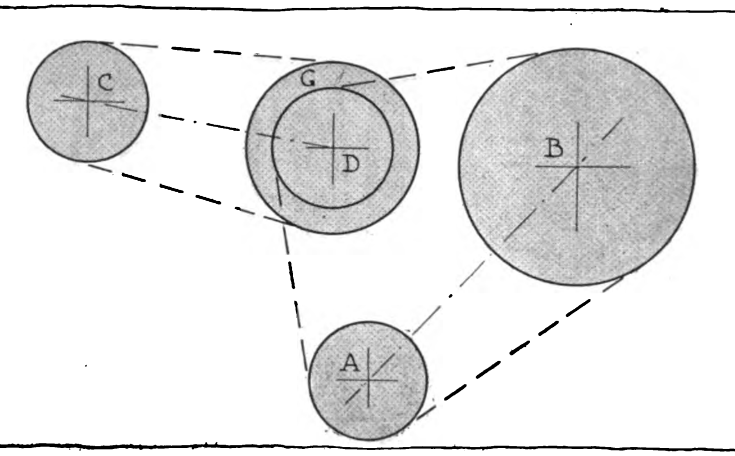

Fig. 2—Popular silent chain-drive arrangement where distance A-C exceeds 7 inches

average speed of 93.8 miles per hour was made, and in the flying half mile, 101.87 miles per hour. These engines tuned for racing purposes give slightly over 70 horsepower.

There have been few changes made in bore and stroke measurements of 1912 models which are continued for the 1913 market. In every case where a change has been made the stroke has been increased as the tabulation on page 326 showing the various 1912 and 1913 English models indicates. These stroke changes generally run as follows: From 120 millimeters to 130, from 100 to 120, from 110 to 120, from 110 to 130, from 115 to 130, etc.

Non-Poppet Situation

The non-poppet valve motor begins 1913 much as it began 1912 with the Knight type gaining in prestige. This is particularly the case on the Continent where Clément, Mors and Gregoire in France have decided to bring out Knight models; in Belgium where Germain has adopted it in addition to the Minerva, and in Germany where Dobey will manufacture it for next year in addition to Mercedes. Panhard will produce 80 per cent. Knight models for next season; Daimler in England builds it exclusively; the English Deasy will continue it in all models, but the Rover of England, which has used it this year in single and two-cylinder types, has discontinued these, and will use poppet valves in its two and four-cylinder 1913 models.

The Argyll motor with its single-sleeve valve will be produced in two models, namely, 80 by 120 and 110 by 130, the former being a new model. In this motor the junk ring in the head has been eliminated, with a resulting gain of reduced friction.

The Itala non-poppet type is being built in two sixes, 25 and 35 horsepower. This valve is a vertical rotating type, one valve serving as intake and exhaust for two cylinders.

Apart from these non-poppet types there is little change compared with a year ago. A great number of experiments have been carried out and many new engines tested or given long demonstrations, but the majority of them have been rejected. One that is now before the public is the improved Reno-Sphinx with its internal sliding valve. An English company has taken over the patents and has developed a neat design. The valve shaft is worm-driven from a vertically inclined shaft, the inclination being for the purpose of bringing the camshaft close to the cylinder walls thereby making the engine more compact. The engine is 90 by 130.

In reviewing the motor design tendencies, one is impressed with the great leaning towards increasing the number of crankshaft bearings, so that for next year the two-bearing shaft with a four-cylinder motor is rarely met with, one of the few examples being the new 10-12 Star model 80 by 120. There is not a perceptible tendency to increase the number of crankshaft bearings for a four-cylinder motor to more than three, but the shaft diameters are being increased, and the 40-millimeter shaft is quite common for a motor with an 80-millimeter bore. Die-cast white metal bearings are increasing; a few concerns adhere to the method of lining up gunmetal backings with bearing materials, and the Austin is one of the very few still using phosphor bronze.

The en bloc system of casting cylinders is decidedly on the increase, and in practically all recent designs is predominant. These cylinder castings are found in connection with the Wolseley, Star, Sunbeam, Vauxhall, Swift, Arrol-Johnston and Straker-Squire and many others.

Vauxhall is the only company which has increased the number of models for 1913 by the introduction of a four-cylinder 95 by 140. The practice adopted by this firm as regards bore-stroke ratio has been worked out not only on scientific lines, but also in connection with the many successes achieved by the Vauxhall cars on the racing track. In the O'Gorman trophy race held during last month the winning Vauxhall, 89.7 bore by 118 stroke, and with a piston swept volume of 2,983 cubic centimeters, achieved a remarkable record of an average speed of 92.5 miles per hour over a distance of 30 miles.

An examination of this list will indicate that there is a tendency towards the reduction of the number of models made by individual firms. For instance, the Wolseley company has ceased to construct its 79 by 120 model and the 100 by 130, and will in future construct only one four-cylinder model, namely, the 90 by 120 R. A. C. rating, 20 horsepower.

Prices show only slight alterations, and in only a few cases will any reduction be found.

Few Sixes for 1913

Referring to the six-cylinder models this class of car has been dropped entirely by the Standard company, which has hitherto constructed two sixes. No new six-cylinder models are projected, which is evidence that the six-cylinder car has not increased in popular favor. The prices in this class remain practically stationary, with a reduction of $50 in the case of the six-cylinder Sunbeam. The bore and stroke of this class also remain practically stationary.

The Daimler company will no longer build its 80 by 130 model, having increased the bore to 90 millimeters, whereas the Sunbeam company has, on the other hand, reduced the stroke of its 90-bore from 160 to 130 millimeters. This reduction in stroke is a notable modification, as hitherto the Sunbeam company has been the pioneer of the long-stroke engine. The change is probably due to the fact that the long-stroke engine is never quite so smooth in its running as the comparatively shorter stroke.

Undoubtedly the lack of popularity in connection with the six-cylinder cars is due to the improved controlability and silence of the four-cylinder models, which meet in every way the requirements of the average motorist.

There is no general disposition on the part of the manufacturers to rate their engines at any higher rating than they arrive at by the R. A. C. formula, in fact, in the majority of cases the manufacturers' ratings compared with the R. A. C. ratings are found to be at a slightly lower figure.

The method of driving cam and magneto shafts by means of chains introduced by Daimler in the Knight engine is now universally adopted. One of the most generally used arrangements is shown in Fig. 1, and has proved satisfactory in every instance where the chains have been of sufficient dimensions, and where the distance A-C does not exceed 7 inches. In this diagram two drives are shown from the crankshaft pinion, the wheel B being on the camshaft and wheel C on the pump or magneto shaft. The centers in connection with this arrangement should be fixed. An alternative arrangement, Fig. 2, which should be use where distance A to C exceeds 7 inches. In this case the crankshaft pinion A drives the camshaft wheel B by means of a chain running over the adjustable wheel D, mounted on a bracket which swings about the center of C, so that the centers of C and D are fixed, while adjustment is provided from the camshaft chain. The wheel G may be of equal size to the wheel C or larger according to the speed required at C. The adjustable axle of the wheels D and G may also be provided with suitable means for driving a fan. The width of chain to be employed for camshaft drives is governed by the bore, valve diameter, spring pressure, cam profile and the auxiliary drives from the camshaft such as oil, water pump and fan. Experiment has shown the best results are to be obtained from adopting the chain slightly shorter in its over-all length than is finally required, running in the chain on an adjustable jig mounted over wheels slightly smaller in diameter until the shortage above named has been taken out by the running in process. The result is that the component parts of the chain have by this process been allowed to settle down, such settling being caused in great measure by the initial sag of any chain.

The proportion of cars fitted with thermo-syphon is still in the majority, being well over 50 per cent. The well-known firms fitting pumps to all models are Austin, B. S. A., Talbot. Daimler, Deasy, Napier with its six-cylinder cars, Lanchester, Rolls-Royce, Sunbeam, Vauxhall and Wolseley. These firms have made no departure from their last year's practice. The six-cylinder Sheffield-Simplex 89 by 127; Crossley four-cylinder 101 by 139, and Humber 105 by 130 are probably the most powerful motors in the thermo-syphon list.

With regard to radiators, the honeycomb type is not so popu-

A study of the above tables is of interest because they show the English trend. They show that for 1913 the average horsepower for four-cylinder English cars is 19.8, while for 1912 it was the same; for six-cylinder cars the average for 1913 is 36.8, while for 1912 it was 34.74. 90 per cent of the changes made for the new season have been towards a higher horsepower, but this has been neutralized by the number of small cars newly brought out. The average horsepower of the American car for 1912 was about 34.3

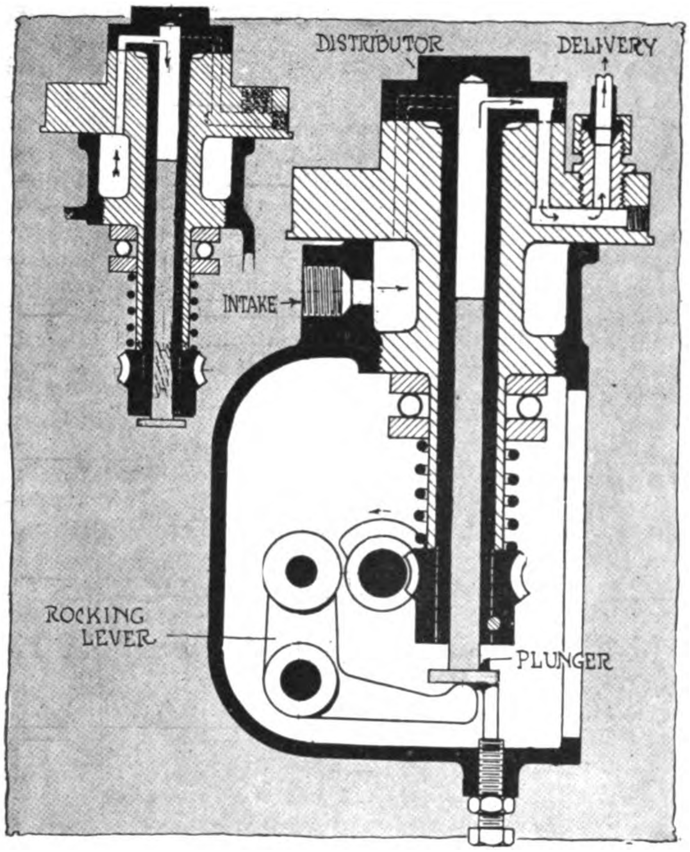

Fig. 3—Dodson oil pump on suction and discharge stroke

lar as the ordinary gilled-tube type, and Wolseley is the only conspicuous firm to adhere to it. The disposition of the radiator on Renault lines is found in connection with the Dodson, Deasy and Arrol-Johnston cars, and does not appear to be in any degree more popular than in previous years, nor is it likely to be in view of the tapering bonnets and scuttle dash boards which are the prevailing fashion. In all the best made cars of both small and high power the radiators are hinged to the side members in order to take up strains set up by deflection of the frame. Little or no change is apparent in the contour or shape as seen from the front, the only variation being in the radius of the curve adopted by the various makers.

The position with regard to lubrication is practically the same as previously. The entirely forced system to all bearings adopted by Crossley, Napier, Armstrong, Star, Vauxhall, Maudslay, Rolls-Royce and Sunbeam in past years is still in evidence, but the more popular system is still the forced to main bearings and trough systems to the connecting-rods. Practically no engine is now built which relies on splash alone. Makers generally are showing no disposition to alter their various systems which have previously been adopted, but are simply improving in detail. Rotary pumps are the most usual for circulating the oil, but where higher pressure is desired the forced pump comes in. A pressure of 20 to 30 pounds is usually found to be quite ample for ordinary work, which can easily be obtained by the rotary pump. For very high-speed work considerably greater pressure has been found necessary, and many of the cars which have done so well at Brooklands during the past season have had oil pressure of over 70 pounds per square inch.

One difficulty arises in connection with the entirely forced system, and that is the tendency to over-lubrication of the pistons by reason of the oil being forced through at too high a pressure. To prevent this baffle plates and scraper rings to the lower end of the piston are frequently adopted. Another method is to fit baffle plates, above which a chamber is formed to run along the whole length of the crankcase immediately beneath the cylinders. This provides an inter-communication between the various cylinders so that the piston suction of the ascending piston is compensated for by the descending one, and thus the oil spray from the crank-chamber is not drawn on to the cylinder walls to the same extent but merely the oil which has been splashed through the opening formed in the baffles for the connecting-rods.

Another point which militates against the freer adoption of the completely forced system is that of initial cost.

Except for racing purposes very little has been done in the way of insulating the oil reservoir from the crankcase for cooling purposes, nor does the ribbing of the outside surface of the sump receive any serious attention. For indicating the operation of the oil pump a pressure gauge is more usually fitted than an indicator.

An expensive but extremely efficient type of plunger pump is that used with the Dodson motors, Fig. 3.

This pump is comprised of a rotating barrel with a plunger that operates within it. In the upper end of the barrel is an opening which registers in turn with the intake and delivery port. As the plunger goes down the opening registers with the intake and the plunger sucks in the oil. On the up stroke of the plunger the opening registers with the delivery port and the plunger forces the oil through it. The reciprocating motion is given to the plunger by a cam operating on a rocking lever and the revolving motion is given to the barrel by a worm acting on the same shaft as the cam.

Another type of oil pump is shown in connection with the Vauxhall engine, Fig. 4.

A plunger pump is situated at the front end of the engine. The plunger of the pump, A, has a ball delivery valve B and an oil suction valve is placed at C; this latter ball valve is prevented from rising too high from its seat by the taper pin D. Oil enters the pump from the lower part of the sump E and passing the valve B on the downward stroke of the piston, flows through the drilled passage F in the first place into the air chamber G, which latter relieves the oil passages and pipes of any shock that might be due to the intermittent action of the pump. It will be noticed that the pump plunger has at its upper end a second piston H and the purpose of this piston is merely to prevent the passage of oil otherwise than through the drilled port F when the plunger is taking its downward stroke.

This method of construction, while it does away with the necessity for a stuffing box or long guide, enables the plunger to be withdrawn with facility and despatch. The pump is driven by a small crankpin having a ball bearing J. The oil on passing out of the air chamber G flows to the longitudinal pipe K, whence by way of short curved pipes, such as L, each of the main crankshaft bearings is fed from the underside through the bearing cap. Oil escapes from the bearing and drops into the sump E, whence it is filtered before again being drawn into the pump. A small chamber M is attached to the side of the crank-chamber; this chamber contains a float N of similar construction to those used in connection with the constant level of the gasoline supply. The float has a needle O which at all times registers the depth of oil in the sump. This needle is easily visible by lifting a flap of the bonnet and is not at all in an inaccessible position as are some glass gauges used for the same purpose. A pressure gauge on the dashboard shows the pressure in the lubrication circuit, and a tell-tale rises and falls at each stroke of the pump and indicates that the system is working and in order.

A very neat fitting is furnished in connection with the clearing of the oil sludge from the crankcase. The Vauxhall has used this particular fitting for a couple of seasons, but it deserves to be described here. A body piece is screwed into the bottom of the oil sump and this contains an ordinary mushroom valve pulled in a downward direction by a spring. Onto the underside of the body piece is screwed a cap and the length of the spindle of the valve is such that when the cap is screwed home the valve is forced from its seat. In this position any dirt or thick oil falls to the bottom of the cap, and is not affected by the pump suction. On removing the cap the valve is permitted to seat itself and thus seal the opening in the sump bottom, while the contents of the cap may be thrown away and the cap replaced in its original position.

A small air pump is employed to deliver aid for lifting fuel from the gasoline tank. This pump has its trunk piston driven from the same pin which operates the oil pump. Both the suction and delivery valves are steel balls retained upon their respective seats by light helical springs. The piston, it will be noticed, does not reach the top of the pump cylinder, so that a high compression of the air would not be possible under any circumstances. There is, however, a small spring loaded safety valve at R which can be adjusted as to the pressure at which it shall blow off by the milled nut S. Air passes to the gasoline tank by way of the pipe T.

The Bosch magneto has become almost a standard feature with the British manufacturers. The fitting of the ordinary type or dual type is simply a matter of the price of the car, dual ignition being found in practically every car over $2,000. The dual system is most usually worked with one set of plugs. Two complete systems, magneto and coil, with separate distributers and plugs are only found on the very expensive cars, and generally in these cars the two systems are separate and independent. In view of the great reliability of the high-tension magneto the luxury of these two sets seems to be almost superfluous. Automatic advance is not taking on, while fixed ignition is only found with cheap cars. With regard to protection of magnetos the Bosch company has recently introduced a waterproof type which is entirely damp-proof in every possible way.

The number of firms who are discarding their own type of carbureter and taking up well-known models is becoming very prevalent. The Zenith, Claudel, Hobson, S. U., Solex and White & Poppe take a very large proportion of the trade. The Wolseley company has recently adopted the S. U. and the Sunbeam the Claudel-Hobson. It is quite clear that the manufacturers are leaving the question of carbureters in the hands of firms devoting themselves entirely to this component which is not only a saving of work done in the companies' factories, but a direct economy as well.

Self-starters are just beginning to receive serious attention. Wolseley is fitting as stock a self-starter on its six-cylinder models and at a charge of $100 to its four-cylinder models. The starter is a compressed-air type, Fig. 5. The air pump is driven by chain and sprocket provided with a clutch coupled to the end of the lay gearshaft. The compressor has two vertical cylinders with a pair of atmospheric outlet and twin delivery valves, and non-return outlet valve being placed in the air delivery pipe. The air is compressed into a steel reservoir, a gauge on the dash registering the pressure. The distributer has four cams driven from the end of the camshaft. The cams lift the distributing valves through tapered fingers which are withdrawn except when the distributer is moved into the starting position. Normally when the vehicle is running the pump is out of engagement, depending of course upon the pressure in the store tank. The shut-off valve is conveniently placed at the side of the chassis, which is closed when the vehicle is not in use and opened before starting. All the joints are most carefully made with the same material as is used for Diesel engines. The pipes are of steel with special connections used in submarine work. Spring loaded non-return injector valves are fitted in the exhaust valve caps of the cylinder. The distributer is so arranged that when not actually starting the engine no parts are in motion. The starting lever on the dashboard is so arranged that it throws the tappet levers into position between the starting cams and valve stems, this being combined with a motion which opens the air admission valve. Of course, the air compressor can be arranged to pump the tires, thus increasing the operator's comfort in more than one way.

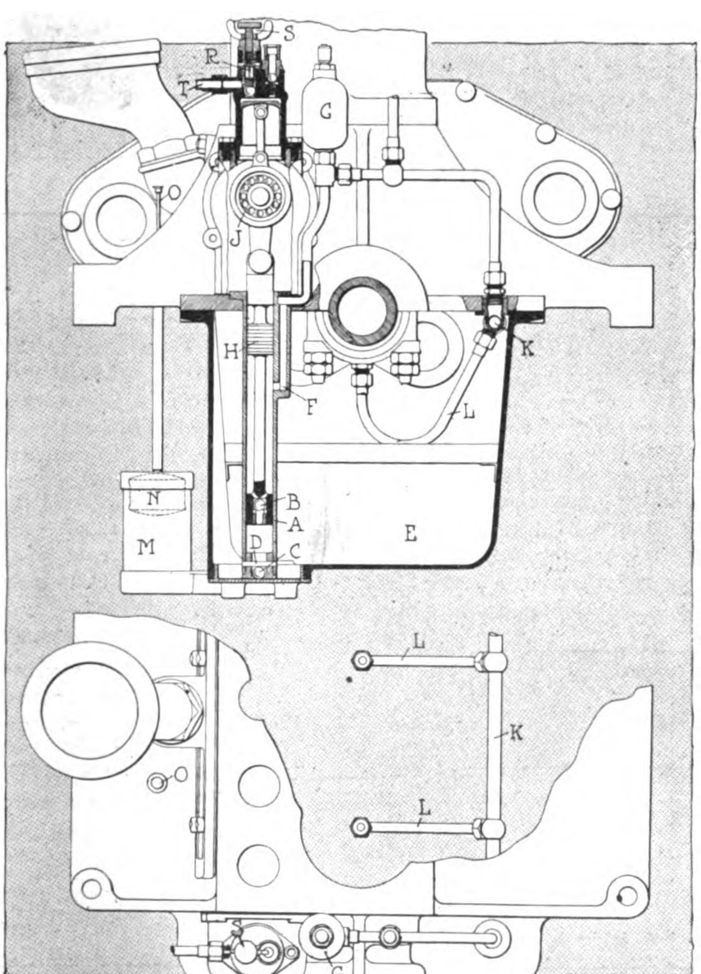

Fig. 4—Vauxhall motor oiling system

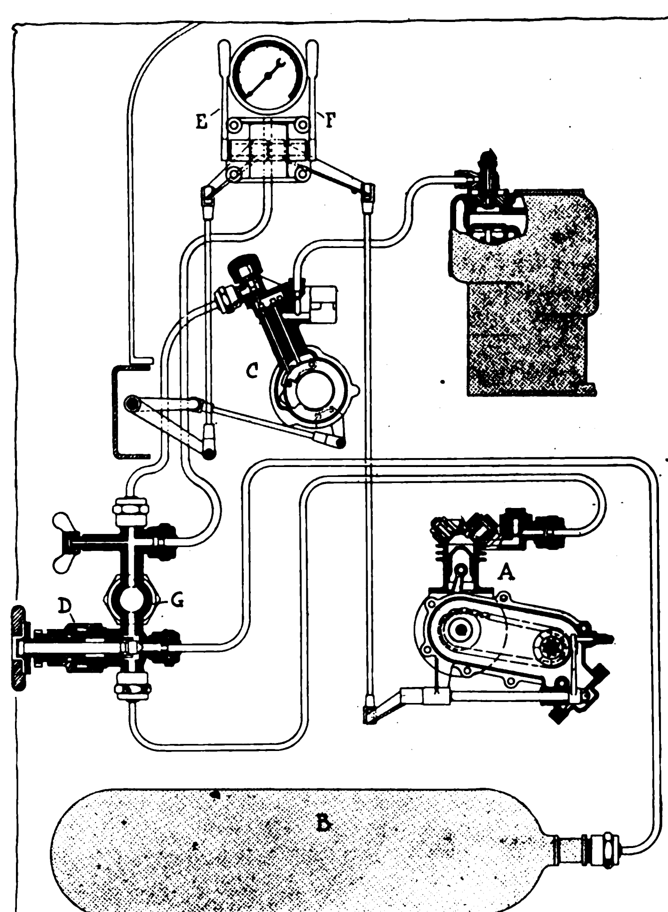

Fig. 5—Wolseley compressed air self-starter, one of the two self-starters in use on English cars

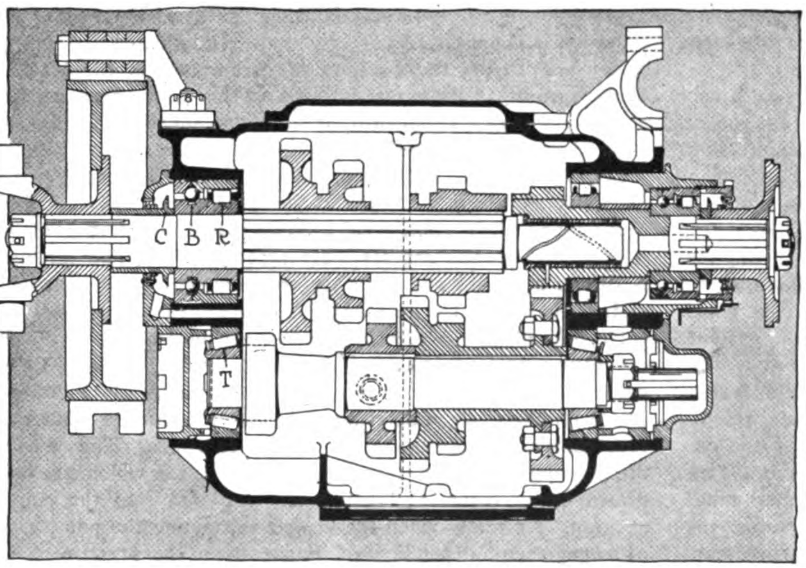

Fig. 6—Wolseley gearbox for 16-20-horsepower car

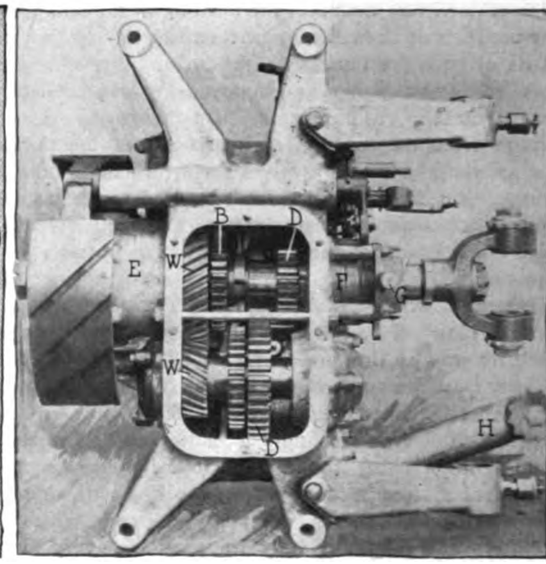

Fig. 7—Napier six-cylinder car gearbox

Wolseley is the second firm in this country to adopt the self-starter as stock equipment, the previous one being the Adams, also using compressed air. Now that a start has been made in fitting self-starters the further adoption will make more rapid progress. Many firms are looking closely into the proposition, and the most favorably received are compressed air and electric Acetylene starters as used in America are not looked upon with any favor.

Detachable wheels are making great headway, and the makers supplying these without extra charge have doubled for 1913. The detachable wire wheels of the Rudge-Whitworth or Riley type predominate, and a larger number of makers is using the pressed-metal wheel of the Sankey pattern, and this type is receiving considerably more favor than during the past season, one of the reasons being that it more nearly approaches the wooden wheel in apparance. It is a very much easier wheel to clean and has proved itself in practice to be as strong as the wire type. The chief advantage of the wire type is in connection with the saving effected in the wear of tires. This saving was demonstrated by the number of Daimler cars of heavy construction which have been used for hiring purposes. Fifty were fitted with wire and fifty with wooden wheels, and after a very extended period of time it was found that the total mileage of tires fitted over wire wheels was 172,731 and the total mileage of the tires fitted over wooden wheels was 102,524. The tire sizes were 935 by 135. The writer's own experience confirms this to some extent, as with the same car 33 per cent. extra mileage was got out of the tires when fitted to the wire wheels.

Where changes are being made in the number of speeds it is found that such change is from three to four. A notable change has been made by the Napier company with their 15-horsepower Model de Luxe, which has hitherto been fitted with only three speeds. For the future a four-speed gearbox can be supplied. Humber is adopting four speeds in its 68 by 130 and its 75 by 130. Standard, Dodson, Dennis, Calthorpe, Bell, 10-horsepower; Austin 12-horsepower, Swift and Sheffield-Simplex are all supplying four-speed gearboxes in place of last year's three-speed models. With these modifications the four-speed gearboxes are considerably in the majority. Short, compact gearboxes of the one-piece casting type notably give the best results, and the aim of every manufacturer is directed to this end. The multi-spline shaft is universally adopted, and the six splines are increasing in numbers, although not predominating. Spigot shafts are in many cases fitted with ball bearings.

Fig. 6 shows the latest Wolseley gearbox product for its 16-20 four-cylinder chassis. This gearbox is remarkable inasmuch as it is fitted with three different types of bearings, namely, the parallel roller R, Timken roller T and ball B. The gearbox

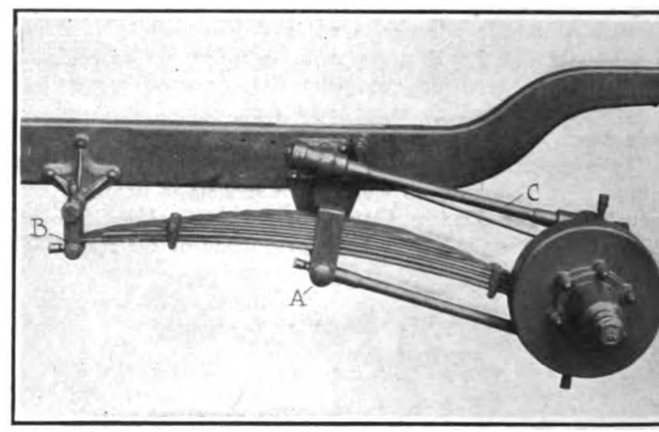

Fig. 7 A—Deasy Lanchester spring system

is arranged for four speeds, and there are six splines on the shaft carrying the sliding gears. There is no longitudinal division of the gearbox, and special means are taken for preventing the oil from escaping along the shaft, oil catchers C and felt pads being employed. The size of the brake drum fitted to the shaft is typical of the better-class British cars. Brake diameters and widths have increased to very substantial proportions. The large diameter of the gearbox shaft is worthy of notice.

In the gearbox of the six-cylinder Napier, Fig. 7, compactness is the cardinal characteristic, so as to make the shafts as short as possible for stiffness and for silence of gear changing. The box is aluminum suitably webbed. The countershaft is driven by helical-cut gears and the second speed sliding gear acts as top speed direct driving dog which meshes with internal cut teeth in the main shaft helical gear.

The gears are of large proportions, the mainshaft is specially interesting, runs on ball bearings, and at the rear end revolves in a large double row bearing within the casing projecting beyond the gearbox proper. The shaft is thus supported immediately under the brake drum and will properly withstand strains thrown upon it by application of the brake, which, again, is an entirely new type internally expanding, having all its mechanism inside the drum. The mainshaft has a large adjustable stuffing-box at either end so oil cannot escape on to the brake.

The front stuffing-box has its gland notched and a spring bolt locks in any position after adjustment.

The oil filler is conveniently arranged under the driver's footboard; it also acts as a level indicator as when filling the oil should be poured in so that it just appears in the orifice.

An interesting method of gearbox lubrication is shown in connection with a patent taken out by Wolseley, No. 20,228. Although this arrangement of lubrication is not standardized, it, however, foreshadows construction which may materialize as a commercial practice at a subsequent date.

Fig. 8 requires but little explanation. The gears revolve in troughs and in the bottom of the gearbox is a sump which contains a quantity of oil. This is circulated by means of a pump in a similar manner to the troughs provided for lubricating the connecting-rod ends. The principle is shown applied not only to sliding gearboxes, but also to worm drives, and for lubricating chains in connection with engine timing gears.

The chain-driven gearbox is making no headway in connection with pleasure cars, an objection to it being the extra weight. Maudslay introduced this type last year, but is not continuing it.

A recent patent taken out by Wolseley, Fig. 9, shows a combination chain-and-spur gearbox which indicates that considerable thought is being directed to the chain-driven gearbox. The chain box has been so successful with omnibuses that its adoption for pleasure cars is certain to be more conspicuous in the near future. With the Wolseley box the third gear is directed by dog clutches, the second speed is by silent chains and the first speed by gears. Reverse is partly through chains and partly through gears. The driving shaft is shown at A and the driven shaft at B, this being connected to the propeller shaft as usual. For the direct drive the dog clutches C are engaged. For the second speed the dog clutches D are engaged when the power passes through the chain wheels E (chain not shown) to the layshaft, reaching the driven shaft B through the chain on the chain wheels F. For the first speed the dogs D are disengaged and the gear sleeve G moved to the left. The power then passes through the gears H, and so to the gear sleeve G, and thence through the gear wheels J to the driven shaft. The gear sleeve G is mounted on bearings upon the layshaft so that the two can rotate independently. For the reverse gear the sleeve G is moved to the right, meshing the dogs K, while the gear wheel L engages the wheel J on the driven shaft B. The reverse is therefore through chain wheels E and gears J and L, the layshaft and sleeve then revolving in the same direction.

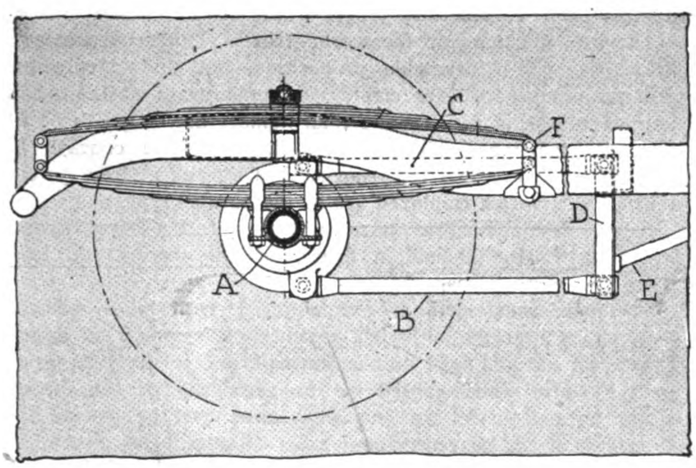

Fig. 7 B—The Austin featured rear spring system

The underslinging of wheel springs is becoming more prevalent. Wolseley adopted this last year, and now Daimler is following with its 20-horsepower model. This practice of underslinging is but a return to a practice which was common 10 years ago. The chief advantages are that it enables the springs so to convey the torque of the axle casing when the drive is first taken up or the brakes are applied, and that the dithering which is common under these conditions to a large number of cars is prevented. The radius and torque rods minimize this feature, but there is no doubt that with a carefully designed underspringing the best results can be obtained without the additional fitting of torque and radius rods. The objection from the user's point of view is the fear of breakage from the spring clips, but of course it is quite a simple matter to provide a sufficient strength in these parts. Daimler is employing two spring clips placed diagonally instead of the more usual parallel system.

Springs are to be long, wide and with little camber so that when loaded they are practically flat, and the three-quarter elliptic is most favored. The dimensions with a well-designed car suitable for a covered body will have springs 48 inches long, 2.5 inches wide and composed of about six plates. Instead of shackle plates under the two parts of the spring shock-absorbers, or in reality spring shackle plates are usually provided.

The Lanchester system of springing adopted by Deasy, Fig. 7A, consisting of an inverted half elliptic leaf spring at each side in combination with parallel link motion. The spring is fixed to a bracket which is pivoted at A. Its front end is attached to the shackle B, while its rear end is housed in a slide attached to the ends of the back axle. At A is pivoted the radius rod, which is articulated to the back axle immediately below the spring pad. The radius rod forms the link which conveys the propulsive thrust of the driving wheel to the chassis, and, as will be seen by reference to Fig. 7A, the link is attached to the back axle end by means of a universal joint.

Torque rod C is likewise articulated to the back axle casing, lying parallel with the radius rod. The function of this torque rod is to prevent the tendency the engine has to try and rotate the axle casing against the resistance of the road wheel. The

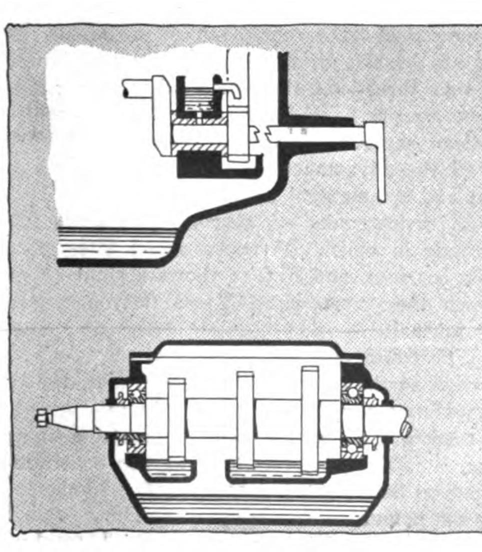

Fig. 8—Wolseley patent for gearbox oiling

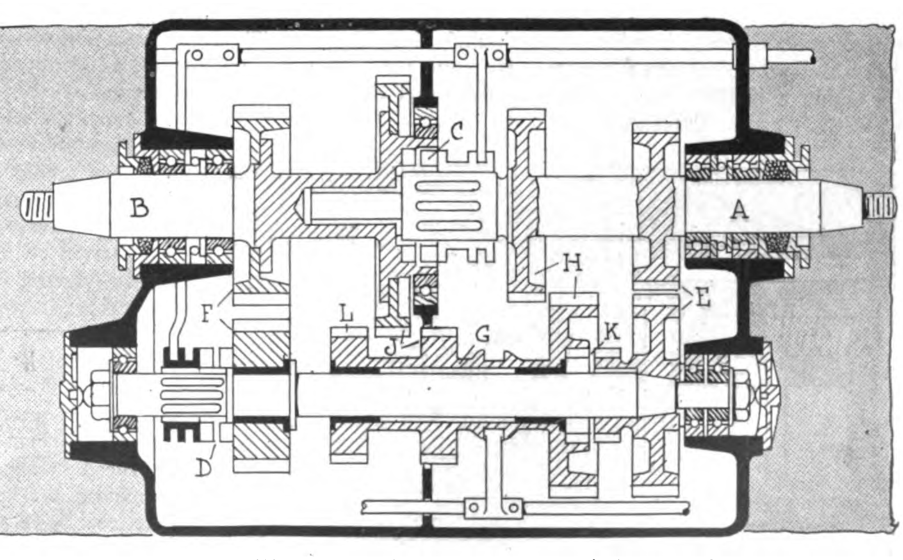

Fig. 9—Wolseley combination gear and chain gearset

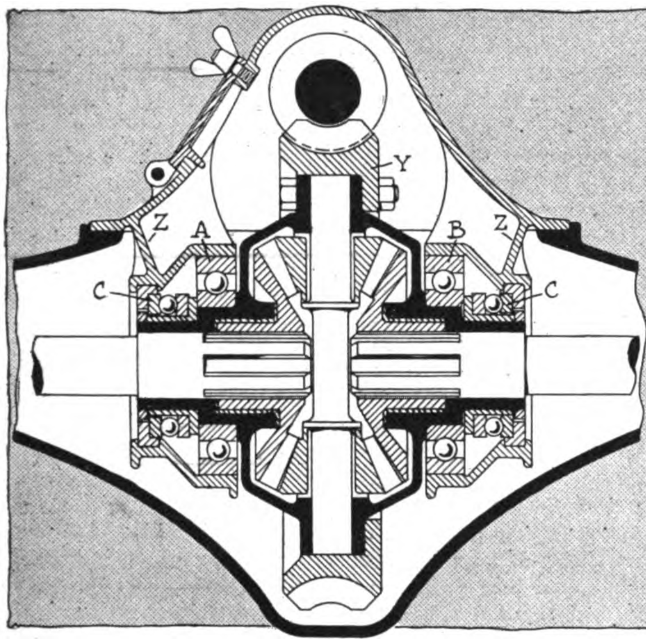

Fig. 10—Worm mounted midway between annular bearings

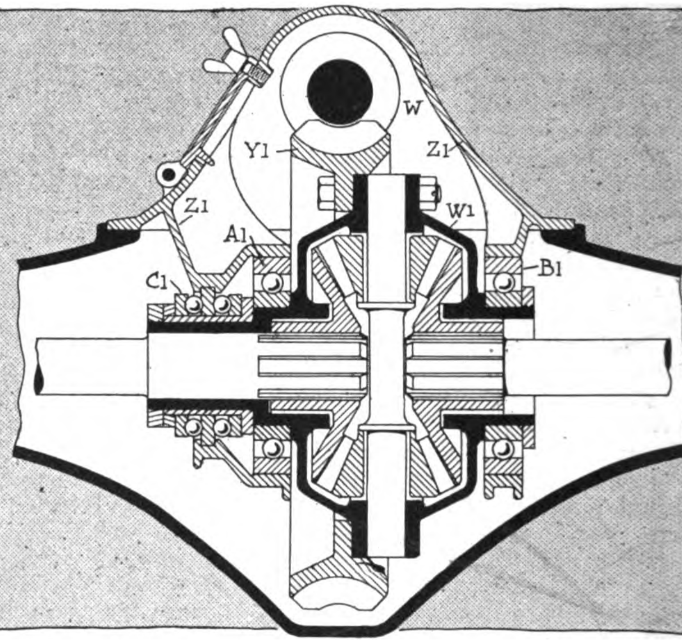

Fig. 11—Worm mounted out of center between bearings

rod effectively prevents this action, and in order to avoid any possibility of shock or jar being transmitted through it, it is provided at its rear end with a telescopic joint, in which it works against the action of spring buffers. All the moving parts throughout this mechanism are fitted with efficient means for its lubrication and is thoroughly waterproof. The suspension on each side of the axle is quite independent; the illustration shows the detachable wheel removed for the sake of clearance.

Another spring suspension off the ordinary lines is the Austin, Fig. 7B. In this arrangement to take the live axle torque and also the strains of driving and braking effect, the axle casing A is connected by parallel rods B and C to a rigid hanger D which is connected by struts E to the frame. By means of the parallel link system B C the axle is prevented from twisting as it moves in relation to the frame when so permitted by the springs. As will be gathered, the ends of the axle are not restrained by means of the rods C from moving backward and forward, As it is desirable to check such movement, the front ends of the springs at F are fixed to the frame, so that this movement of the axle is resiliently resisted.

The worm drives do not appear to be making any marked progress. Taking 131 models in 1912, forty-eight were fitted with the worm drive, equal approximately to 36 per cent. of the total. Compared with 128 models in 1913 forty-seven are fitted with worm drives, or approximately 37 per cent. This year Sunbeam discarded the worm drive, and for 1913 Maudslay is taking a like action, returning to the bevel drive. In each case there are local reasons.

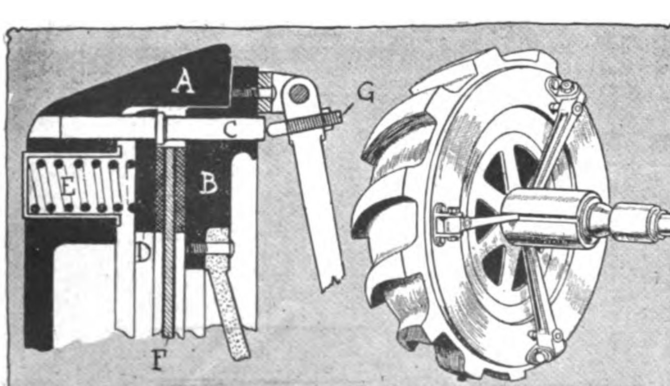

Fig. 14—Deasy clutch in section and perspective

Daimler, Argyll, Armstrong-Whitworth, Deasy, Lanchester, Vulcan, Dennis and Thornycroft continue worm drive. Several makers, however, appear to be undecided, and supply either bevel or worm at the purchaser's option. This does not appear to be a very satisfactory method of dealing with the proposition, and it must entail considerably larger works costs.

The best position for the worm, that is, either overhead or below, is still a debatable proposition, but undoubtedly the greatest number of cars employ the underneath position, and only about 25 per cent. of the total number are found to be of the overhead type. The relative merits of the concave or parallel worm are still far from settlement, and at least 50 per cent. of the worms employed are of the parallel type.

A well-designed worm drive is that made by David Brown & Sons, of Huddersfield, a firm supplying worms and back axles for many British cars.

The more usual method of mounting a worm wheel midway between its bearings, although presenting a symmetrical design throws an unequal load on the journals due to the side thrust on the worm wheel caused by the angularity of the thread. These unequal loads can only be counteracted by placing the worm wheel out of center, and exact distance being dependent upon the angle of inclination of the worm thread and the pressure angle of the teeth.

Where the worm wheel is so placed out of center, the design presents an unsymmetrical appearance, but if a double ball thrust is arranged on the side of the journal remote from the direction of the side thrust on the wheel, then the correct position of the wheel to give equal loads on the bearings will be approximately midway between the two extreme points of the unit, thus giving all the advantages of increased efficiency together with a neat and symmetrical appearance.

Fig. 10 shows an arrangement of gearing as applied to a worm-driven rear axle in which the worm wheel Y is placed midway between its bearings, and Fig. 11 shows a similar form of gearing in which the worm wheel Y1 is unsymmetrically placed between its journals.

In Fig. 10 the differential gearing is mounted on two bearings, A and B, carried on the case Z and on either side of these journals are mounted two thrust washers C. In this arrangement of gearing, assuming the power to be transmitted on the low speed is approximately 30 horsepower at 300 revolutions per minute, the load on bearing A is 7,530 pounds and the load on bearing B is 4,350 pounds.

Referring now to Fig. 11, W is a worm which transmits motion to the worm wheel Y1 mounted on the differential casing W1 which contains the usual differential gear and is set out of center. The differential gearing is mounted on two journal bearings A1 and B1 carried by the case Z1. In this arrangement of gearing an equal load is obtained on each bearing.

The Brown improvement consists in applying a double-acting thrust bearing. C1 located on one side of the worm or spiral gear wheel whereby a symmetrical design and increased efficiency of the gearing is obtained, the thrust in both directions being taken up by said bearings.

The worm arrangement of the Thornycroft car is typical of many others. Fig. 12 shows a longitudinal section through the axle and Fig. 13 a transverse section. The worm is of the type having a concave face and it is not solid upon its shaft, but is driven on to four splines on solid keys formed upon the shaft. Presumably this is done to facilitate, or in any case to cheapen, the replacement of the worm should such replacement become necessary. A double ball thrust bearing is fixed on the back end of the axle. The dome-shaped cover on the top of the casing, which can be readily removed, permits great accessibility to the internal parts, and it will be seen that the driving axles have fluted ends that engage with the bevel pinions of the differential gear; thus these axles may be pulled out to permit withdrawal of the worm wheel, differential casing, bearings, etc.

The leather-faced cone clutch is still the most popular type. In 1912 58 per cent. of the British cars were fitted with this type, while the proportion for 1913 works out at 59 per cent. The multiple-disk clutch takes second place, and the figures for 1912 are 25 per cent and for 1913 27 per cent. The figures for the single type for 1912 are 13 per cent. and for 1913 11 per cent., the balance being accounted for by other types, such as the metal expanding.

The Deasy clutch, Fig. 14, is completely inclosed within the flywheel. A diagrammatic section of part of it indicates the manner in which the clutch is arranged. A is the rim of the flywheel, to which is screwed a disk B carrying a dished aluminum center, spoked as shown. Supported in these two members are three sliding pins C, the shoulders of which abut against a flat ring D, which is in turn supported by the pins C, and is pressed into engagement by six spiral springs arranged circumferentially, one of which is shown at E. These springs are carried in the web of the flywheel in brass thimbles.

Between the ring D and the inner edge of the rim B is interposed a disk F carried in the aluminum center, within which it is free to rotate. Mounted on B and D are rings of asbestos fabric. The effect of the springs E is to grip the center plate F

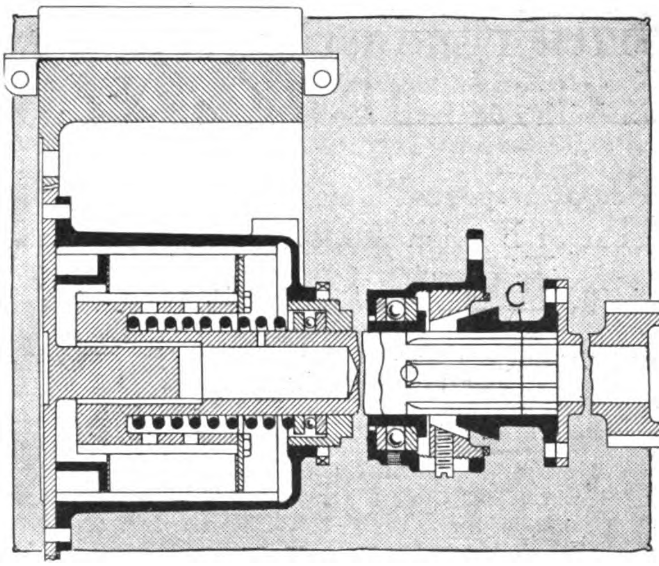

Fig. 15—Section through Thornycroft plate clutch

between the fabric-lined surfaces of D and B, and as the friction thereby produced is very large, owing to the nature of surfaces, only comparatively light springs are necessary.

A thrust ring carried concentrically with the clutchshaft and actuated by the clutch pedal operates three rocking levers pivoted to the rim of the flywheel. These levers carry thrust pins G which press against the outside ends of the pins C, and pressure upon the clutch pedal therefore throws D clear of F and allows the clutch members to run free of one another. A small additional spring is introduced on the clutch shaft to allow the disk F, when the pedal is depressed, to run clear of the surface of B.

In the Thornycroft plate clutch, Fig. 15, the piece which transmits the drive from the plates is one piece with the shaft and this shaft is drilled from its front end so as to take the supporting tail shaft as well as for the sake of lightness; this same shaft is fluted at the rearward end into the coupling C. The whole constitutes perhaps a somewhat expensive piece, a point worthy of consideration if renewals are likely to be necessary. The ball thrust bearing that comes into play on the withdrawal of the clutch is a heavy one and certainly, having in view the comparatively light clutch spring, would not appear to be overloaded.

British Industry from Critical Point of View

Price of Imported Cars Has Fallen While That of English Automobiles Has Been Raised, Cutting Out Cheap Grades

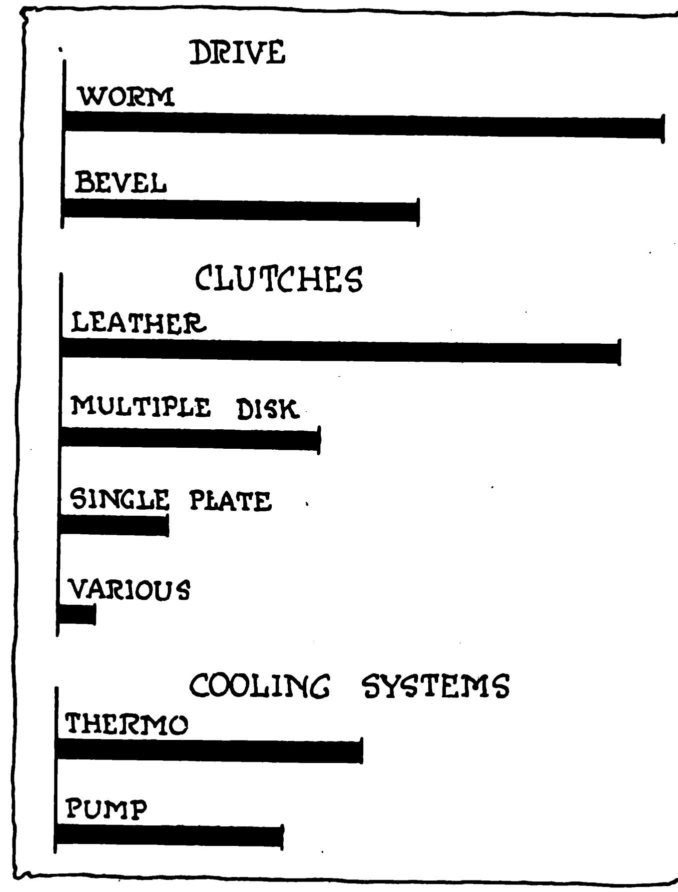
Practice of Making Many Models in Small Factories Eliminates Competition on a Strict Basis of Price

AFTER reviewing the mechanical features of the exhibits which are being installed at the Olympia Hall on November 8, it will be interesting to consider the present state of the British motor industry. Great Britain has no tariff or import duty, and therefore the world's productions can be offered for sale on an equality with the home made constructions. The pros and cons of the fiscal policy of the British Government are not within the scope of this review. The question of tariff reform must be left to the political arena, and the only connection free imports have with the general aspects of the automobile industry is in regard to the means which the British manufacturer has, or may adopt, to keep out foreign competition.

Upon reflection it appears somewhat strange that the British manufacturer has only been roused, or perhaps to be more correct, the British public, in this direction, by the comparatively recent importation of cheap American cars. For years past, ever since the automobile industry became a live one, the imports of cars, chassis and parts from the Continent of Europe has each year assumed large and increasing proportions, in fact, as the popularity and usefulness of the motor has developed, so have the imports increased.

There is good excuse for the purchase of the cheap high-powered American car by the British user, for the reason that hitherto neither the Continental, nor the British makers have provided that type of vehicle, that is a powerful four-cylinder car, light in weight, and not exceeding £200 in price.

While constructors on this side have been making expensive cars for the wealthy buyer, the American constructors have been working out the proposition of supplying a lower grade article, cheap in first cost, and cheap to renew, which is within the range of a man of moderate means, and there is distinct evidence that the importation is having an effect on the British productions with those makers who have attempted in a feeble manner to produce a low-priced car. Importation, however, is having an effect which is proving beneficial to the manufacturer of higher class cars here. The American car has been the means of educating a large number of people in the use of motors who have since learned to enjoy the pleasures which the



Graph showing ratios of constructive features as shown on British automobiles for 1913

ownership of an automobile brings with it. Once a motorist always a motorist is a truism, and many who have commenced their motoring experience with a cheap car are now owners of more expensive types of vehicles.

It will be of interest to give some particulars of the importation of cars into this country, and the accompanying table gives the imports from 1908 to 1911.

For the 9 months ending September 30, 1912, the value of imports was as follows:

Cars, 6218, value	£1,478,397
Chassis, 6906, "	1,490,726
Parts, "	2,483,562
Total	£5,452,685

In 1911 the corresponding figures were:

Cars, 4927, value	£1,286,351
Chassis, 5198, "	1,353,568
Parts, "	1,925,274
Total	£4,565,193

The value of imports from the United States has been ap-

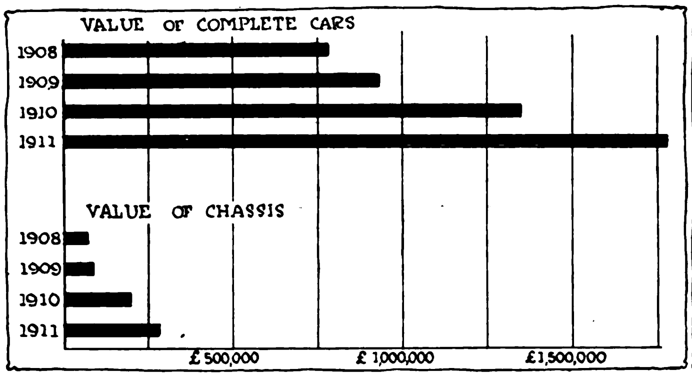

Diagram illustrating total values of British automobile exports for the last 4 years

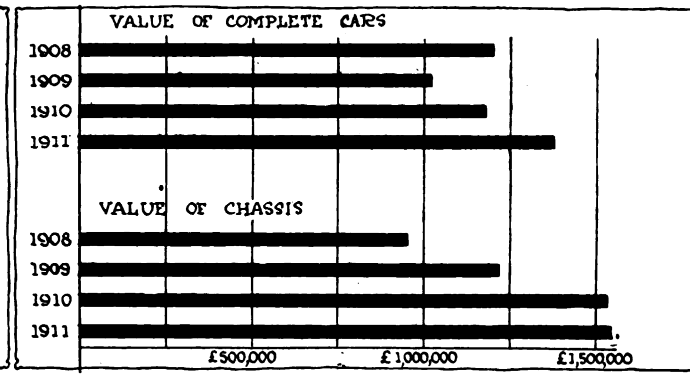


Respective values of Great Britain's automobile and chassis imports since 1908

proximately as follows: Complete cars, chassis and parts, 1910, £495,383; 1911, £676,053; and for the first 9 months of 1912 £631,318.

From these figures it will be seen that the figures for 1912 will considerably exceed the figures of 1911, for on September 30 the figures showed an increase of £135,935 over the figures for the 12 months of 1911. From the figures relating to the American productions one finds that 4,001 vehicles were imported from the United States in 1911, and 2,340 for the first 5 months of this year, while there is evidence that the numbers imported are increasing at a rapid rate, so much so, that very shortly the United States will be the greatest exporter of complete cars and chassis into this country, both in numbers and total value.

While the imports rise it is encouraging to see the exports also rise, the figures relating to which are set out in the accompanying table.

For the 9 months ending September 30, 1912, the total exports amounted to £2,532,573 as against £2,126,602 for the year 1911.

In view of the many records achieved by British cars it is obvious that the importations are not due to their inferior quality. Looking at the average prices during the past years of the imports and exports, it will be seen that the price of the imported cars has steadily decreased, while the average price of the British-built exports has increased. In 1908, the average price of cars imported was £363, falling to £253 in 1911, whereas the average price of exported cars has risen, from £361 in 1908 to £397 in 1911. It therefore appears evident that the manufacturers of Great Britain intend to increase the price of their constructions, and that they do not trouble themselves to set about the production of cheap automobiles. What is the reason of this attitude, and why is Great Britain content to allow this large proportion of its purchases to go to the foreigner, and, further, what is the British manufacturer doing to meet the situation? First, the manufacturer of repute has no inducement to do otherwise than he is doing at the present time. With the capital he has at his disposal he is getting all the trade he is able to cope with, and therefore has no desire to reduce either quality or price. As regards output and profit he is quite content, and every year one sees the gradual increase of plant and buildings, paid for mostly out of profit.

Great Britain Can Build Cheaply

Some 2 years ago the writer went most carefully into the cost of manufacturing automobiles in Great Britain, with the head of one of the largest automobile factories in the United States, and the conclusion arrived at after a most careful and elaborate study in connection with the conditions of labor, cost of materials both in England and America, and also in Europe, was that in no country in the world could automobiles be built more cheaply than in Great Britain.

However, the British constructor has little initiative. He wants his market sure at the outset, and is not running any risk of setting out to make goods of which there is an element of doubt as regards their disposal. In other words, he has no confidence in his selling organization, and he therefore runs his business on safe and sure lines.

There is abundant evidence that cheap cars for the multitude can be built here at competitive prices, and such cars would, now that the motoring fever has not only developed to the fullest extent, but is rapidly extending to our Colonies, sell in large numbers, yet no financier or financiers are yet forthcoming to provide the necessary capital.

Another factor in connection with the British motor industry which does not tend toward cheap production is the policy adopted by the majority of manufacturers in making a large range of models, and trying to satisfy every inquiry that comes along. Even the smallest firms are constructors of three, and, in many cases, four models.

It does not appear likely that any of the well-established firms will in any way modify their existing policy in producing only expensive models, in fact, it would be prejudicial to their best interests to do so. As an example, some 2 years ago, one of the largest firms made a substantial reduction in its prices. Did it sell more cars? On the contrary, the public at once said that the firm had reduced quality, and the sales actually fell, only to be recovered by a substantial increase in the following year.

Foreign Vehicles, Chassis and Parts Imported to Great Britain

	1908	1909	1910	1911
Complete cars	3,830	3,666	4,516	6,778
Re-exports	434	550	822	1,047
	3,396	3,116	3,694	5,731
Chassis	3,370	4,855	6,553	6,672
Re-exports	236	224	332	494
	3,134	4,631	6,221	6,178
Value of complete cars	£1,389,552	£1,223,053	£1,439,962	£1,717,983
Value of re-exports	161,561	177,064	234,458	308,569
	£1,227,991	£1,045,989	£1,205,504	£1,409,414
Value of chassis	£1,063,077	£1,321,596	£1,671,593	£1,723.889
Value of re-exports	88,446	78,271	104,842	152,735
	£974,631	£1,243,325	£1,566,751	£1,571,154
Total net value	£2,202,622	£2,289,314	£2,772,255	£2,980,568
Average price per car	£363	£333	£319	£253
Average price per chassis	£315	£272	£255	£258
Value of parts less re-exports	£1,550,518	£1,633,467	£1,840,401	£2,336,182
Total value of all imports	£3,753,140	£3,922,781	£4,612,656	£5,316,750

British Vehicles, Chassis and Parts Exported to Foreign Countries

	1908	1909	1910	1911
Complete cars	2,216	2,580	3,555	4,539
Chassis	225	221	564	733
Value of complete cars	£800,636	£952,431	£1,376,886	£1,805,025
Value of chassis	£75,984	£85,356	£213,536	£295,289
Total value cars and chassis	£876,620	£1,037,787	£1,590,422	£2,100,314
Average price per car	£361	£369	£387	£397
Average price per chassis	£337	£386	£378	£403
Value of parts	£381,939	£525,818	£1,015,105	£1,085,403
Value of all exports	£1,258,558	£1,563,605	£2,605,527	£3,185,717

Automobiles, like other commodities, are not sold solely on their merits. In fact, other influences in many cases count for more than merit.

The American importation has already had this effect on the British trade. It has entirely killed the one and two-cylinder cars. No less than fourteen models of the one and two-cylinder type have been discarded. The Rover Company has discontinued four models of the one and two-cylinder type, and will construct for 1913 only two four-cylinder models, namely 12 horsepower, 75 by 130 millimeters at a chassis price of £275 and a larger 20-horsepower model, 90 by 130 millimeters, the chassis of which is listed at £375. Last season this firm listed a one-cylinder car complete at £135.

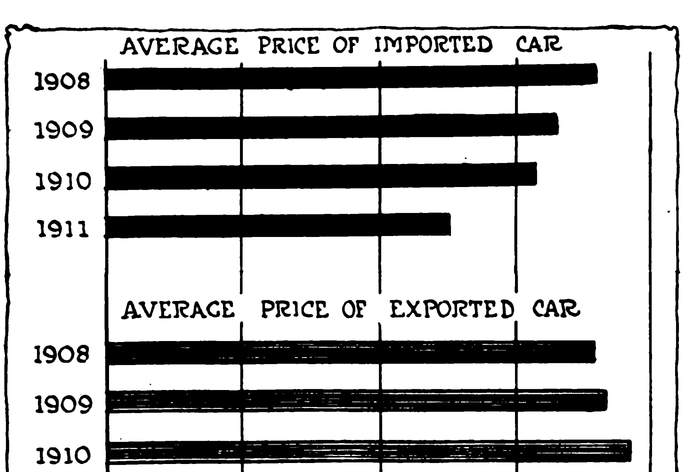
The Swift Motor Company is also discarding its one and two-cylinder types, and will in future only construct four-cylinder models. The smallest size is a 10-horsepower, 65 by 100 millimeters, chassis listed at £175, or with body, £195. This latter model is an attempt to compete with the American cars. In comparison, this British car has roughly only half the horsepower and is considerably more expensive than some of the importations.

The decease of the one-cylinder car will be regretted by none, and it is amazing that it has been permitted to exist for so long a time.

A new type of car, termed the cycle car, is being introduced by more than one firm. The Humber and Singer, among others, are in the market with a light four-cylinder machine selling for about £125. This class of vehicle is very light, built on cycle lines, and has been allotted a special class by the R.A.C., weight being the basis of the class. The cycle car, as termed by the R.A.C., is a car, the weight of which does not exceed 6 hundredweight, and such cars are not permitted to compete with so-called motor cars in any contest under R.A.C. rules. These vehicles are designed to run at a cost not exceeding 1 penny per mile for tires and gasoline. It is doubtful if this type of car will in any way meet the foreign competition, but it will certainly replace in a number of instances the cycle and side car, the use of which has, during the past 12 months, reached enormous proportions. With this light type of car a two-cylinder engine is usually employed.

Hoosier Trade Decides on Show

INDIANAPOLIS, IND., Nov. 11—The annual motor car show of the Indianapolis Automobile Trade Association will be held March 24-29 and probably will be held at the Coliseum at the state fair grounds, north of Indianapolis. At an election held recently the club elected a new board of directors.



Average price per car of Great Britain's automobile imports and exports

Manx Race for Next Year

Announcement of British Classic for 1913 At Olympia Show Meets Hearty Approval of the Automobile Industry

Attendance at Exhibition Sets New Mark and Affair Is Called Best Body Show World Has Seen

LONDON, Nov. 12—*Special Cable*—Announcement was made at the banquet held on the evening before the Olympia show opened that the Royal Automobile Club had decided to organize a race to be held on the Isle of Man in 1913.

The announcement was received with the utmost enthusiasm. The object of the race is to give the British manufacturer an opportunity to show that he can produce a car at moderate price of such quality that it can stand the severe test of a road race lasting 2 days.

There is a distinct spirit of optimism prevalent throughout the whole industry. The show attendance is a record so far. No less than 34,672 persons visited the show on Saturday last, which is 30 per cent. above last year's figures. Many makers have sold their output before the doors were opened.

There is little that is actually novel in chassis construction but improvements in details abound. The attractions chiefly center around the superb examples of carriage work. All the most renowned carriage builders of Europe are represented. The automobile body construction shows more advance than any other section of the industry and the present exhibition will take rank internationally as the finest exhibition of carriage building ever held. Large enclosed cars predominate and the ordinary landaulet is almost entirely superseded by the limousine-landaulet. Great inerest is being shown in self-starters. The feeling generally is in favor of the electric combined with a lighting outfit. Several experimental plants of this type are on view but no makers are yet adopting any as a standard equipment.

Detroit Dealers to Draw for Show

DETROIT, MICH., Nov. 11—A meeting of the entire membership of the Detroit Automobile Dealers' Association will be held on November 23 at which the first drawing for the annual show at the Wayne Gardens will take place. All applications for space must be in hand by November 20 to participate in this drawing, which will be conducted by Walter Wilmot, who will again be in charge of the affair.

Many applications have already been received and Mr. Wilmot predicts the largest show yet held in this city and the largest possible with the space and facilities available. This year's show will be on the National show circuit, hence greater importance will attach to it than to similar events held here in the past. Many of the Madison Square Garden exhibits will be brought here before being sent to Chicago for the annual gathering at the Coliseum.

At the meeting various details as to allotment will be decided. This first drawing will be for the members of the association. Space allotment for non-members will take place November 25.

Dealers to Finance Toledo Show

TOLEDO, O., Nov. 9—The members of the Automobile Dealers' Association held a meeting early this week at the Commerce Club and voted to form an exhibition company to float an automobile show in January. Incorporation papers have been sent to the secretary of state at Columbus. Automobile dealers and accessory men only will be permitted to subscribe for shares of stock in the company, the capital of which will be $10,000.

3-Liter Race the Feature

Grand Prix May Be Abandoned for Lack of Interest and Chance Exists for Small Cars to Compete in It

Savannah Again Seeks Vanderbilt Cup and Grand Prize if Entry List Is Guaranteed to Local Club

PARIS, Nov. 6—At the moment the entry lists for the French Grand Prix were closed with a total of sixteen out of the minimum of forty cars required—thus probably entailing the abandonment of the race—the rules were made public for the Coupe de l'Auto, or 3-liter race to be managed by the newspaper *L'Auto*. In all probability this will be the only race of the year, for *L'Auto* is opposed to allowing the big cars to join in with the 3-liters, as was done at Dieppe this year, and the national club cannot hold its race independently with only sixteen cars. There is a possibility that the club, having failed to get the required number of entries for its own event, may ask to be allowed to join *L'Auto* in the organization of the 3-liter event, thus giving an official character if not adding to the importance of this race.

It is now certain that the 3-liter race to be held on Sunday, June 29, over a course yet to be selected, will be the most important European speed contest of the 1913 season. Races have been run under these rules in 1911 and 1912, and next season will see their last application, the organizers being of the opinion that full advantage will have been got out of them after 3 successive years' experience. Though the same in principle, there are a number of important detail changes in the regulations. Feeding the cylinders by any mixture at more than atmospheric pressure is forbidden.

Last year Hispano-Suiza built a set of cars with a couple of additional cylinders acting as compressors of the explosive charge. These cars were not entered for the race, but it was feared that similar attempts might be made to pump a charge into the cylinders and thus falsify the results of the race. The new rule says that at the moment of introduction to the cylinders the mixture must not be at higher than atmospheric pressure at 760 millimeters of mercury.

It is no longer necessary that the driver and mechanic should sit side by side. The latter may be behind the former, and probably will be in most cases, with a substantial decrease of head resistance. It is argued that stream line forms are to the final benefit of the car owner and should be encouraged and not discouraged in all races.

A return has been made to the conditions prevailing prior to 1906 by allowing work to be done on the cars by attendants and authorizing the establishment of depots at any point around the course. It was the experience of the late David Bruce Brown and the Peugeot driver Goux, both disqualified for taking gasoline on the course at Dieppe that has led the organizers to make this change. So far as tires are concerned, the difference will not be enormous, for with the general use of detachable wheels big tire changing staffs are not required.

Instead of a minimum chassis weight of 1,763 pounds, a maximum of 1,984 pounds has been imposed. It is believed that in the last two races manufacturers did not sufficiently study the problem of weight reduction, for while there were a few cars which held to the road perfectly although remaining very close to the minimum mark of 1,763 pounds, many of them were built up to nearly 2,000 pounds under the belief that lower weight cars would not stick to the road. The weight is taken without water, gasoline, oil, spares, tools, etc. The two men must scale 308 pounds, any deficit being made up by ballast. Entries for the race close on December 31, and at double fees on March 31. For a single car the ordinary fee is $200; for two cars, $360; for three cars, $500, and for a full team of four cars, $600. The place of the race has not yet been decided.

The sixteen cars which sent in their engagement for the Grand Prix of the Automobile Club of France (14 miles to the gallon) represent the firms Sunbeam, Peugeot, Delage, Mathis, Itala (with valveless type), Opel, and Schneider. The sporting committee of the A. C. F. will unite in a few days to decide what shall be done. There appears to be but two courses, either abandon the race altogether or allow entries to be received at ordinary fees until January 1. Probably the formeer course will be preferred, for the manufacturers object to being kept in doubt as to the holding of the race until such a late date as January.

The charge is made in certain quarters that the club is not at all enthusiastic over its own race, or it would have announced the event as certain whatever the number of cars received and fixed the closing of the lists after the European motor shows. From private sources it is learned that the French firms Peugeot, Delage and Schneider, as well as the English Sunbeam Company, will transfer their Grand Prix entry to the 3-liter or 183 cubic inches race. It is probable that Mathis, Itala and Opel will do the same. A big field for the 3-liter race is practically assured.

Colonels Enjoy Sociability Run

LOUISVILLE, KY., Nov. 11—Participants in the sociability run of the Louisville Automobile Club to Lexington returned home to-night. About 100 persons made the trip, over splendid roads and without mishap. The route to Lexington was via of Shelbyville, Frankfort and Versailles, with the entrants in the contest running in a bunch at the finish and with the average time of 4 hours, 23 minutes and 56 seconds. The winners, in order, are: A. J. Senf, Mrs. C. S. Gibson, Mrs. W. R. Nisbet, F. E. Van Patton, Dr. C. W. Karraker, A. B. Patterson, T. Trammel, Miss Virginia Weikel, Miss Lois Reid, Mrs. Ethel C. Standiford, H. W. Cooper, H. L. Lewman, E. C. Jacobson.

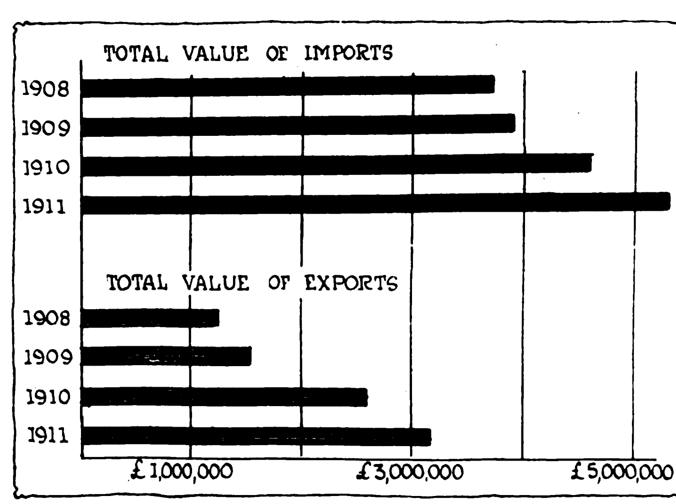
Savannah Wants Big Races Again

SAVANNAH, GA., Nov. 13—*Special Telegram*—Providing a sufficient number of entries are guaranteed, the Savannah Automobile Club wants the 1913 Vanderbilt Cup and Grand Prize races.

At a meeting of the club last night it was decided to apply for both races conditioned upon a minimum number of participants.

By Way of Correction

The description of the 1913 Stearns car, issue of October 31, should have stated that the Vesta generator is used in the lighting plant of these cars instead of the system named.



Values of Great Britain's total automobile imports and exports, including parts

Flanders—U. S. Motor Merger After Sale

Walter E. Flanders Will Assume Presidency—In Court, Interference by Minority Interests Is Checked and Order Issued To Frame Decree of Sale Providing for Virtual Auction in Six Parcels or as an Entirety—January Date Probable

DETROIT, MICH., Nov. 12—(*Special Telegram*)—Absolute confirmation of the reported merger of the Flanders Motor Company of this city and the United States Motor Company was given out last night following the decision of Judge Hough, of the United States District Court in New York in which he denied the petition of some of the stockholders of the United States Motor Company for intervention in its reorganization plans.

Walter E. Flanders will head the enlarged corporation and the headquarters of all the plants except that of the Stoddard-Dayton at Dayton, Ohio, will be moved to this city.

The plans as now formulated contemplate the purchase of the Flanders Motor Company for $3,750,000 of which $1,000,000 will be paid in cash and the remainder in stock.

It is stated that while W. E. Metzger and B. F. Everett will withdraw from active participation they still retain stock interests.

The bringing of the executive offices of the various United States Motors subsidiaries to Detroit means much to the city. The Sampson and Brush plants will probably be reopened, giving employment to some 500 additional workmen, while it will also mean the location of various manufacturers of parts here, so that in the end some 10,000 new workers will be added to the already great array of industrial operators now engaged in the many automobile lines in this city.

Officers of the Flanders organization could not be reached today so that it is impossible to get at details of the transaction other than those given.

Winding Up Legal Affairs in Court

What in effect is practically an auction sale has been ordered by Judge Charles M. Hough with regard to the assets of the United States Motor Company. Of course, there will be no "Going, Going—Gone" feature such as mark regular auction sales, but in the essential particulars the disposition of the property will be by an auction sale.

Next Monday the court has signified its intention to sign a final decree of sale and while the time for its consummation has not yet been fixed, it is certain that it will take place some time in January.

Under the form of order prepared Monday in the United States District Court the bidders will have the opportunity to bid on the assets divided into six parcels or on the whole as a single lot. A certain qualifying amount of cash or certified check will be required from each bidder and the deposits together with the formal bids may be placed in the custody of the court between the hours of 11 o'clock in the morning and 3 o'clock in the afternoon of the day fixed for the sale.

The auction feature arises from the fact that bidders will be allowed, under the tentative form of the final order, to increase their offerings at any time prior to the hour set for the closing of the sale.

The division of the assets will be along these lines:

Parcel No. 1 shall consist of all the property of the United States Motor Company.

Parcel 2, all the property of the Alden-Sampson Manufacturing Company; No 3, Brush Runabout Company; No. 4, Columbia Motor Car Company; No. 5, Dayton Motor Car Company, and No. 6 Maxwell-Briscoe Motor Company. The parcels will be offered in the order of their numbering. Immediately after the bids have been concluded for the various parcels, the whole property will be offered as an entirety.

There was little comfort in the proceedings for the elements that have made objection to the immediate settlement of the company's affairs. They were on hand in court, but the rulings from the bench were against them. The three-headed demurrer which was informally filed on behalf of certain stockholders was dismissed. The demurrer alleged that the court had no jurisdiction; that insufficient facts were set out on the bill of complaint and took up other technical grounds. Judge Hough held adversely to the demurrer on the ground that the court did have jurisdiction; that sufficient facts were stated in the bill and that the affirmative action of the officers of the various defendant concerns bound the stockholders in the absence of allegations of fraud.

It was stated by one of the objecting attorneys that the court ought to name a referee to investigate the alleged shrinkage of assets between the time of the last annual report when it was shown that they footed up to over $23,000,000, while at the time the receivers completed their work there was a nominal loss of over $12,000,000. It was explained that the apparent shrinkage was due to the elimination of all items not directly representing some tangible assets from the report of the receivers and further that the last annual report of the company represented the assets in the light of the seller, while that of the receiver looked at the case from the buyer's point of view.

In referring to the future of the company, the court and attorneys informally considered the plan of reorganization. Judge Hough prefaced his remarks with a statement that the reorganization plan was not before him in his judicial capacity, but that it was a matter of common notoriety. He said: "Reading between the lines of the bill of complaint it is apparent that the creditors having assumed control of the company's affairs in June and having administered them up to the time of the receivership, found them in worse condition than they expected. The creditors should not assume the attitude of mortgage holders foreclosing upon the property of the debtor. The character of their claims is not of mortgage degree."

Mr. Curtis, representing a large amount of preferred stock, said that the creditors who were represented to the extent of $10,000,000 of claims by Joline, Larkin & Rathbone, were the only parties in position to bid on the assets when it came time for the legal sale. This, he explained, was due to the fact that they could put in their claims with the bids submitted, while all others would have to bid actual cash. Thus the situation resolved itself into a contest between paper and cash with all the advantage on the side of the paper.

A suggestion was made by James N. Rosenberg that an offer had been submitted to lease the Brush and Sampson plants in Detroit during the receivership. He said that if such a lease could be consummated it might help the whole property at the sale.

At the session it was not stated who the prospective tenant might be, but after adjournment it was announced that it might be the Flanders Motor Car Company, although the definite statement was not made.

It was stated that the Flanders company required extensive manufacturing facilities and that as both the Brush and Sampson plants were practically closed down, the deal would be an excellent one from every point of view. The court gave assent to leasing the plants, but limited the term to the receivership.

Mr. Rathbone, of Joline, Larkin & Rathbone, said that the merger between the United States Motor Company and the Flanders Motor Car Company had been tentatively arranged on the best possible terms and that Walter Flanders would be the next president of the United States Motor Company, in all probability. He said that it would be impossible to make a more definite statement pending the action of the court. The proposed contract must be ratified by both sides, but it is said that it has been prepared in final form.

Mr. Rathbone said that the Flanders company would be taken over free from all but its current indebtedness, dealers' deposits and current accounts.

Fully 91 per cent. of the claims against the United States Motor Company have been deposited under the plan of reorganization and a considerable fraction of the remainder, consisting of about $1,000,000, would be deposited within a week.

The stock deposits are coming in at a slower rate. About $4,000,000 par value of both issues have been turned in, but the amount so deposited is of relatively small importance to the reestablishment of the company. It is estimated that the total deposits of stock under the plan will reach at least $15,000,000 out of a total of $23,000,000 outstanding. If that develops to be true, the burden to be carried by the underwriting syndicate will be only $1,920,000.

It developed at the hearing that one of the main elements in the problem of the receivers was to finance not only the 1913 manufacturing campaign, plans for which have been outlined and financed by the order of court, but the importance of the experimental campaign for 1914 was referred to as the principal hope of the stockholders.

Hartz to Manage R. C. H. Company

DETROIT, MICH., Nov. 11—At a meeting of the directors of the R-C-H Corporation November 8, J. F. Hartz, president of the J. F. Hartz Company and officer and director of various other leading Detroit business concerns, was chosen general manager and treasurer of the corporation. Other officers for the coming year are: President, R. C. Hupp; vice-president, C. P. Sieder; secretary, L. G. Hupp and assistant general manager, F. R. Hupp.

The directors are G. W. Rogers and J. G. Robertson of Akron, C. G. McCutchin of Jackson, Mich., J. F. Hartz, John Kelsey, C. P. Sieder, F. M. Randall, J. H. Clarke and R. C. Hupp of Detroit.

The active management rests with an executive committee of five composed of Messrs. Hartz, Kelsey, Randall and R. C. Hupp of Detroit.

In entrusting the affairs of the corporation to Mr. Hartz, one of Detroit's most successful business men is brought actively into the industry. He is president of the J F. Hartz Co., Ltd., of Toronto, Canada, and the H. H. Hester Co. of Cleveland, allied firms of the local concern. Mr. Hartz became actively associated with the automobile business 4 years ago when he organized the C. M. Hall Lamp Co. He is also vice-president of the Williams Brothers Company, director of the C. W. Warren Co., publisher of the Detroit Medical Journal and director of the Detroit Times Company.

F. R. Bump becomes assistant general manager.

As stated in these columns last week, 16,500 R-C-H cars have been contracted for by dealers in American and foreign countries for delivery during the season.

Export business for the year was exceedingly good, over 1,000 cars having been sold abroad in 41 foreign countries. From contracts already entered into abroad it is believed that between 3,000 and 4,000 cars will be required for export alone during the next 12 months.

The R-C-H plant consists of a completely equipped foundry, forge, machine shop, paint shop, assembly buildings, large power house, administration and other buildings. It has a capacity of 60 cars per day and during the heavy output season gives employment to 1,600 men.

The corporation maintains branches in New York, Philadelphia, Boston, Buffalo, Cleveland, Atlanta, Chicago, Minneapolis, Kansas City, Denver, Los Angeles, San Francisco, Detroit and Walkerville, Canada.

Offer Made for W. C. P. Assets

The creditors' committee of Wyckoff, Church & Partridge, Inc., which corporation is now in the hands of John S. Sheppard, Jr., as receiver, have notified all creditors that an offer has been made by Howard C. Dickinson, of the firm fo Kearney & Dickinson; George A. Ellis, of the firm of Booth & Ellis, and Chester Griswold, of the Motors Engineering Company, for the assets of Wyckoff, Church & Partridge, Inc.

Should the creditors approve of this offer it is probable that Messrs. Dickinson, Ellis and Griswold will form a company to continue the manufacture of the Vaughan car and Commer truck. Mr. Dickinson and Mr. Ellis represent banking interests and Mr. Griswold in joining these gentlemen will act as the consulting engineer for the new company.

It is reported that both C. F. Wyckoff and E. S. Partridge are likely to be identified with the new interests should plans for rehabilitation be consummated.

H. B. Hollins & Company, bankers, are behind the committee. The amount of the offer is $150,000 in cash to be paid in instalments of $50,000 each, respectively 4, 8 and 12 months from the date of transfer.

The property included in the offer includes all the real and personal property of the bankrupt company except what is in possession of the Driggs-Seabury Ordnance Company or claims against that company. It consists of two New York leaseholds; furniture and fixtures; twenty-six Commer trucks; several Vaughan cars, bodies, etc., together with accessories; the factory building at Kingston, with its contents. Against the property are mortgages and bank liens of approximately $270,000.

John S. Sheppard, Jr., receiver, in a supplemental report to the United States District Court shows that according to his estimate there is the sum of $39,304 either in his possession or due to him and collectible as of November 1, thus making the total amount subject to division under the offer, $189,304.

The unsecured claims of the estate amount to $575,000. The appraised value of the property covered by the offer, adjusted to November 1 by deducting property sold, is about $171,000. This would mean, according to the calculation of Mr. Sheppard, a dividend of 25 cents to 27 cents on the dollar to the unsecured creditors.

Colwell-Ideal Merger Accomplished

DETROIT, MICH., Nov. 9—The Colwell Lead Company of New York City has purchased the Ideal Manufacturing Company of Detroit, large manufacturer and jobber of plumbers' supplies and articles such as pet cocks, piping, joints, etc., for the automobile trade. The deal is one which involves considerable capital, and is perhaps among the largest to be consummated in this city in some time.

Both the purchaser and the Ideal company are old established firms, the former having been begun in 1866, while the latter has been doing business in Detroit since 1887. The consolidation will increase the capitalization of the greater organization to about $2,000,000 and it is stated that it will bring to Detroit additional capital and business and increased opportunity for the employment of labor.

Adams Patent Is Upheld

Injunction Against Hartford Rubber Works—Phillips Patent Does Not Cover Use of Anti-Skid Wire

A. A. A. to Have Chicago Meeting in December—M. A. M. Fixes Date for Annual Meetings

OVERTURNING the judgment of the United States District Court, District of Connecticut, the United States Circuit Court of Appeals has reversed the findings of Judge Platt in the suit of the Metallic Rubber Tire Company against the Hartford Rubber Works involving the Adams and Midgely treads. In the lower court Judge Platt dismissed the bill and found in favor of the Hartford company. The upper court sustains the Adams patent, decrees an injunction against the Hartford company and orders an accounting as between the parties and gives a decree for costs against the defendant.

The suit was instituted by the Metallic Rubber Tire Company alleging that the Hartford company infringed its patent rights under the Adams patent, as outlined in a former issue of THE AUTOMOBILE. The Hartford company responded by setting up defenses of invalidity, non-infringement, abandonment and want of equity and Judge Platt found for the defense, dismissing the bill in the first instance.

Appeal was taken by the complainant to the Circuit Court of Appeals and the full bench consisting of Judges Lacombe, Coxe and Noyes heard the arguments which were presented by Alfred Wilkinson for the complainant and E. W. Vaill for the defense.

Judge Noyes wrote the opinion, the more pertinent parts of which are as follows:

"Concededly the nearest approach to the patent in question is the Phillips English patent, and the question of anticipation may well be determined by examining that patent and comparing it with the one in suit.

"The principal object of the Phillips patent was to protect and strengthen pneumatic tires. It illustrates numerous ways for stiffening and protecting tires, and among others, points out that the tread or wearing portion may be reinforced or strengthened by stitching the rubber with metal wire, threads, cord and the like. Some of the drawings of the patent are very similar to those of the patent in suit. The prevention of slipping, however, is not stated to be either an object of the Phillips patent or a result of the use of its structure. Moreover, it is not clear that the non-skidding effect would be obtained by following the teachings and drawings of the Phillips patent.

Phillips Patent Points to Covering Wires

"Wire sewed into a tire to reinforce the rubber would naturally be flexible wire, while only stiff wire would furnish the hard bearings, required to prevent slipping, especially after the wearing off of the loops. The Phillips patent shows that rubber tires may be stiffened and protected by wire stitching but, in our opinion, does not teach that exposed wire stitching will make hard bearings to prevent skidding. Indeed, many things in the Phillips patent point in the direction of covering the wires and it is never essential that the stitches should be flush with the surface of the tread."

The court then dismisses the objection raised as to the validity of the Adams patent by commenting on the fact that the Hartford company has had a license to manufacture under a patent and upon the expiration of the license has put out a product which, even if not infringing, closely simulates the patented structure.

In conclusion Judge Noyes says:

"In our opinion, the defendant's structure infringes. The claim covers the combination of the wire and rubber as a result and we think that the defendant should not be permitted to escape the charge of infringement by combining its wire and rubber in a different way from the stitching or weaving illustrated in the specification.

"The decree of the District Court is reversed with costs and the cause is remanded with instructions to enter a decree for the complainant for an injunction, an accounting and costs."

A. A. A. To Meet and Dine in Chicago

The annual meeting of the American Automobile Association has been scheduled for December 2-3 at Chicago. The banquet, which is always a feature of the meeting, will be held at the Auditorium on the evening of December 2. It is expected that the attendance will be very large at all the sessions as well as at the banquet.

M. A. M. Schedules Annual Meetings

The Motor and Accessory Manufacturers will have a lively session during the annual show. The association will probably hold the only formal banquet of the 1913 show season and the program that has just been outlined includes numerous activities.

During the week that preceded January 15, all the committees will hold conferences either at headquarters, 17 West 42nd street, or at the Waldorf. These committee meetings have not been definitely scheduled, but will be held nevertheless. On January 14, the Board of Directors will assemble at headquarters to clean up the fag-end of the 1912 business. The following evening at 6 o'clock the annual meeting will be called to order at the Waldorf. The chief business to be transacted will be the presentation

Automobile Securities Quotations

THE whole list of automobile securities advanced during the past week with the exception of a few stocks. The greatest bulge was in Goodyear common which shot up to $400 a share bid with no sellers in sight. This is a net gain of $32 a share since last week and is due to the prospective character of the annual report, due next month. The skyrocketing of the stock may have been accomplished in some degree by a small panic among shorts but the basic reason for it is the expected melon. At this level Goodyear is worth $175 a share more than it was a year ago and its holders say it is cheap at that. The table:

of annual reports and the election of four directors. The annual session of the association is always very brief and at 8 o'clock the members will move over to the College Room, where the annual banquet will be spread.

The directors will assemble on January 16 to choose officers for the ensuing year. No slate has been proposed so far, and following the usual course the selection of the new officers will be accomplished with as little formality as possible.

The following members were elected to the Motor and Accessory Manufacturers at the last meeting of that organization: John W. Blackledge Manufacturing Company, Chicago; James L. Gibney Rubber Company, Philadelphia, and the Westinghouse Electric & Manufacturing Company, East Pittsburgh.

S.A.E. Committees to Hold Meetings

The regular monthly meeting of Council of the Society of Automobile Engineers was scheduled for Wednesday morning. The program consisted of hearing the treasurer's report; considering about forty applications for membership; transfers in the various classes of membership; settling the details of the winter meeting of the society which is scheduled for January 16-18 at the Hotel McAlpin with the annual banquet on January 17.

The society is arranging to receive the visit of the British engineers next summer. The party, according to latest estimates will consist of from thirty to forty members and will be somewhat in the nature of an official repayment of the visit of the S.A.E. to England last year.

A revision of the by-laws is also in contemplation.

The Truck Wheel division will hold a meeting Wednesday afternoon to take up and consider a number of minor changes in the recommended standards.

Market Changes for the Week

DURING the past week the market has experienced its usual variance in prices. Open-hearth, for instance, rose $1.00, due to heavy trading, while tin declined $.02 from lack of trade. Bessemer steel remained at its old price of $28.00 per ton. Rubber rose $.02 due to London influences, as did copper electric and copper lake, both increasing $.00 1-8 per pound, closing Tuesday at $.17 3-8 and $.17 1-2 respectively. Lead, antimony, gasoline and beams and channels, were constant throughout the week. The chemical market experienced no change, cyanide potash and sulphuric acid both closing at their old prices of $.19 and $.99 respectively.

Marvin on Car Shortage

Explains That Limited Number of Railroad Freight Cars Are Useful for Automobile Transportation

Local Dealers Should Co-operate with Factories for Prompt Return of Freight Cars

IN the belief that a full understanding of the question on the part of the several thousand automobile dealers in the West and South will be of value in helping the car situation at automobile factories and inducing the return of automobile freight cars to the manufacturing territory, J. S. Marvin, General Traffic Manager of the National Association of Automobile Manufacturers, Inc., has outlined the situation as follows:

"There is a certain limited number of freight cars having wide side doors or end doors into which automobiles can be loaded. There are twenty times as many box cars into which automobiles cannot be loaded because they have doors too small. The automobile cars are scattered all over the country. They are being used for other freight in the West and South instead of being returned to the territory where automobiles are manufactured. The result is that even thus early in the season it is impossible to secure automobile cars fast enough at the factories to get out the shipments of finished machines.

"The situation is therefore going to become critical unless those automobile cars that are being held in the South and West are located and sent back to the automobile manufacturing territory.

"Therefore, each dealer should take this matter up with his local freight people as follows:

"First—The important point is the disposition made of an automobile car after you unload it. If the local freight agent or superintendent permits some shipper to load it farther South or farther West, the car is lost to the automobile industry for weeks or months.

"Second—Your local freight agent or superintendent would not permit this abuse of automobile equipment if he realized how serious a matter it is and that you are interested in what becomes of that automobile car after you have unloaded it.

"Third—Your patronage is valuable to your local freight agent and the railroad he represents. You can exact, in return for this patronage, their cooperation in solving this problem which faces the automobile industry and the railroads in the manufacturing territory upon which the burden of supplying these cars to the factories rests.

"Fourth—The cooperation that you should exact is that they confine the loading of automobile cars to points in the automobile manufacturing territory; this applies to cars that you unload and also any other automobile cars that may happen to come to your station loaded with other goods and thus be under local control when made empty; request your freight agent to report to you the disposition made by him of cars which you unload.

"Fifth—You should advise the factory of every instance wherein your local freight agent or superintendent fails or refuses to comply with this request.

"You can readily see what a great help it is going to be if every dealer in the West and South follows this matter up; they are in close touch with the situation where the trouble exists. If these cars are not sent back it is going to be impossible to ship machines from the factories."

It will be remembered that during the past few weeks, as during the corresponding period of 1911, the limited supply of freight cars presented a serious obstacle to the business of hundreds of dealers.

Exports for 9 Months Increase 55 Per Cent.

From January 1 to October 1, 1912, American-Made Automobiles Sold Abroad Totaled $21,859,709

American Automobile Imports of France Increase—Gain Is 78 Per Cent., or $285,420, to September

WASHINGTON, D. C., Nov. 12—The summary on commerce and finance issued by the Bureau of Statistics shows that the total imports of automobiles and parts for September were $42,000 more than they were during the corresponding period of 1911. The comparison is as follows:

September, 1912	$189,901
September, 1911	147,295

The showing for the first 9 months of the calendar year, however, indicates a decrease in the total imports of $60,000. The figures are:

First 9 months 1912	$1,625,908
First 9 months 1911	1,685,816
First 9 months 1910	2,214,920

These figures show that there has been a steady decrease in the use of foreign made automobiles in the United States.

In the matter of exports a material increase is shown for the month and for the first 9 months of the calendar year. The following export figures tell the story:

September, 1912	$1,720,815
September, 1911	1,336,822

For the 9 months ending with September the showing is as follows:

1912	$21,859,709
1911	13,988,293
1910	10,419,999

Canada again takes first rank as a purchaser of exported automobiles, taking $473,465 during September, 1912.

Crude Rubber Steady in New York

Despite some weakness in the market for crude rubber in London, the New York trading was on a steady foundation based upon about $1.04 for up-river fine. The British downward movement amounted to about 2 cents a pound, but the response locally was small. The demand was largely of a jobbing character and there were some bids for the better grades just under the market. This condition did not have its usual effect of checking the volume of offerings and as a result trade was of satisfactory scope.

Benjamin Briscoe, retiring president of the United States Motor Company, was the guest of honor at a banquet given by officers and employees of the United States Motor Company in the Hotel Astor. The banquet was intended as an expression of the esteem in which Mr. Briscoe is held by the members of the organization, and their tribute to him not only included the well wishes of the employes but was manifested by the gift of a handsome Tiffany watch and fob from the men and a large bank of chrysanthemums from the young women of the company.

Crops Greater than First Reports

WASHINGTON, D. C., Nov. 11—Predictions made in the past few months of bumper crops in the big agricultural sections are being justified by bulletins just issued by the Department of Agriculture in which comparisons are made, not only with the 1911 crops, but, also with the average yield of recent years. Not only in the real agricultural centers but in practically every section of the country the story is the same, a decided percentage of increase over 1911, and over the average yields of recent years. In the grain states such as Illinois, Wisconsin, Iowa, Missouri, Kansas, Colorado, the Dakotas, Nebraska, Wyoming, Texas, etc., the percentage of increase in production is so great as to insure a year of exceptional prosperity for the people of these sections. In the estimates made by the department, as above suggested, the crops of all kinds are combined, and only the states specified.

Preliminary estimates, however, of certain crops, taking the production as a whole, and not specifying the localities, tell the same story. As compared with 1910 and 1911 the year 1912 will produce the following:

	Production		
Crops	1912	1911	1910
Corn, bushels	3,169,137	2,531,488	2,886,260
Wheat, bushels	720,333	621,338	635,121
Oats, bushels	1,417,172	922,298	1,186,341
Barley, bushels	224,619	160,240	173,832
Rye, bushels	35,422	33,119	34,897
Buckwheat, bushels	19,124	17,549	17,598
Flaxseed, bushels	29,755	19,370	12,718
Potatoes, bushels	414,289	292,737	349,032
Hay, tons	72,425	54,916	69,378
Tobacco, lbs	959,437	905,109	1,103,415

Some 1913 Factory Expansions

KENOSHA, WIS., Nov. 11—The Thomas B. Jeffery Company, Kenosha, Wis., manufacturing the Rambler, is at this time more than 700 cars behind its orders for immediate delivery and has on its books contracts for 40 per cent. more cars than were produced by the works throughout the 1912 season. The new and sole Rambler model for 1913 was announced only 73 days before November 1, and this condition is due in a large measure to intensive sales methods evolved by the Jeffery forces in marketing the 1913 Rambler Cross-Country, with unit gasoline-electric power plant, as its sole model. During the period from July 15 to October 15, fifty salesmen engaged in a contest. Ten prizes were awarded. This contest greatly increased the number of orders in all sections of the country.

HARTFORD, WIS., Nov. 11—The Kissel Motor Car Company, of Hartford, Wis., intends to continue its building and expansion activity throughout the cold months, more as a matter of necessity than convenience. Work has just been started on a large addition to the woodworking plant and another core oven is being built in the foundry department. As soon as these improvements are well along, attention will be turned to the work of providing more facilities for the commercial vehicle division, which is now cramped for room.

SYRACUSE, N. Y., Nov. 9—The H. H. Franklin Manufacturing Company announces that it will make this season 1,800 cars. The only changes will include some features of refinement and but one car will be added to the line, a victoria phaeton on the Little Six chassis with a 30 horsepower motor. Forty per cent. of Franklin sales the past year have been on the Little Six model.

French Imports from U. S. Increase

PARIS, Nov. 1—Out of a total imports of automobiles into France during the first 8 months of 1912 valued at $1,765,860, the United States sent cars to the value of $578,340. The total shows an increase, for during the same period of 1911 France imported $1,692,420 worth of foreign automobiles, of which $338,580 came from America. It will thus be seen that the American increase is high. The total French exports for the period January 1-August 31, 1912, shows an increase of $6,066,060 compared with the corresponding period of 1911. The increased business was done with Great Britain, Germany, Belgium, Switzerland, Spain, United States, Brazil, Argentine, and

Algeria. The following are the official figures of French exports for the first 8 months of 1911 and 1912:

	1911	1912
England	$7,301,040	$7,883,400
Belgium	3,777,480	6,041,880
Algeria	1,404,540	2,228,040
Germany	1,748,160	2,203,380
Argentine	1,184,700	1,873,200
Brazil	801,240	1,213,920
Switzerland	656,400	683,220
Spain	360,000	656,580
United States	368,460	653,880
Italy	548,180	328,860
Russia	382,560	236,100
Austria-Hungary	355,140	148,680
Turkey	255,600	96,000
Other countries	2,060,940	3,024,360
	$21,205,440	$27,271,500

Hoosiers Invading Illinois Field

INDIANAPOLIS, IND., Nov. 11—About 150 members of the Indianapolis Trade Association will leave on a special train tomorrow for a 3 days' trade extension trip through Illinois. Several tons of advertising matter will be carried and the Indianapolis News Newsboys' Band will give a band concert in each city and town where a stop is made. The association is made up of about 250 manufacturing, jobbing and wholesale concerns of the city, including all lines of trade. Practically all of the motor car manufacturers of the city are members of the association.

The itinerary tomorrow will include stops at Danville, Muncie, Fithian, Ogden, St. Joseph, Urbana, Champaign, Mahomet, Mansfield, Farmer City, Leroy, Downs and Bloomington, where the party will spend the night.

On Wednesday stops will be made at Heyworth, Wapella, Clinton, Maroa, Decatur, Harristown, Niantic, Illinopolis, Buffalo, Dawson, Riverton and Springfield, where the night will be spent.

The itinerary for the third day will include stops at Rochester, Breckenridge, Edinburg, Taylorville, Owaneco, Pana, Tower Hill, Shelbyville, Windsor, Gays, Mattoon, Charleston, Ashmore and Kansas.

Box Ball Concern to Make Automobiles

INDIANAPOLIS, IND., Nov. 11—The American Box Ball Company of this city, of which the chief owners are J. I. Holcomb and Fred Hoke, is about to embark in the automobile business and expect to put out a six-cylinder car to sell in the neighborhood of $2,750. No details of the new car have yet been announced.

Mr. Holcomb is not by any means new to the automobile trade, having been one of the partners in the Willis, Holcomb & Haywood Company a few years ago, who controlled the local agency for the Packard and several other cars.

Receiver Named for Dayton Company

DAYTON, O., Nov. 11—William Miller, formerly bookkeeper for the Dayton Automobile Company, Dayton, O., has been appointed receiver for the concern by Judge O. B. Brown. The application was made by T. J. Weakley, vice-president of the concern, and other stockholders. The suit is an amicable agreement between the stockholders and officers, and the business will be continued for several weeks, pending the dissolution of the firm and the sale of is assets. The officers of the company are: J. E. Sudebaker, president; T. J. Weakley, vice-president; A. S. Iddings, secretary, and Dr. I. N. Agenbroad, treasurer.

BUFFALO, N. Y., Nov. 12—The Frey Auto Supply Company, filed a petition in voluntary bankruptcy yesterday afternoon with the clerk of the United States District Court. Total liabilities are said to be $18,500.87 with assets of $22,344.55, most of the creditors being Buffalo firms. The largest creditor, however, is Lockwood, Luelkenger, Henry Company, of Cleveland, O., which claim amounts to $981.60.

Imperial Club Rules Motordom in Russia

Injured Personal Feelings of American Dealer Tend to Bring About Faction in Exhibition Work

American Business Man in Czar's Capital Says That the Opportunities for American Automobiles Are Great

THE AUTOMOBILE has received a communication from Charles L. Preston, an American business man stationed in St. Petersburg, Russia, outlining the conditions that surround the automobile industry and annual shows held in the Russian capital. Mr. Preston makes a special plea to the American industry to take part in the Russian show.

"ST. PETERSBURG, Oct. 29—As an American, having resided in Russia for the last 9 years as the manager of the Walk-Over Shoe Company's Russian business and as resident buyer for eight large American tanners, I naturally interest myself in American business in Russia, and wish to call the attention of every automobile dealer and manufacturer to the following facts:

"The Imperial Automobile Club, of Russia, located in St. Petersburg, practically controls the automobile and motor life of Russia, having as a patron and supporter his Imperial Majesty, the Emperor. The club gives every year one or more endurance contests and an exposition for the exhibiting of all kinds of motors with their accessories. This exhibit is open to all the automobile dealers and manufacturers of the world without reservation or discrimination; even the spaces for exhibiting purposes are drawn by lot, so that every exhibitor has an equal chance with his competitor. The club has even made arrangements possible in order to attract exhibitors.

"Russia has no automobile factories of her own, consequently the Imperial Club must look for foreign exhibitors, so it is naturally a foregone conclusion that the club will offer all the inducements possible in order to attract exhibitors and to make each exposition more successful than the previous one.

"Unfortunately for all concerned the Imperial Automobile Club was recently forced, by the demands of the other manufacturers and dealers selling automobiles in Russia, to publicly deny in the interest of accuracy and fair play certain statements and representations, made by the Russian agent of one American company doing business in Russia. By doing this the Imperial Automobile Club has incurred the enmity of this agent to such an extent, that the latter as a measure of revenge is endeavoring to organize a rival show to take place at the same time as the official exposition. This is certainly a very foolish move as the Imperial Club has a tremendous influence on the motor future of Russia and any manufacturer or dealer who exhibits at this proposed rival show forfeits all chance of taking part in any government trials or receiving prizes or awards.

"This agent is at the present time in America and is without doubt trying to discourage manufacturers or dealers who have intentions of sending exhibits to Russia from sending them to the official exposition.

"Personally, I dislike to be involved in any controversy, but in the first place as an American, with American interests at heart, and in the second place as a member of the Imperial Automobile Club, I wish to correct any false impressions which may have been caused by the above unpleasant incident and wish to assure any and every American manufacturer and dealer who has any wish or idea of exhibiting at the coming exposition in St. Petersburg next May that he will be heartily welcomed and will be treated with the greatest courtesy and consideration."

Two Methods for Perfecting All Grades of Steel in the Ingot—Gear Speed Matters Illustrated—The Variations in Brinell Tests—Lead Battery Negative Plates Improved by Inert Admixture—Easier Steering of Heavy Trucks

SOUND Steel Ingots—The constant temptation at steel works and rolling mills to make the discard from steel ingots shorter than it should be has resulted in many fatal flaws in the steel shapes rolled from the top end of an ingot or from a billet of the defective material. In the case of expensive steels, compressive molds have been used to some extent to squeeze the pipe and the blowholes out of the ingot while it is still in the fluid state and to concentrate the segregation of impurities in a small upper layer. Two new methods have now been perfected which are much cheaper and more effective. Sir Robert Hadfield, of the Hecla Works at Sheffield, England, has developed one of these and Dr. Hans Goldschmidt, of Essen, Germany, the other. Both are in the very front rank as practical and successful metallurgists, and the new methods therefore warrant the hope that in the near future defects will be a rarity in the very large bars of steel from which crankshafts and some other automobile parts are forged, although such bars are necessarily rolled from those large-sized ingots in which the defects have been most commonly encountered. The Hadfield method is indicated in Fig. 1. It consists in heating the fluid steel in the upper part of the ingot, or other mold which may be used, and maintaining it in a liquid condition, while the rest of the ingot is cooling, by playing a blast of air into charcoal heaped on top of the molten metal. To prevent loss of heat by radiation from the metal a layer of cupola slag is placed between it and the coal. The general result is that the fluid top-portion of the ingot sinks and fills the pipe as fast as it is formed. Pipes in the lower portions of the ingots are obviated at the same time, as these are also caused by irregularities in the cooling and the molecular flow in the metal and the top-heating regulates this factor to some extent throughout the mass. It is figured from the experience of the past few years, applying to a production of many thousands of tons, that the discard may be reduced from an average of about 20 per cent. to about 7 per cent. with an all-around gain in the quality of the product and that the saving on a large output may amount to from 8 to 12 shillings per ton, the value of the discard metal for remelting being fully considered.

The Goldschmidt method consists in an important modification of a similar method which had been previously tried without definite success. As generally known, Goldschmidt is the discoverer of the thermit material by means of which local fusion of metals may be readily effected, and his system for producing sound ingots consisted at first in sinking a can of this material into the top of the ingot after a crust had already been formed thereon. This caused the remelting of the portions surrounding the already formed pipe, and as soon as the remelting was effected the hole was filled by pouring in fresh liquid steel from the ladle. But the results were not satisfactory. Now the method consists in plunging the sheet-metal cartridge filled with thermit down to the bottom of the ingot before solidification has set in and before any of the defects have been developed. Fig. 2 shows the form of the cartridge and the rod used for pushing it through the fluid ingot. Owing to the action of the thermit, the method is mainly of advantage in the case of steel to which no silicon has been added either in the furnace or in the ladle, while, on the other hand, according to Dr. Goldschmidt, any method which depends upon top-heating is inapplicable unless the steel is siliconized. The effect of the new thermit process is to cause a strong ebullition of the liquid contents of the ingot mold with violent expulsion of the gases which are just beginning to separate from the mass. This drives the segregation upward. Another effect of great value is that the metal in the mold sinks down more than a hand's-breadth and that the density of the material is increased in proportion to the reduction of its volume. In the case of plates made from slabs treated in this manner it was found that only 0.3 per cent. of the plates had to be rejected on the ground of faults traceable to the ingots, while the rejection at many works amounts to 15 per cent. This applied to the production from 4,000 ingots varying in size from 1 to 8 tons. In all 17,891 ingots from 1,436 different heats were treated by the new thermit process at the Schultz-Knaudt steel works from November, 1911, to July, 1912.—From papers reprinted in *Engineering* of October 4 with many illustrations.

FOUR or Three Gear Speeds in Trucks—To show the advantages obtained by having four gear speeds rather than three in heavy motor trucks Captain Renaud of the French army, who was associated with the one-month trials of army motor trucks held this year within a 30 mile radius of Versailles, sets forth the points at which there will be a difference in the operation of two trucks, both weighing 6 tons with load and both developing a power of 1235 kilogrammeters at the wheel rims, but one equipped with four gear speeds and the other only with three. With the power mentioned both will be able to climb a 15 per cent. grade at a speed of 1.20 meter per second on the low gear and both can reach a speed of 5 meters per second on a 2 per cent. grade on the high gear.

IN THE CASE OF FOUR GEAR SPEEDS

With a gear scale arranged in geometric progression, the quotient being 1.6, the four vehicle speeds of the truck when the motor turns at its normal speed are:

1.20 meter....1.92 meter....3.07 meters....5 meters.

and from the number of kilogrammeters available at the wheel rims it may be deduced that the road grades which may be climbed at these speeds are in round figures, respectively: 15 per cent., 9 per cent., 5 per cent. and 2 per cent.

The diagram, Fig. 3, may be drawn on this basis, the grades being marked on the abscissa axis ox in number of centimeters of rise for each meter of distance and the vehicle speeds in meters per second on the ordinate axis oy. In considering what will take place at the various combinations of speeds, it should of course be remembered that poor road conditions may be equivalent to grades in necessitating the use of the lower gears.

The curve A represents approximately the progressive variation of the truck speed for all grades from level to 17 per cent. on the low gear. On the same plan the curves B, C and D may be drawn, corresponding to second, third and high speed gears. The limit curve drawn tangentially to A, B, C and D at *a, b, c* and *d* represents the vehicle speed which the motor should be capable of imparting, according to the grade to be climbed, while developing continuously its maximum power, and provided the gear speed could be changed gradually instead of step-wise. The triangles ***dpc, cnb*** and ***bma*** indicate the imperfection of a step-wise gear system. The most obvious practical conclusion from the diagram is, however, that for all speeds other than those corresponding exactly to the points *a, b, c* and *d* it is impossible to utilize the motor at exactly its most economical speed, and that this shortcoming will be so much more onerous as the points *m, n* and *p* are farther removed from the theoretical curve *abcd.*

IN THE CASE OF THREE GEAR SPEEDS

The two extreme speeds are the same as before and the intermediate gear may be chosen so as to give, for example, a vehicle speed of 2.4 meters per second, or twice as high as on low gear. [To get the best possible results it should be lower, however, and the disproportion in the selection made is indicated plainly in diagram Fig. 4 by the great difference in the areas of the two triangles $a_1m_1b_1$ and $b_1n_1c_1$. Through this disproportion the showing made by the author against the three-speed gear has been somewhat aggravated.—ED.]

Under these conditions the grades which the truck may climb at normal motor speed are in round figures: 15 per cent., 7 per cent. and 2 per cent.

The diagram may now be drawn as before and Fig. 4 shows by the larger areas of the shaded triangles the larger variations from the best and most economical motor speed which it is necessary to submit to.

A numerical example brings out more sharply the advantage of the four-speed gear for trucks. Suppose that a day's trip of 100 kilometers includes 15 kilometers of 4 per cent. grade, 1 kilometer of 7 per cent. and 2 kilometers of 9 per cent. With four gear speeds the 4 per cent. grade can be taken on third at 3.5 meters per second, and the 15 kilometers will be traversed in 1 hour 11 minutes 25 seconds. The 1 kilometer of 7 per cent. grade will require the second gear giving a vehicle speed of 2.3 meters and an elapsed time of 7 minutes 14 seconds. The 2 kilometers of 9 per cent. grade will be covered on second gear, giving 1.9 meter vehicle speed and an elapsed time of 17 minutes 32 seconds. The total time spent on the grades will thus be 1 hour 36 minutes 11 seconds.

With three gear speeds only, the same grades will be climbed as follows: The 15 kilometers on second gear, working up to 3.1 meters vehicle speed per second, in 1 hour 20 minutes 38 seconds; the 7 per cent. kilometer also on second but at a reduced vehicle speed of 2.4 meters, making the time 6 minutes 57 seconds; the 2 kilometers of 9 per cent. grade on low at 1.6

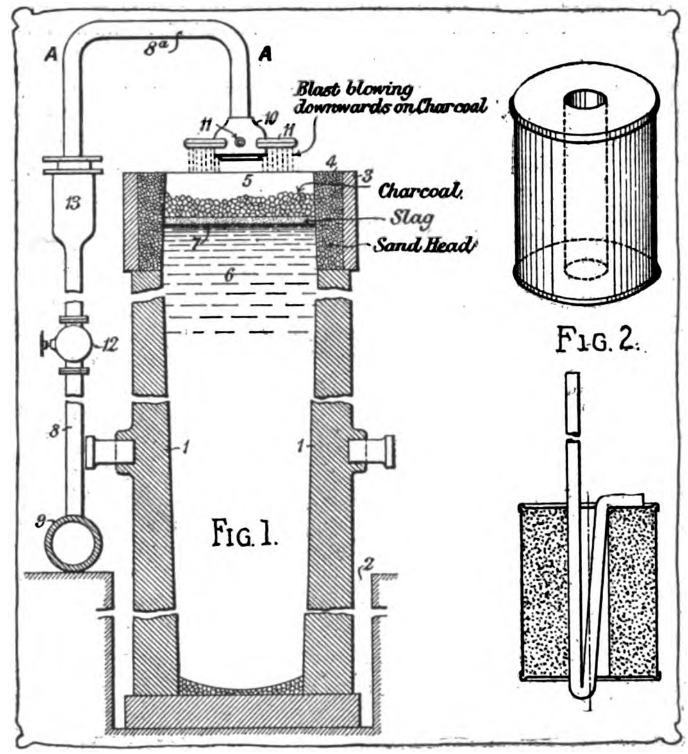

Fig. 1—Hadfield method for producing sound steel ingots. Fig. 2—Thermit cartridge used by Goldschmidt

meters and in 20 minutes 50 seconds. The total time spent on the grades will thus in this case be 1 hour 48 minutes 25 seconds. The time loss as compared with the four-speed truck is for the day 12 minutes 14 seconds. If the motor consumes 0.4 liter of gasoline per horsepower-hour or 9.6 liters per hour, the four-speed gear box results in an economy of about 2 liters for the day.—From *La Technique Automobile*, September.

BRINELL Test Probed—Despite the very general adoption of the Brinell method for testing the hardness or density of a metal by measuring the impression made in it by a steel ball of given diameter and under a given pressure, and of deciding the tensile strength in a rough and ready manner by multiplying the density number on the Brinell scale by a constant, there has been a suspicion in many quarters that this convenient testing method should be accepted only with many reservations. It has been conceded from the start by its author that the figures obtained by means of it have mainly a relative value and that only those derived from tests made with balls of the same diameter and under the same pressure should

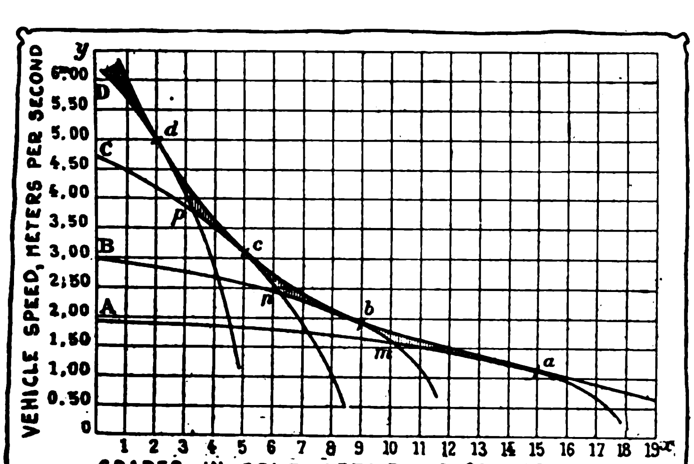

Fig. 3—Utilization of motor with four gear speeds

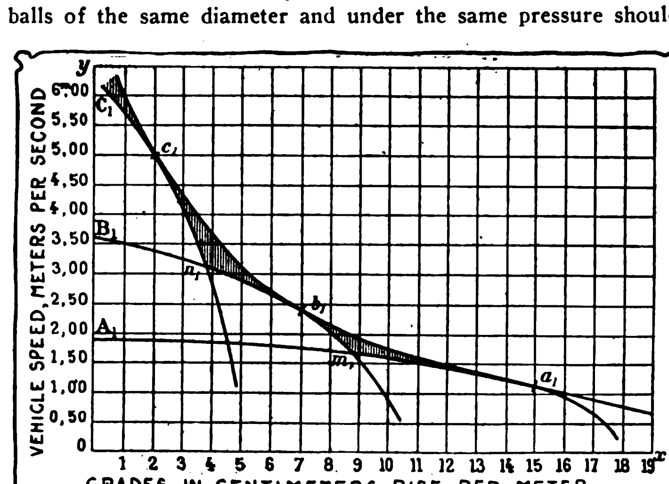

Fig. 4—Utilization of motor with three gear speeds

be compared. With this limitation in view the testing machines have been standardized in two sizes and the hardness number is tabulated from a conversion formula in which the diameter of the ball and the pressure are both considered; see details in THE AUTOMOBILE of July 4. It has, however, been found by Prof. Prandtl that the method is entirely inapplicable to cast iron.

Now the results of a searching analysis of the method, conducted by Mr. Hanriot, have been presented to the *Académie des Sciences* by Mr. Henry Le Chatelier, and while the facts mentioned by the investigator confirm the suspicions by which the research was prompted they also point out a corrective to the method lending it a greater scientific value while not detracting from its industrial convenience.

Hanriot shows first that aluminum bronze gives a density of 95 when a pressure of 1,000 kilograms and a ball of 10 millimeters diameter is used and only 67 with a pressure of 30 kilograms and a ball of 3 millimeters diameter; that nickel likewise gives 80 under the first condition and 60 under the other and coin silver 68 and 55. [Mr. Hanriot does not use the approved conversion formula, however, but obtains his density number by simply dividing the pressure figure by the figure expressing the area of the impression of the ball. His investigation is purely scientific.—ED.]

Lead is found to give the same density number whether the ball and the pressure are large or small, and from this the author inferred at first that the variation in the results with harder metals is due to the *écrouissage*—molecular upsetting—of the metallic structure of the latter. To test this inference he measured the density of a plate of nickel, getting 80 under a pressure of 1,000 kilograms and 61 under a pressure of 30 kilograms. He then filed away the imprints and measured the metal immediately under each of them by means of the small ball and small pressure alone. This gave the figures 117 and 67, showing that the metal had been affected by the very pressure of the balls previously used, and naturally more by the heavy than by the light pressure. It then occurred to him to see if annealing would remove the upsetting and make the reading alike for different pressures and ball diameters, but it was found that while repeated annealings gradually reduced the density figure very considerably, it did so in almost exactly equal degree for the heavy test as for the light one. The relation between two corresponding figures was a constant for all conditions, showing that molecular upsetting does not invalidate a test, although it had been shown previously, as referred to, that a test cannot be repeated in the same place of the metal where another test has been made without recording the structural effect of that test. Numerous experiments with different metals showed that the relation between the figures obtained with heavy and with light pressures was always a constant for any one material in the same structural condition and that therefore, once this constant is known, the density may be determined with any chosen ball diameter and pressure whose effects have been recorded [thus confirming the principle of the Brinell conversion formula and the tables based on it.—ED.] The constant was found to be 1.45 for aluminum bronze, 1.33 for nickel, 1.18 for coin silver, 1.02 for gold and 1.00 for lead.

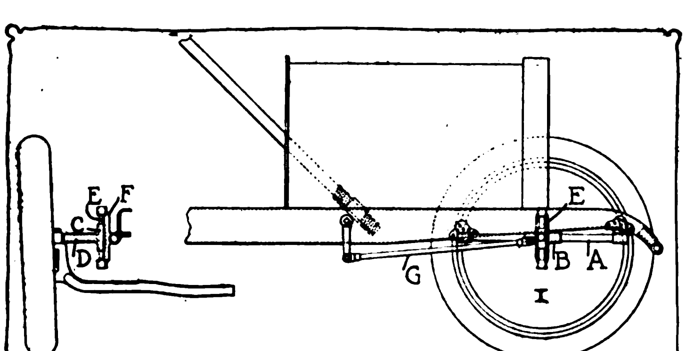

Fig. 5—Heilmann truck steering system applied to car

Another conclusion drawn by the experimenter from the facts ascertained by him is that the Brinell method gives far too high figures for annealed metals, as, for example, the hardness of aluminum bronze is much inferior to 24, which is the figure obtained after many repeated annealings and after obtaining 94 from the first test of the unannealed metal. The test seems to give a complex figure in which the hardness or density and also the facility with which the structure may be upset are combinedly recorded.

It is seen, he continues, that the results of the experiments are insufficient to explain the different readings obtained with different pressures. There is a source of error whose importance it is difficult to estimate. This is the elasticity of the metal. In reality, the imprint which should be measured is that existing at the moment the pressure is applied. The imprint which is actually measured is smaller, as the metal comes back resiliently when the pressure ceases. This exception to the method is confirmed by the fact that it is the relatively inelastic metals, such as lead, gold and silver alloy, which give the smallest difference in the direct readings under different pressures. The Brinell method gives thus only a gross idea of the density of metals, but even so its practical importance remains unimpaired, provided the figures obtained from it are used only for comparative estimates and are not supposed to possess absolute intrinsic value.—From *Génie Civil*, October 26.

LIFE of Storage Battery Plates—Two experimenters, Messrs. Askenasy and Putnoky, obtained from the factory of Gottfried Hagen, near Cologne, Germany, battery plates which had been prepared with chemically pure materials, and some of the negative plates were subsequently immersed in a solution of barium salt and sulphuric acid, so as to cause a deposit of inert sulfate of barium in their active material. They then proceeded to determine the effect of these deposits upon the capacity and life of the plates. In order to reduce the duration of the test they subjected them to successive charges and discharges lasting one-half hour each and produced by currents much stronger than normally used. After 500 to 750 discharges they restored the material of these plates by a fundamental charge in opposite direction. It was then established by the tests that the capacity of the plates at first increased slowly, in all of them, up to about 500 discharges. Thereafter it dropped rapidly, but less rapidly in the plates containing inert matter than in the other ones. The general result of the investigation was thus that the addition of inert matter is without influence until the capacity of the negative plates has been developed to its maximum and begins to decrease, and it was also ascertained that the total life of the plates is notably increased by the admixture.—From *Zeitschrift für Electrochemie*, June 15.

—

PROPOSED Steering System—In connection with the Heilmann truck wheel, which was illustrated and described in part in THE AUTOMOBILE of October 31, a steering system has been proposed which has the advantage over the customary method that the leverage with which force is applied grows larger instead of smaller the more the wheels are turned. Also, the steering rod moves in one plane, so that ball joints become unnecessary. A guide rod, A in Fig. 5, is secured to the frame reach. The sleeve B is mounted to slide upon it and forms a part of the knuckle F with pin E, upon which there is mounted the sleeve C with hollow lever arm D adapted to telescope upon a pin integral with the steering pivot and wheel spindle. Sleeve C can slide up and down on pin E in conformity with the action of the vehicle springs. The steering gear control is the usual one and the steering rod G attacks the sleeve B, moving it forward or backward on the rod A. The usual tie-rod connection from one wheel to the other is contemplated but is not shown in the drawing. The type of truck for which this steering system was specially designed has the spring suspension built into the wheels.—From *Bulletin Officiel*, September.

Overheating the Engine

What Causes a Lasting Rise in the Temperature of the Water Circulated To Cool the Motor Cylinders

The Evil May Be Due to Any One of a Number of Reasons—How the Nuisance May Be Prevented

PERHAPS few problems in the earlier days of gas engine manufacture puzzled the designer more than cylinder cooling. This is, perhaps, not surprising when it is remembered that the earlier internal combustion engineers gained their professional knowledge in the steam engine school, where the object aimed at was the retention of heat by inclosing the cylinder in a jacket of exhaust steam, which naturally had the reverse effect to that desired in a gas engine.

Although various cooling systems have been brought to a high state of perfection. doubtless finality has not yet been reached, and it is very questionable whether the ordinary motor user—both master and servant—has given that attention which he should to the cause and effect of undue cylinder heating. It is an acknowledged fact that over-cooling is undesirable, but the cases when it occurs must form a very small percentage of the whole, as the natural cylinder surroundings and conditions all tend in the opposite direction.

It is, however, with the problem of overheating that we are dealing, and before diagnosing the causes we will first study the effects. The space occupied by gases of all kinds is determined by their temperature, and as vaporized petrol is no exception to the rule, this has a very important bearing when considering motor-driven vehicles. The cubical capacity of the cylinder, other things being equal, determines its horsepower; such space must be charged with the correct quantity of fuel, which in turn must receive the treatment that enables it to give the best results.

If the water circulating system is in any way defective the cylinder becomes overheated and the incoming charge expanded beyond its usual dimensions, so that a full quantity is not drawn into the confined area.

Other things invariably follow overheating, such as pre-ignition and want of compression, the lubrication is all upset, as an oil that may be an excellent anti-friction element when subjected to a certain heat naturally has its limit, and when this is exceeded, fusion takes place, the lubricating properties are lost, and, instead of the piston rings taking an easy sliding gas-tight travel up the cylinder sides, a grinding frictional movement follows. In this way more heat is generated, until perhaps seizure takes place, or, if events take another course, a broken connecting-rod or crankshaft may result.

The fact of a little steam escaping from the radiator is not a sure sign that there is anything materially the matter. This remark applies even with greater force in hot climates in summer time, or where continuous long runs have to be encountered with steep gradients.

Cheap oils are false economy; one should only use a lubricant that carries entire confidence. The writer had an instance recently with a car which when running slowly and using a low-grade oil showed loss of power, and, though a careful examination of the circulation and lubrication systems proved all was in order, the trouble still continued. The oil was tested and found to be quite good for low temperatures but almost valueless in high ones such as those met with in the class of engine we are considering, as almost the moment it entered the cylinder it was burnt up so that part of the piston traveled in unlubricated ground. Deposits of carbon are much more likely to accumulate under the adverse conditions named, and eventually the carbon becomes an incandescent substance, giving rise to what is known as pre-ignition. Whether this is taking place may be easily proved by switching off the spark; if pre-ignition is taking place the engine will continue to run so long as there is a vestige of life left in the carbon deposits referred to. As such action takes place before full compression has been reached, it will readily be understood that an engine running under these conditions is extravagant in fuel and wear, and weak as a tractive agent.

Having mentioned some of the evil effects of overheating we will pass on to the causes. **The choking up of the radiator and circulating pipes is a very common source of trouble. When such is the case much depends upon the water that has been used; if only dirty, washing out is all that will be necessary; if water of a hard and brackish nature is employed, the hotter it becomes the quicker the solids are deposited on the pipes and furring follows.** The writer was in charge of some engines and boilers where surface condensers were in use, and where a 9-inch pipe carried the water off from the condenser tanks. In less than 3 years the pipe was so clogged with a hard lime deposit that only a 2-inch stream of water could pass by. This is mentioned to bring home to motor users how important it is with the small-bore tubes at their disposal to take every precaution against sediment.

If a circulating pump is the medium for water circulation it is not an uncommon error to assume that so long as this part of the engine is working the water is moving along the prearranged lines. This is not necessarily so, as an air lock may have been set up. Nearly all radiators are fitted with a draw-off tap, and if trouble is suspected from the direction suggested this should be opened and the air released; when there is not a tap, it is better to break a joint than to allow the trouble to continue. **One frequently sees exhaust pipes that have been subjected to intense heat, and many users at once attach blame to a sooted-up silencer, and are much puzzled, when taking it down, to find such is not the case. As often as not the seat of trouble is in the water-circulating system or action.**

Improper driving will produce overheating, particularly in hilly districts, by hanging on to the third or fourth speeds when ascending inclines and so causing the engine to labor; the effect of such action is equivalent to overloading. Unduly-heated bearings or broken balls are active agents as friction producers, and bring about much the same result.

In dry weather any leakage from the radiator or connecting pipes is soon seen, but in wet, damp or foggy times it is not so apparent, and an insufficient water suply is much more readily produced from loss of water by leaking than boiling. A dirty car oftentimes shows a tendency to cause overheating troubles. This is not surprising, for there are few better non-conductors of heat—and, consequently, are excellent heat retainers—than road mud.

When an engine has been lying unused for some time rust will often accumulate in the cylinder jackets, and, being heavy, it falls to the bottom, collecting any other particles with it and forming into a solid mass, thus preventing the cooling element from getting to the lower portion of the exterior walls. Some, and even experienced users, recommend softening agencies that do not easily dissolve absolutely, but the writer strongly deprecates the introduction of any substance that does not form a saturated solution. **There is nothing better or cheaper than common washing soda, which has the advantage that it can be obtained at any village store. It is best to dissolve the soda in warm water before pouring it into the radiator, otherwise the crystals drop to the bottom and it may be some time before a proper solution is obtained.** —From the *Motor-Car Journal*, September 28.

Carburetion

Part I

Subject Digest

Carburetion is more or less perfect according to how air is mixed with the molecules of liquid fuel.

Fuel mixing may be accomplished in three ways—passing air through liquid fuel, spraying liquid fuel, and evaporation by applied heat.

Heat is required to convert a liquid fuel into a gas, and the amount of heat so needed is in proportion to the latent heat of the fuel.

The latent heat of gasoline is difficult to state, but it approaches 320 British Thermal Units per pound evaporated.

The temperature at which a mixture of gasoline and air will remain stable is important, and varies with the richness.

To obtain carburetion and maintain it with low temperatures it is necessary to either make the mixture abnormally rich or to carburet only with light fuels.

by Robert W. A. Brewer

BY the use of the word carburetion in the following article, it must be understood that this word will designate **the art of mechanically mixing or blending a liquid fuel with a certain amount of air, and that whether this art is carried out to the limits of perfection or not is an indication of whether the carburetion is good or bad, and carburetion will be considered to be more or less perfect according to how the air is mixed with the molecules of the liquid fuel and to whether the fuel is divided into its finest possible particles, and every particle of fuel is surrounded by a certain quantity of air to the limit of homogeneity of the mixture.**

Fuel may be mixed with air in at least two ways: The first and the oldest form of carburetion is by passing the air through a volume of liquid fuel; on the other hand, the volume of air can be treated by spraying into it a certain quantity of fuel in a more or less finely divided state.

There is still what might be another form of carburetion which is virtually distillation or evaporation by means of applied heat, and it is quite conceivable that if a volume of air is passed over a liquid, and a higher temperature than the normal is applied to this liquid, the evaporation of the liquid will be accelerated above what it is under ordinary atmospheric conditions, and assuming that the rate of evaporation of the fuel is in proportion to the amount of air passing, and that the air is brought sufficiently near to the surface of the fuel, a satisfactory form of carburetion will follow.

It is naturally somewhat difficult, when dealing either with air or with fuel in quantities, to obtain a homogeneous result in the mixture, and for this reason it is preferable to treat small quantities as desired. Furthermore, when small quantities of air and fuel are dealt with, there is not so much risk of any involuntary ignition of the explosive mixture in the generating chamber as is the case where a larger volume is dealt with in a chamber of considerable capacity.

An engine such as is used in the modern automobile is not running under constant demand, and therefore, it is preferable to create an explosive mixture in accordance with the demands of the motor, rather than to store up any quantity of explosive mixture to meet any sudden demand which may come upon the engine. In this practice we are more nearly approaching the modern trend in stationary gas-engine practice, where a suction producer is fitted, and the suction producer in that case corresponds to the carbureter of an engine, rather than to the gas holder which was previously used when coal gas was employed as the fuel for large stationary internal combustion engines. We find in a gas set, where the engine sucks directly upon the coal carbureter, the amount of carbureted air which is drawn in is in direct response to the demands of the engine.

Now it is very obvious from general principles obtaining in nature, where a body is converted from one state into another, that is either from a solid to a liquid state, or from a liquid to a gaseous state, **a certain amount of interchange of heat must take place in order to effect this change of state, and the amount of heat absorbed is,** of course, in **proportion to the latent heat of the body.**

In the case of a liquid such as gasoline, which is of a complex nature, one cannot exactly state what its latent heat of evaporation is, but it is of the order of 160 calories per kilogram, equal to 320 British Thermal Units per pound of fuel evaporated. **That means to say that every pound of gasoline which is passed through the carbureter requires an addition of heat equal to 320 British Thermal Units in order to evaporate it, so that the resulting mixture shall remain at the same temperature as the incoming air.**

This heat can, as we know, be applied in two ways, either by raising the temperature of the incoming air by drawing that air over, say the exhaust pipe, or by heating the induction pipe between the mixing chamber of the carbureter and the engine valves. **It does not really signify how the heat is added so long as the temperature of the resulting mixture remains as desired.**

Now by this latter expression, of course a great deal depends upon the locality and the duty which the car has to perform, and theoretically it is more suitable for the temperature of the incoming mixture to be as low as possible consistent with the liquid remaining in the evaporated or suspended state without precipitation. Supposing we predetermine what the final temperature of the incoming charge of carbureted air should be, it is a fairly simple matter to calculate what temperature the air should be which enters the carbureter inlet, knowing the specific heat of the air. If we take this figure as 0.259, which means to say that 1 pound of air heated through 1 degree Fahrenheit requires 0.259 British Thermal Unit, it will be obvious that in cooling this 1 pound of air through 1 degree Fahrenheit we abstract 0.259 Thermal Unit.

Taking for example a ratio of air to fuel, by weight, of 15, a final temperature of the mixture of 60 degrees Fahrenheit, we find that 15 pounds of air will give up 15 pounds $\times$ $0.259 = 3.9$ British Thermal Units per 1 degree fall of temperature. Now, as we mentioned, the latent heat of the evaporation of the fuel is 320 British Thermal Units, we find that the temperature drop, assuming that there is no other heat interchange, is $320 \div 3.9 = 82$ degrees Fahrenheit.

Now if we consider the temperatures at which mixtures of gasoline and air will remain stable, we find that for a correct mixture the minimum temperature is 3.6 degrees Centigrade, but if the mixture is enriched with 20 per cent. of fuel, the temperature can be reduced to practically 0 Centigrade, that is, 32 degrees Fahrenheit. The richer the mixture the lower the temperature, but we may take it that at the freezing point of water we have practically the limit at which a carbureter will work. **It is therefore obvious, if we have a drop of 82 degrees in the carbureting system, the temperature of the air must be at least 82 degrees Fahrenheit above the freezing point, in order to satisfactorily carburete the air without precipitation taking place.**

Next we come to the explanation of a fact which is not generally understood, that is, why it is that a fixed carbureter, or carbureter in which the relations between the air flow and the fuel flow are predetermined, does not always work well until it is warmed up, and that it is sometimes necessary to flood the carbureter before the engine will start. This is entirely due to the complex nature of the fuel and to the absence of sufficient heat supply to effect carburetion.

From the previous figures, in which it was pointed out carburetion would not remain stable unless the mixture was abnormally rich, it will be obvious that **in order to obtain carburetion and maintain it when the temperature is low, it is necessary to do one of two things, either to make the mixture abnormally rich or to ignore the heavier functions of the fuel and carburete only with the lighter ones, allowing the heavier ones in the first instance to be carried through the engine and consumed.**

It is often pointed out that the so-called automatic carbureters are difficult to start, and will not work until properly warmed, and that it is essential for their working that they be either water-jacketed or heat-jacketed in some way. This is perfectly true, as in a properly designed carbureter of that type the fuel is correctly proportioned for running under normal conditions, and at other times the air supply must be shut down or the fuel supply temporarily increased.

It may occur to the reader that there is one other way of adding heat to affect carburetion, that is, adding it to the liquid before it is mixed with the air; but on consideration it will be obvious that as the relative weight of liquid to air is small, of the order of 1 to 15, that although the specific heat of the liquid is very considerable as compared with that of air, it would be impossible to add sufficient heat to the liquid in order to supply the necessary thermal units required for the latent heat of evaporation.

The specific heat of the liquid is only about three times that of the air, and as there is about fifteen times as much air as fuel by weight it is quite obvious that it would be necessary to raise the temperature of the liquid to say five times the range that it is necessary when dealing with the air, and of course this is quite impossible as the lighter factions of the fuel begin to come off at a fairly low temperature. Some carbureters certainly do heat the liquid fuel, but not to the extent here indicated, and furthermore, it must always be borne in mind that in those types in which the fuel is heated, there is another effect, that is, that of altering the viscosity of the fuel so that a greater quantity passes through the same orifice under similar conditions than would be the case were the fuel used cold.

A hot-water jacket in a carbureter, in addition to heating the fuel, does, of course, heat the incoming air, but it has been found in modern practice that an extension of the hot-water jacket is really necessary and the jacket is, therefore, carried some distance along the induction pipe.

Change in Carbureter Adjustment Needed for Winter

PERHAPS the owner of an otherwise well-behaved car will be surprised to find that his motor has developed an appreciable miss seemingly overnight, when he starts to take it out on one of the cold, frosty mornings that have now become common throughout the more northerly states of our country. If he is motor wise he will know that the time has come when he must readjust his carbureter.

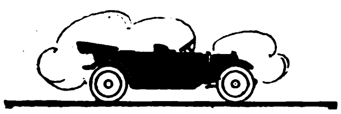
The reasons for this are many, and, after a moment's reflection, obvious. The assistance of a certain amount of heat is necessary in vaporizing the gasoline. In some motors this heat is applied by taking the air from a tube surrounding the exhaust pipe, while in others a hot water jacket is used for the same purpose as is explained in the above article. When the temperature of the outside air drops to a considerable extent the means provided for heating the air do not raise the temperature as far as is required by the carbureter adjustment that was satisfactory for summer. The air, being colder, does not evaporate the gasoline and as a result a misfire will develop.

There are two cures for this trouble. One is the taking of extra precautions to secure a warm supply of air and the other is to make a change in the carbureter adjustment. The first is that generally adopted by the carbureter makers who provide fittings to be attached to the carbureter when the cold weather sets in. The second method is the step that the owners of carbureters not having the hot-air attachment are compelled to take. **The adjustment consists simply in supplying a greater quantity of gasoline for a given weight of air.**

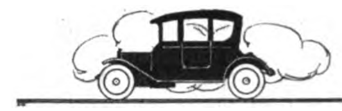
For the more progressive owners who desire to get away from the change of carbureter adjustment, which means the supplying of a richer mixture and hence a drop in the economy of the car, **the use of the dash control has been suggested.** In European practice and on many of the more expensive American cars this attachment has been fitted, although many have left it off with the idea of reducing complication. The driver with this attachment is able to take care of a climatic change without making any delicate needle valve adjustments. The dash control merely takes care of the amount of air supplied and does not interfere with the gasoline adjustments in the least. **When the misfire occurs in cold weather it is merely necessary to shut off the supply of air slightly and thereby allow the motor to draw in a richer charge.** After the motor has been run long enough to allow it to warm up the amount of air supplied in proportion to the charge can be increased.

With many carbureters, the problem is merely one of starting. After the motor has been running a few minutes there is no trouble whatever. Flooding the carbureter and priming are common means of starting in cold weather, as is also the shutting of the air passage, allowing the full suction of the motor to fall upon the spray nozzle. These should not fail with a motor that has been running well up to that time. With a cold and stiff motor, however, even priming will fail at times and the other methods produce no effect whatever. **In such instances five drops of ether to each cylinder of the motor have been found efficacious by many physicians and others who know of this method. Another trick that has been tried with success is the placing of about a tablespoonful of carbide in a small tin having a friction top.** A hole is then cut through the cover and the cover placed on the tin. Through the hole in the cover is run a small rubber tube or a piece of hose into the air intake of the carbureter. Through another opening in the tin is poured a half glass of water. After waiting for about a half minute the motor is cranked.

Roustabout and Coupé for 1912 Cole



Regular Runabout Model May Be Easily Converted Into a Closed Car for Winter



By George G. Mercer

THE individual owner of a model B 1912 Cole chassis with runabout body has little to fear of winter's sternness because he can, at a limited expense, have it converted into a winter roustabout or a coupé design, either transformation calling for practically no change, other than the positions of the gear-change and brake levers. The roustabout style, Fig. 5, can be had for $300 and the coupé body, Figs. 1 and 6, will approximate $1,000.

The roustabout is a most economical and novel method of transforming on open body into a winter one without adding any appreciable extra weight and giving a flexible type as the top can be lowered and the glass tops of the doors hidden, giving an open runabout with a stationary windshield. Such a body is ideal for the early spring and fall. It has an interior height of 38 inches from the cushion to the top bow. The coupé body, Fig. 6, seats two persons with space for one emergency seat and adds a load of approximately 450 pounds as compared with the open runabout.

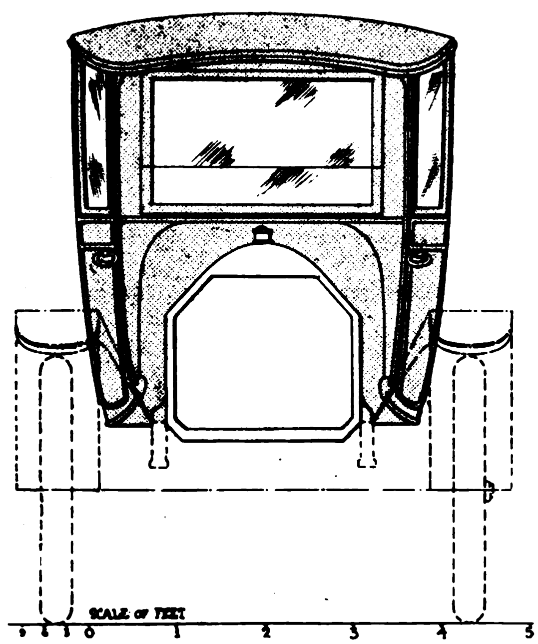


Fig. 1—Front view of Cole coupé design

The model B Cole chassis has a 122-inch wheelbase, four-cylinder motor with cylinders 4.5 inches square and wheels carrying 36 by 4-inch tires. Fig. 5 shows the roustabout body, consisting of the runabout body with a collapsible top, higher doors with upper glass halves and a stationary windshield.

All the conditions at the rear of the body remain unchanged. The coupé is roomier, because it is wider than the runabout and the doors are wider. The body design is similar to the old Sedan chair in appearance and is well adapted to carry out an altogether harmonious effect.

Considering the two designs, the winter roustabout, Fig. 5, has been made by adding to the original body. In other words, Figs. 4 and 5 are identical up to the line where the new parts forming the top and glass front have been added, with one exception, namely, the location of the change gear and brake levers. In the original car, Fig. 4, these levers are located so that they are operated outside of the body, whereas in the roustabout body, the levers are brought farther in so as to permit of their being operated on the inside of the body. The Cole cars are made with the levers located for either inside or outside driving, hence it cannot be much of a problem to make the shift on an old car, the parts being manufactured and consequently readily accessible.

Having made the shift in the position of the levers, the car is now ready for the body changes. All the parts that are added to make the roustabout are intended to be fastened so that they can be removed in the spring and the original body attached.

The windshield is made with two uprights, fastened to the body posts at the front of the door. There are cross members at the top of the posts and across a line where the cowl intersects the front of the windshield framing. The cowl is fastened at the front to the cowl of the body and serves as a brace to the windshield. A divided glass is used with the upper part made to swing outward and serves as a storm visor.

The doors are of the regular type with a wood panel added to the top to make the sides higher. To the new top line of the door A, Fig. 5, a glass frame B is attached by hinges and when locked in the position illustrated, it forms an integral part of

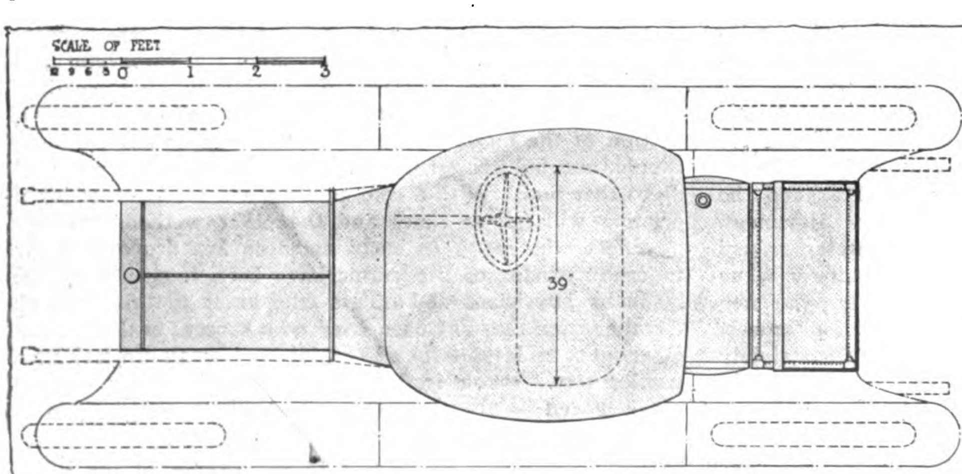

Fig. 2—Plan view of suggested coupé for 1912 Cole runabout chassis

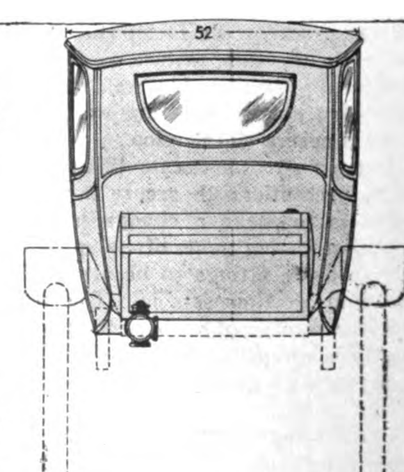

Fig. 3—Rear elevation of coupé

the door, when the latter is opened and closed. It fits against the door posts at the front and back and effectively shuts out the draft, and, with the top down, this glass frame is made to disappear by revolving on its hinges and lying flat against the inside of the door. Dotted lines B1 show the frame in this position.

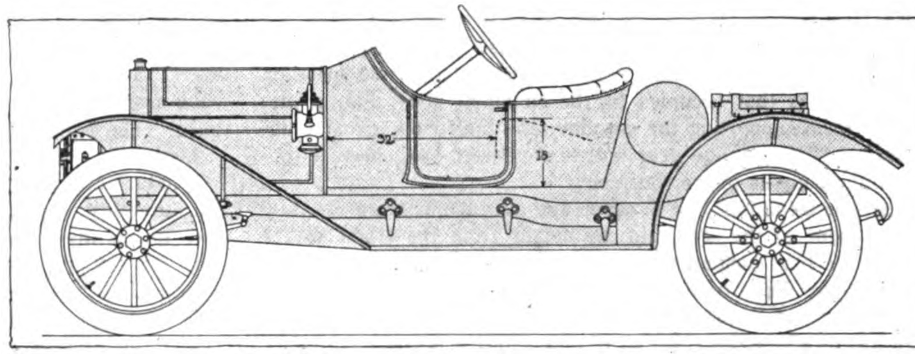

Fig. 4—Cole 1912 runabout type which may be adapted for either coupé or roustabout

A bow C extends from the body line on one side to the corresponding point on the other side, and is made wider to a height level with the top of the door glass frame. This is to provide a stop for the latter as well as to serve as a wind-break. The cut D is the point at which the top breaks when in the down position and the hinge is indicated on the back of the bow. The two rear bows travel with the bow C, but the horizontal bow E is lifted out of the connection F and fitted into F1. This bow E, when in the horizontal position and with the top raised, is fastened at the front end by a strap on each side to the windshield post. To make it an easier proposition to remove the top in the spring, a shifting rail is used, top irons being placed in the body to receive them. The lower edge of the top material is stitched to this rail and there is also a lug projecting on each side of the car to receive the lower end of the side joint.

The top material fastens to the back edge of the bow C by a metal molding extending from the bottom to the top of the door glass, or approximately up to F. On the bow E it is similarly fastened at the front, beginning from the windshield post. From this point back to F the material is loose from the bow and is reinforced and stitched forming a flap which covers the top edge of the door glass frame. This flap is lifted by the frame when the door opens.

The size of materials used to construct this top is so well understood by the trade that it would be superfluous to make mention in detail here. The bows are a standard commercial article, as are the joints. The shifting rail is made from .75- by .375-inch oval machine of C. R. steel and the cowl from aluminum sheet, No. 16 gauge. The wood frame of the door glass is heavier than usual at the bottom to give room for fastening the lockcatch. As the frame is unsupported by any framework other than itself above the door, a wider bearing is necessary.

The top material would preferably be English Burbank, a material with a heavy texture and well adapted to keep out the cold. To insure greater comfort, the top should be lined with light-weight broadcloth. One small celluloid window is placed each side between the two last bows and in the rear curtain a similar light of generous proportions is placed.

The cost of the changes from Fig. 4 to Fig. 5, but not including the change of the levers, will be approximately $300. This will cover specifications for the best English Burbank top material, a fair quality American broadcloth for inside top lining, the ironing of the pillars and the putting in of the new top iron supports, adding to the door height, making the door-glass frames and the front windshield and adjusting with suitable fastenings. Straps are used to keep the top steady when it is lowered and between the two last bows a small block or buffer is used to keep them apart, and thus protect the celluloid side light from being broken when the top is strapped down.

Fig. 6 illustrates a totally different way of providing for winter service with the Cole car. The plan is more elaborate and more expensive, and for the majority of people it will be proportionately more satisfactory, provided the winter service required will warrant the increased expenditure. The most satisfactory body to use for extremely cold weather is one with a permanent upper structure. Any form of collapsible top will deteriorate more rapidly than the former and the more numerous openings or joints indicate a greater likelihood of wind and rain forcing their way through.

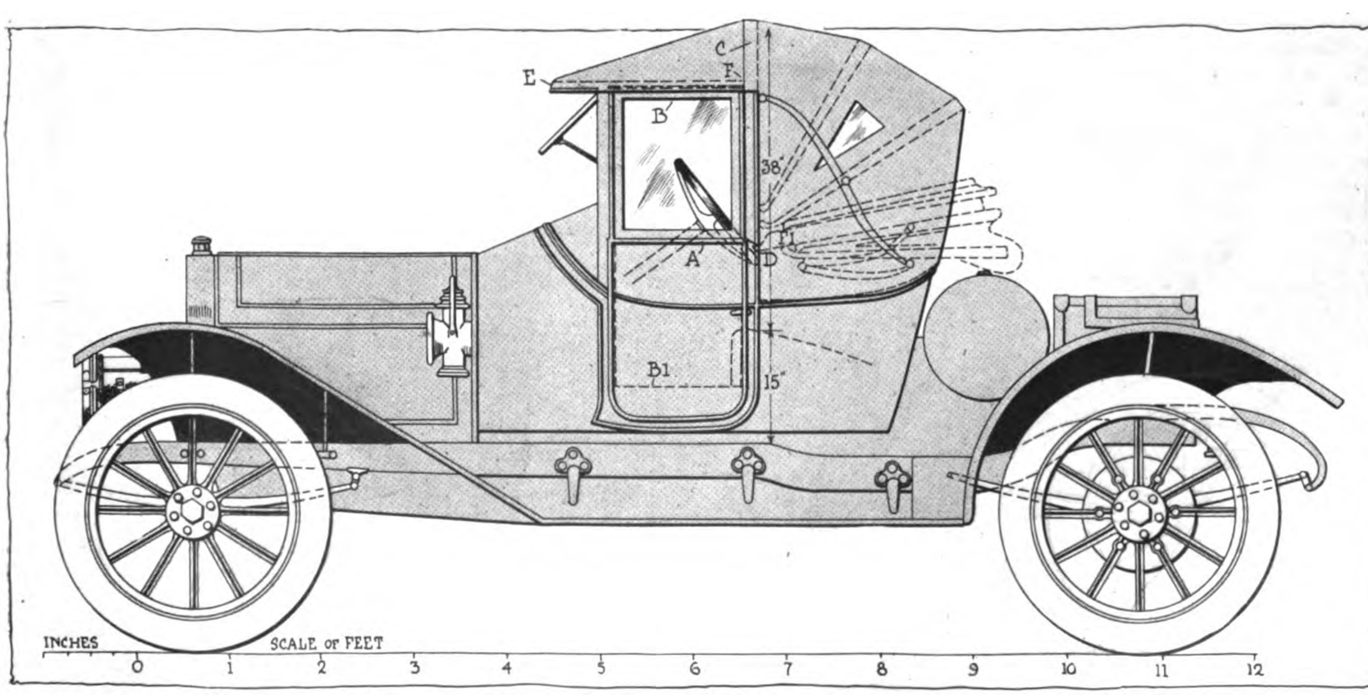

Fig. 5—Side elevation of suggested roustabout body suitable for 1912 Cole runabout chassis

The coupé body, Figs. 1, 2, 3 and 6, is fashioned from the old-time Sedan chair and for the purpose here used it seems extremely applicable. It has been installed in the same space on the chassis as that occupied by the runabout body, Fig. 4, and the platform supporting the gasoline tank and trunk remains undisturbed. The change gear and brake levers have been moved inside the body as in the roustabout.

The side elevation, Fig. 6, shows the dimensions from the dash to the front of the seat, and the height from the frame to the top of the seat cushion to be the same as in the regular body, Fig. 4. The depth of the cushion to the back, approximately 18 inches, gives 15 inches between the back and the steering wheel. The height above the cushion to under roof is 40 inches and the width of the cushion in the plan view, Fig. 2, is 39 inches. The seating capacity affords luxurious accommodation for two people, with space for one emergency seat.

Provision for extra tire carriers has not been installed, the idea in the mind of the designer being to retain the chassis intact as in Fig. 4, with the single exception of changing the levers. In the spring the coupé body can be removed and the former body substituted.

The doors are 23 inches wide over the moldings and as the seat cushions are rounded at the front corners, the change gear and brake levers have been placed in from the side so that the entrance through the right door is posssible.

One noticeable feature with a coupé that is not possessed by a collapsible body is the possibility of having plenty of window space. The windows have the regulation wood frame for the glass. The windows in the doors are made to drop their full length and those at the rear of the doors will drop three-quarters their length. The rear window is stationary. The front glass is divided, the upper part forming a storm visor.

The dash, integral with the body, permits of the body being taken off as a unit, not disturbing the old dash, which in turn is built into the cowl of the runabout body.

The specifications call for an all-metal panel body, the panels of 16-gauge aluminum. Metal moldings are used throughout except the heavy ones on the door and hinge pillars. These are of wood and are worked solid on the framing.

The interior dimensions should be as indicated in Fig. 6 and the width and length of the body outside to be as indicated on Figs. 3 and 6, respectively. The body should be made so as to occupy the same space on the chassis as that occupied by the former body, and without any alteration to the chassis other than the change in the location of the gear change and brake levers. The windows should be as previously described and the wood frames of same to be of American walnut in the natural finish. The body framing should be of good ash and the roof of laminated whitewood.

Specifications for colors bring out the question of good taste and durability. Consideration must also be given to the fact that next spring the coupé body will be removed and the runabout body substituted. Consequently it is wise to use a color for the chassis that will harmonize with either body design and so avoid having to repaint the chassis every time the bodies alternate. The present color is gray; therefore, it would be wise to retain the standard color for the under parts, and for the door and body lower panels of the coupé use a gray of the same shade or slightly darker. For the upper panels black will harmonize well, using black striping for the gray parts.

The body cowl and the short panel below the molding will match the chassis color. This color combination, besides being in good taste and advisable from an economical standpoint, is a combination that will wear well.

The trimming specifications will cover electric dome light in the roof and the suggestion for trimming material would be a combination gray and black Bedford cord of the best quality and trimming lace to match, this cloth to be used on the cushion, sides and back and roof; gray silk for curtains with tassels to match; Wilton carpet for the floor to be gray with small black flecks. Toilet case and card case should have silver mountings and should be covered with gray morocco. All metal parts in the interior to be silver or nickel finish, all visible wood parts to be black walnut finish.

The flat cost of a body, built according to the above specifications and finished according to same and mounted on the chassis ready to run, will be approximately $1,000 exclusive of the charge for changing the levers from outside to inside. The work of the designer is to a large extent suggestive. These two designs are suggestive possibilities and the car owner is the final link in the chain that leads from these possibilities. These designs are applicable to a number of different cars, and applicable to a greater or less extent, according as they are similar or dissimilar to the car used as a model. They are especially applicable, however, to Cole runabout bodies and have been designed with this end in view.

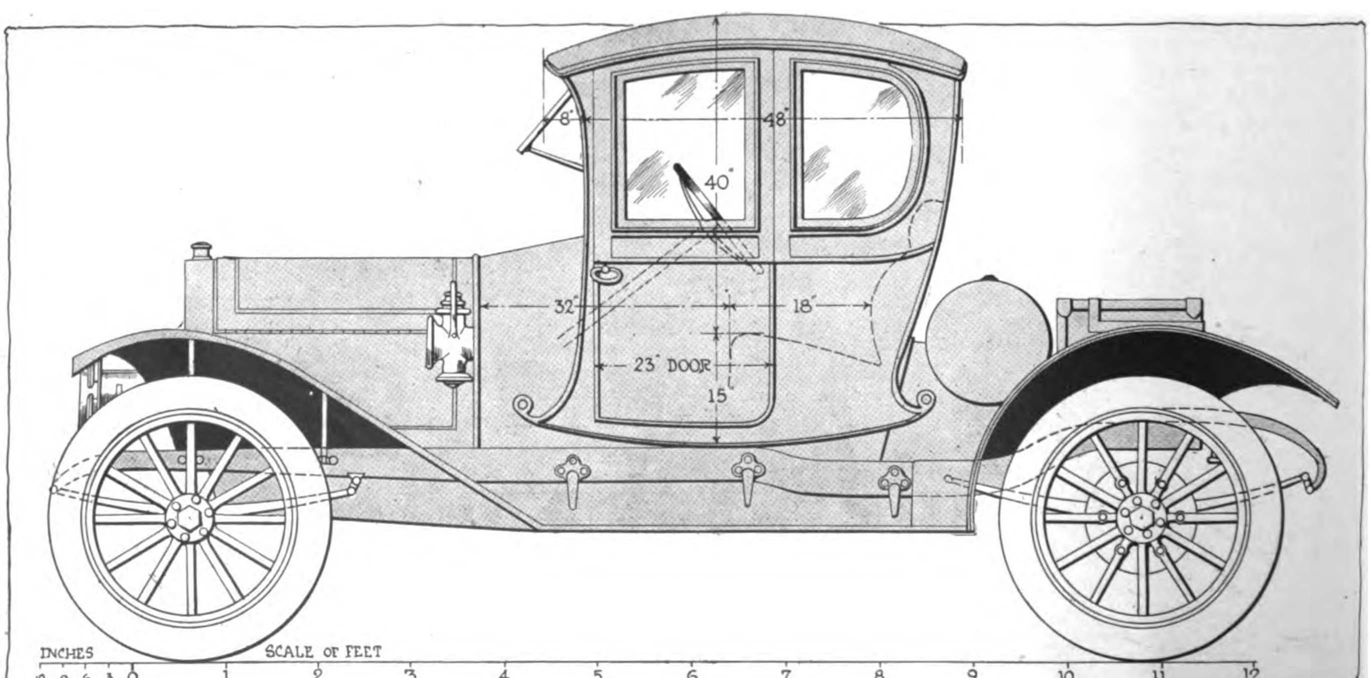

Fig. 6—Side elevation of coupé suggested for winter use on 1912 runabout frame

Good Materials Indispensable for Painter's Success

Red Lead Should Be Used Sparingly, as It Is a Heavy Pigment—Natural Oxide Paints Have Many Points in Their Favor, Especially Durability—Roughstuff, Like Paints, Should Be Very Pure

A READER of THE AUTOMOBILE writes to say that inasmuch as the black paints are coming to be largely used in structural metal painting, and are giving great satisfaction in this capacity, **why not use such pigments upon the metal automobile surface?** He cites the fact that lampblack will absorb 35 per cent. more oil than the light-colored pigments, and as oil is the life of the paint to a large extent, the **lampblack should be nearly unsurpassed as a first coater for the metal surface.**

There is no question concerning the durable properties of lampblack, but it is at the same time doubtful if this pigment will render as good service as red lead on the metal surface. Red lead and pure raw linseed oil, thoroughly mixed, as applied over new metal, either aluminum or sheet steel, will stick with great tenacity to the surface if applied rather thinly and well brushed out. The average mixture of red lead ready for application is 30 pounds of pigment to one gallon of oil. **Never mix red lead ahead of requirements. It is a very heavy pigment and settles quickly.** To retard the settling propensity of the lead, add to every 20 pounds of red lead 2 pounds asbestine pulp (magnesium silicate) and stir this mass into a gallon of linseed oil. Cut this mixture with a little turpentine to give it fluidity and permit only an expert brush hand to apply the pigment.

Natural oxide paints, that is to say, pigments having a mineral base, are likewise coming into favor as priming materials for new work. These oxides have good covering power and durability, and when prepared with plenty of good, raw linseed oil and let down a little with turpentine, they constitute excellent coatings at a saving of from 8 to 10 per cent. over the use of red lead.

The natural oxide paints here spoken of are composed in greater part of oxide of iron and in the family of reds they embrace Indian red, Venetian red, red oxide, etc. In connection with these oxide pigments red ochre, yellow ochre, umber, etc., owe their color to oxide of iron, but these ochres contain numerous other substances. **These pigments, under anything like reasonable conditions, are as nearly perfectly permanent as any pigment can possibly be.** They unite and mix well with all other pigments without in any way affecting them or being affected by them.

In laying coats of surfacing material directly over any of these red lead or natural oxide paints, the pigment used should be chosen with reference to its natural durability and its qualifications as a bodying up and surfacing material. **For this purpose white lead ground in linseed oil has long since demonstrated its value and usefulness.** White oil-ground keg lead is a soft, pliable, elastic, grain-filling and pore-sealing material when properly ground and prepared. Its remarkably soft, fine, elastic texture, unusual adhesiveness, exceptional surface filling and leveling-up properties, all unite in making lead a pigment of nation-wide importance in the automobile industry. And with reference to the use of this pigment the car owner or prospective has well-established reasons for insisting upon the use of a pure lead, or one approximately pure. **Moreover, he should insist upon high-class grinding and preparation of the lead.** A lead need not be chemically pure in order to establish its value and usefulness. But, above all things, it should be ground fine and washed free from foreign substances of every kind. With a lead ground as fine and smooth and soft of texture as good mills will grind it, first-class linseed oil being incorporated in its composition during the grinding, we have a surfacing pigment adapted to go immediately over the lead or other metal primer quite unsurpassed for the qualities which count for most in motor car paint shop work.

A couple of excellent coats of lead laid over the primer of oxide paint, red lead, or over any one of less known pigments, will suffice to give the surface sufficient body of pigment to support what is technically known as filler or roughstuff coats.

Into the roughstuff should go nothing but good materials. The day when scraps and drippings and left over material in general may be safely mixed into a paint, or into roughstuff particularly, has disappeared. The call is fairly, if not quite, universal for a surfacing material that will hold strong and fine upon the car and support to the maximum limit the coats of color and the foundation of varnish used over it. **It has been demonstrated that nothing short of the best paints, surfacing stock, colors and varnishes, will suffice to furnish service and good appearance.**

During the past two seasons the gray colors—automobile gray, French gray, battleship gray—have become exceedingly popular, and very properly so, for, above everything else, they have proved durable. The gray color, whatever its particular designation, is an easy keeper. **It is neutral in effect, shows usage and dirt less than almost any other color, and looks well.** There is one thing, however, to be guarded against in connection with the use of this family of pigments, namely, a tendency to streak out and disclose a glimmer of some one or more of the pigments entering into the composition of the gray. Only recently the writer had his attention called to a case of this streaking. It appears that a gray made up from a white lead base, this base being saturated with ultramarine blue and lampblack, developed dark streaks.

In the event of mixing these colors in large quantities and by a certain prescribed formula, as practiced by color manufacturers, a more intimate mixture is obtained, and the likelihood of the color washing out, streaking, and doing other freakish things, need not be considered seriously.

In previous issues of THE AUTOMOBILE allusion has been made to the practice of using colors ground in japan for automobile work. Such colors, thinned simply with turpentine, as generally advised by the manufacturer, are naturally brittle, and in this condition are ill-suited to the vibration and oscillation strains to which the car is exposed in road service. To overcome this property the use of raw linseed oil is urged. **For colors to be applied over an old paint foundation in itself somewhat brittle and parched, the pigment should carry at least one part pure raw linseed to every four or five parts turpentine.** For the second coat of color increase the quantity of turpentine to the extent of using nine parts of the thinner to one part of oil. Thus establish a safe measure of elasticity for the paint and color fabric.—M. C. HILLICK.

The Engineers' Forum

3-Point vs. 4-Point

Leading American Engineers Discuss the Relative Merits of Two Systems of Motor Suspension

Advantages and Disadvantages of Flexible and Rigid Motor and Gearbox Support Outlined

Part I

Eugene P. Batzell Analyzes Both Systems

Wm. G. Wall Is Against Three-Point System

Charles E. Duryea Favors Three-Point Scheme

Frank Nutt Wants Flexible Four-Point Support

DETROIT, MICH.—Editor THE AUTOMOBILE:—Hardly any doubt can be entertained that a correct engineering principle is embodied in such a suspension of the automobile motors, gearsets, etc., which maintains them free from distortion originated in the vehicle frame structure due to the unevenness of the ground, when the vehicle is either in motion or stationary. The theoretical three-point suspension similar as disclosed in the Huber patent, providing a swivel joint at one end of the suspended party, gives a good example of such a correct suspension, and it serves its intended purpose as well as can be desired in practice. Other kinds of so-called three-point suspensions have no swivel joint but depend on the flexibility of supporting bolts, arms, cross-members, etc., to give the necessary deflection at the third point of support. Though this suspension is not as perfect as the first, nevertheless it is used frequently, giving satisfaction in some cases and causing trouble in others.

In three-point suspension, apparently good results, in the matter of protecting the power plant from stresses due to the frame deflection, are obtained when equipping the supporting points with springs, etc., so that there is an elastic medium between the frame and the power plant. Not only will this construction relieve the power plant from the frame distortion but, as in heavy commercial cars with the front springs calculated to carry a considerable portion of the useful load and offering but little deflection for absorbing road shocks when the vehicle is running empty, the springs interposed between the power plant and the frame should be of great benefit for the life and condition of the former, inasmuch as they carry it, absorbing the road shocks in a manner practically independent of the vehicle load.

This kind of four-point, etc., suspension is less valuable for application to pleasure cars than it is for heavy commercial cars, because the former have a much more uniform load over their front springs, consequently here the rate of protection of the power plant from road shocks also remains more or less uniform and not influenced by the carried useful loads. Nevertheless, this suspension would fulfill the purpose of relieving the parts from the frame distortion in the pleasure cars as well as in the commercial cars. However, there are many constructive reasons why this suspension does not meet with popularity in application to pleasure cars of the existing type, there being fewer reasons against it in commercial car practice.

The supporting of motor transmissions, etc., on rigid subframes is apparently losing in the number of its followers. This suspension cannot entirely relieve the vital automobile drive parts from external frame stresses, though it modifies them considerably and helps to preserve a more or less true alignment between the parts. The first part of this statement can be easily proven by locating an assembled chassis on uneven ground so that the frame is somewhat distorted. Loosening of a motor leg fastenings almost always will leave a gap between this leg and the sub-frame member, which gap is not noticeable when the chassis is on level ground, provided it was properly assembled. The gap indicates that some of the main frame twist is transmitted to the motor crankcase through the sub-frame. The extent of harm which is apt to be caused by this twist can be judged by trying to crank the motor with the chassis on uneven ground once with one motor leg loose and then with this leg drawn tightly to the sub-frame. The motor leg in question should be the furthest from any of the sub-frame braces or supports.

Generally the crankcase of the motor is not stiff enough to prevent one from noticing, that a three or more bearing crankshaft is tighter in its bearings when the motor leg is fastened to the sub-frame. A big advantage of a sub-frame construction is often found in the easier locating and supporting of the different details like steering gear, pedal control, etc., especially when the car is to be assembled from ready bought parts.

The absolutely rigid suspension of the motor, etc., directly on the main frame no doubt presents disadvantages in the more noticeable effects of its distortion by the frame twist than is possible with any of the foregoing kinds of suspension, other conditions being equal. On the other hand, this rigid suspension on four or more points is often made to act as the frame cross members act, that is, assisting to preserve the relative location of the two main frame side members. Of course, this necessitates an extra strong construction of the motor legs and base, but it puts much added strength also into the front part of the main frame, which is generally the weakest part of the whole frame. With increased length of the motor and distance between its supporting legs, the successful construction of a rigid suspension becomes more difficult.

On the other hand, a frame combining great strength and flexibility permits a lighter rigid four-point suspension, which latter can be used here to great satisfaction. Extra rigid frame side members, like those in vogue in commercial cars, particularly frames of rolled channel sections, render a stiff four-point suspension very impractical, because the cases of the suspended parts have to be exceedingly strong. They must withstand the whole frame twist, as no deflection of the side members can be relied upon to partly relieve them from it. A flexible suspension similarly as mentioned before, when the mechanism parts are mounted on a sub-frame which is suspended on springs to the main frame, or when the parts proper are suspended on springs, offers a much better solution of a four-point suspension in the foregoing instance.

The sub-frame on springs or on pivots is best when in addition to other advantages it would help the alignment of parts mounted on it separately in succeeding order: motor-clutch, transmission-jackshaft, etc.

When only a few separate units of parts are used, like power plant, transmission and jackshaft, then their individual suspension on springs or on three points is just as satisfactory in functioning and somewhat simpler in construction than a flexible sub-frame for them.

The correct proportioning of parts and of the frame for a rigid four (or more) point suspension takes considerable study of the subject, which includes practical experimenting besides the mere theoretical figuring based on logical consideration of the matter. Of course, in any case, it is much less troublesome to adopt one of those suspensions, which will wholly or partially protect the vital parts of the vehicle mechanism from the frame distortion. This would decrease the chance for trouble on account of the suspension, but, on the other hand, the rigid bracing of the front part of the frame by a more or less short and stiff motor base construction may have its advantages. At any rate, the existance of a successful rigid four-point motor suspension speaks well for the engineer, who constructed and proportioned it.

The few advantages of a rigid four-point motor suspension cannot be perceived in a four-point suspension of gearsets, jackshafts, etc. These latter parts are better suspended in a different manner, which actually is being followed in practice with but few exceptions.—Eugene P. Batzell, Hudson Motor Car Company.

—

Three-Point System's Disadvantages

Indianapolis, Ind.—Editor The Automobile:—As to the respective advantages of the three-point versus four-point suspension for motors, gearsets, etc., on cars, it appears at first sight as if the argument was in favor of three-point and, theoretically, a great many things can be shown in its favor. I do not believe that these advantages, however, work out in practice, which, together with the disadvantages, makes it questionable as to the utility of this method of suspension.

The three-point arrangement eliminates to quite an extent the twisting due to outside influences, such as road inequalities, but not the shocks due to wheels hitting obstructions in road, and at the same time, by having only three points, considerable more strain is placed upon the material composing these parts, due to the lack of a sufficient number of supports. Also there is considerable strain due to the momentum of these parts, caused by quick stopping and starting and centrifugal force on corners. I do not believe in an absolutely rigid support, though even this has its advantages in preventing the giving of the frame to too great an extent. In other words, without injuring or throwing the motor or transmission bearings out of line, the cases of these parts which have to be rather rigid to hold bearings in line, lend a certain rigidity to the frame which is a great help to the body work, for a frame which twists very easily is very detrimental to the proper working of doors of body and also to the paint, and causes a squeaking noise which it is almost impossible to eliminate.

The National for several years past has used a method of suspending its motor and also transmission by which arms bolted on to these parts have rested in sockets attached to sides of frame and held to these sockets by horizontal bolts, so that there is a hinged action at the end of each of these arms, thus allowing for most of the movement of side members of frame without putting any great strain on the suspended parts, and at the same time lending quite an amount of rigidity to the frame lengthwise and crosswise.

In regard to the Huber patent, while it is of considerable interest, I believe it does not concern a great many manufacturers, as the sub-frame has gone out of use to a great extent and the three-point suspension of sub-frame has been used very little.

Of course, it is up to the courts to decide whether a combination engine and transmission built in one consists of a sub-frame in itself. If this should be decided to be the case, there are a certain number of manufacturers of cars who would be affected by this patent.

I do not see any great advantage of this method of suspension, as it is not practical to make it rigid enough to do away with the flexible coupling between engine and transmission unless it is built into the castings of these parts, in which case it has the objections just mentioned of the three-point suspension. —William G. Wall, National Motor Vehicle Company.

—

Cites Three-Point Merits

Saginaw, Mich.—Editor The Automobile:—Regarding the subject of three-point or four-point suspension for motors and other parts in automobiles, I have but little to say. The thing seems so one-sided that no discussion is possible. As early as 1896 I wasted good time trying to convince mechanical engineers that an automobile must be flexible enough to meet road conditions, and that mounting the various units of machinery on a rigid frame was wholly out of the question. Later I tried to persuade the people that American bad roads required three-wheeled vehicles, because even though one does get mechanism mounted for long life, the body of the vehicle and the passengers will properly suffer more or less, unless they also are three-point supported. For a number of years I built vehicles which were identical, except as to their front wheels, and I have had people especially anxious to secure easy riding try alternately one and the other, and decide in favor of the three-wheeler. I am sure that their decision is right. I can supply from my files testimony showing the durability of carriage bodies of three-wheelers, which, being free from the twisting strains of the four-wheeler do not open at the joints in time.

So far as the mechanism itself is concerned, modern practice breaks this up into separate units, which are usually more or less flexibly connected, and which units are quite often three-point supported, or if more than three-point supported, these supporting points are quite close together. My own practice consists of a three-point frame having the two rear wheels as two points, and a ball-and-socket near the center of the vehicle as the third. Such a frame can get over all kinds of rough roads without being twisted, but on this frame I mount another three-point frame which is the whole power plant, and I can only say that it is the most successful arrangement I have ever tried. It permits delivering out to the wheels a larger proportion of the motive power than any other arrangements I have ever found. I employed this three-point frame as early as 1892, but other considerations caused me to cease using it for some years.

It will interest your readers to know that this double three-point suspension also is arranged to be separated by sliding apart so that the inner frame carrying the power plant can be dropped out of the outer one in about 5 minutes' time. Such accessibility has never been seen in a motor vehicle, and is the solution of the repair bill problem.—Charles E. Duryea, Duryea Motor Company.

—

Three-Point Creates Vibration

Kokomo, Ind.—Editor The Automobile:—In reference to three-point suspension, this construction looks ideal in several ways, but the biggest objection to it that I have is that it seems to bring out motor vibration very noticeably, due to the torque action of the motor, while with the rigid four-point suspension the torque action is very well taken care of, although the twist of the frame is no doubt very hard on the crankcase and motor bearings. We use what is called the flexible four-point support, which, I think, eliminates the objection of both the flexible three-point and the rigid four-point.—Frank Nutt, Haynes Automobile Company.

(To be continued)

Foreign Constructions Designs and Practices

Features of French Truck Design—Steel Bands Replace Rubber Tires—Lubricating the Spring Bolts

Novel Spring Shackle—German Device for Tight Clips—Engineering Observations from Europe

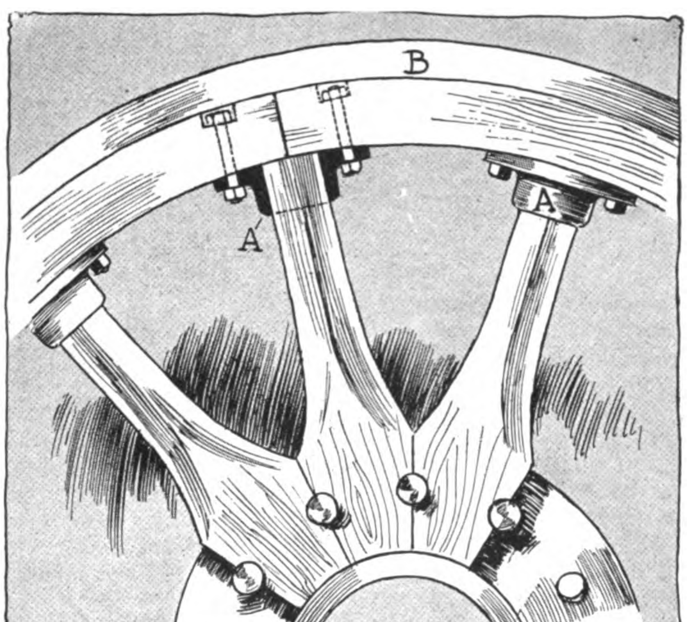

Fig. 1—Section of truck wheel fitted with solid steel band instead of rubber tire, the band measuring 8 inches wide and 1.75 inches thick. The hub takes plain bearings

OBSERVATION tells that a large number of the thoughts which have found lodgment in automobile construction work were borrowed from other arts. But experience has proven that the plagiarists were not always skilled in the art of transplanting. As a rule the simple contrivances of other arts were improved out of recognition and they were rendered so complex in the process that their actual value for the newer purpose became a question; **at all events, so far as Europe is concerned, a decided attempt is being made in the direction of simplifying mechanisms for automobile use.** That some mistakes are being made it is believed, but the field is so broad and the need so urgent that these steps are being taken as a necessity.

As an indication of just what is being done along this line take road wheels for motor trucks, which are being fitted with quills to the exclusion of ball-bearings. The quills are long—about 14 inches—and means for retaining grease, serving also to exclude dirt, are being provided. On a truck seen on the street of Vienna, Austria, the felloe was attached to the spokes as in Fig. 1. The steel band B, shrunk over the felloes, served in place of solid rubber tires, the latter being excluded from use. In this example of wheel work th spokes are about half the width of the felloe and the fastening to the spokes to the felloe, both of wood, is done by means of a metal accommodation piece A and bolts secured by radial bolts through the felloes.

Fig. 2 is of a truck spring, showing the method of fastening the shackle. This is common practice in German railway locomotive spring work and on some of the West Shore equipment. The point is that this railway idea is being used to a limited extent in truck construction in Europe.

Spring shackle bolts are now being supplied with grease cups with means for forcing the grease to the spring-eye bearing. This practice is quite general in Europe. Considerable trouble is being experienced in truck work, however. It seems to be extremely difficult to get the grease to pass out through the holes. Fig. 3 shows, in section, one of these bolts. It will be seen that, if the bushing rotates, it will cover the holes, where appearance, as on a truck, may not be the first consideration.

Lubricating the Spring Bolt

Fig. 4 offers relief from the trouble complained of as above referred to. The pin B should be of cementing steel, case hardened and ground to size. The idea is to get a good bearing surface for the bushings and great strength of the pin. The bushings E should have thin walls; 1-16 inch thickness of walls is enough. The heads on the bushings serve the dual purpose of providing a spacer as a washer and preventing the bushings from working endwise. Oil grooves or grease channels should be made in the bushings for one-half the distance out from the center. The shackles S should be drop-forged steel with a carbon content between 20 and 25 points, but the sulphur and phosphorus constituents should be under 0.03 per cent. on account of the nature of the work. To anneal the shackles after forging is a necessity also.

In freight automobile work, to use a trailer is frequently considered an advantage, but the average truck is not designed to accept a drawbar pull. Quite a number of trailers are to be seen in service in Europe, especially in Germany and Austria. It is worthy of note that provision is made in each of these cases for the drawbar pull of the trailer, the idea being to save the tractor from the consequences of a longitudinal as well as a vertical load. There are several detailed methods of accomplishing the end. In Fig. 5 the principle is shown. The pull comes on the rear axle at two points close to the wheels, but a spring bumper member is interposed in order not to impart too much of the shock of starting to the rear axle.

Drawbar Design for Trailer

Referring to Fig. 5, showing the axle X cut away at the center for purposes of clearness, the backarm A takes its support at two points between the spring perches and the road wheels—the space usually given up exclusively to distance or radius rods. The drawbar B has a bearing in this backarm and a second bearing in the inner support C, as it is called. The buffer spring S presses against the backarm and puts thrust upon the drawbar in the forward direction

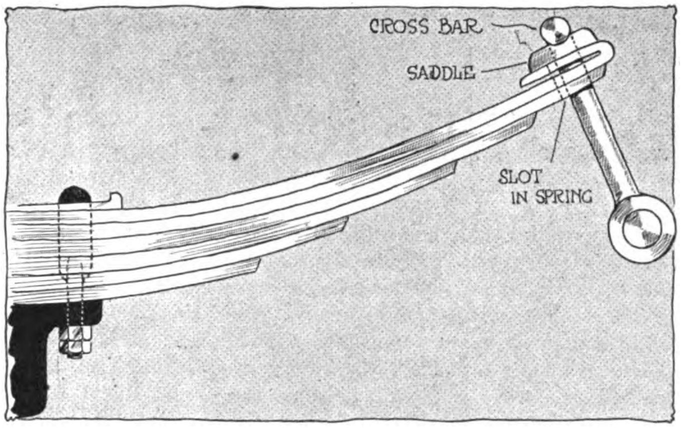

Fig. 2—European spring suspension for trucks, which has its origin in locomotive practice, and which is again in favor with truck makers

through an integral collar on the drawbar. A second stout spring S1, with a few coils, fills the space on the drawbar between the collar and the inner support. The drawbar passes under the axle. When the drawbar pull of the trailer comes on, it compresses the buffer spring until the pull is overcome. If the trailer overhauls the tractor the reaction spring S1 takes the load. Proper clearance of the drawbar must be allowed at all points. The tongue of the trailer is shackled at the universal joint and should have its weight supported at the trailer. The details of the radius-rod connections to the axle would have to be worked out with the details of the backarm. There is very little room to spare on the back axle of a truck, and this fact will influence the design.

German Wedge Spring Clip Tightener

Spring making in Germany is reduced to the level of a fine art. Good material for springs is regarded as necessary to entire success. But if the springs are not properly clamped to the perch, it is more than a superstition here that good material, excellence of workmanship of the spring maker, and proper proportioning of the springs will do very little good. It is said of springs that, unless they are firmly clamped to the perch, they will fail in exacting service.

The German Railway Engineers, having much experience with springs, clamp them somewhat after the fashion illustrated in Fig. 6. Some of the advanced automobile engineers are following along these lines also. Between the axle and spring are three members: First, a box A resting on the axle as secured thereto by a center bolt passing through the axle vertically; second, a plate with a curved contour bearing against the bottom leaf of the spring, and, third, a wedge or way between these two parts, so designed that by tapping with a hammer the fit of the spring within its clips can be tightened and held at any tension by the set screw C.

The above points are of special interest in view of the trouble that has been found in some of the American cars from breaking springs due to the condition that the spring pad did not have the same curvature as the spring. The fact that the curved spring rested upon the flat pad gave rise to the situation that a mere line contact was obtained in place of the flat seat. It is impossible to keep the clips tight where such a condition exists and, as a result, the springs work the clips loose and at the first heavy rebound they break. Some makers have placed a fiber block curved to the shape of the spring beneath the lower leaf and have obviated the difficulty in this way. Spring clips are especially apt to come loose in new cars.

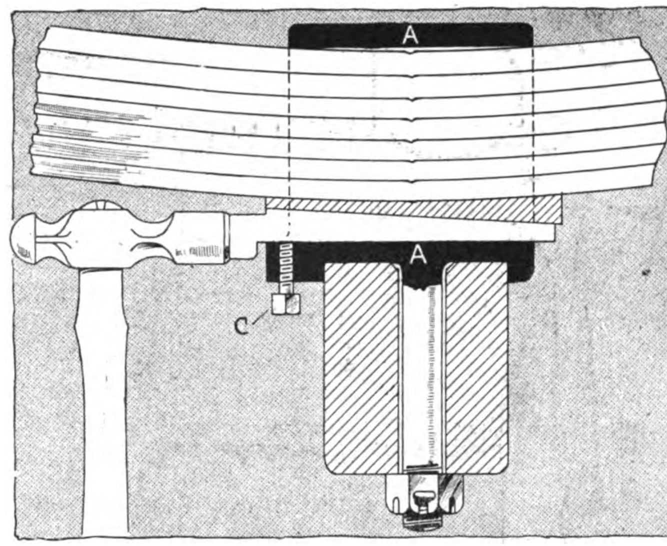

Fig. 6—German method of using wedge to insure tight spring clips, which is considered essential to good spring action and endurance

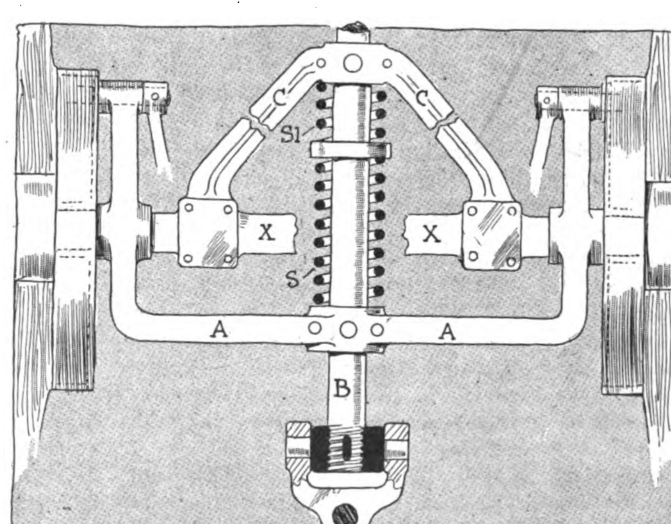

Fig. 5—Diagram of device for tractor-trailer use, showing the principle of taking care of drawbar pull of the trailer. Parts are: Axle X; drawbar B; buffer spring S; reactive spring S1; backarm A; inner support C

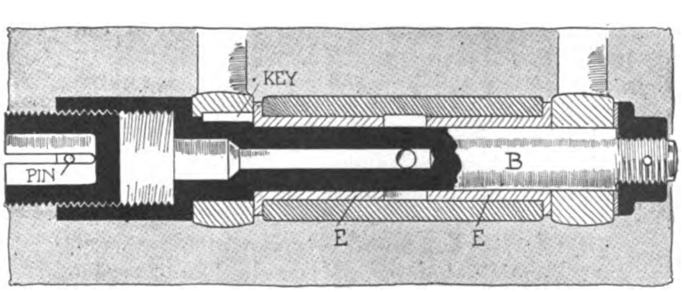

Fig. 4—New European form of spring shackle for motor trucks, showing two bushings E with clearance space for grease between their opposite ends, also means for using a long, powerful screwdriver to place the necessary pressure on the grease

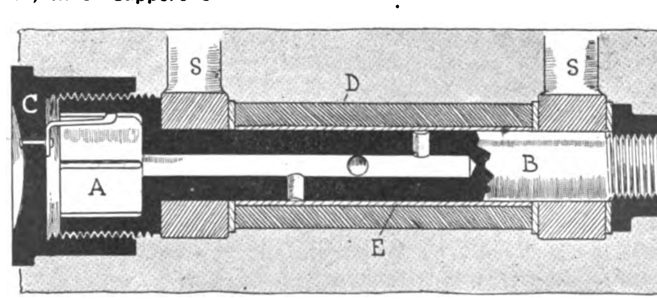

Fig. 3—Section of spring bolt for motor truck in which bolt B has a grease-cup head with screw cover and means for locking. The grease flows through the central channel and through holes H to the thin bronze bushing E in the spring eye D

The Chemistry of Cylinder Oils

Resinous Elements in Oil Give Acid Reaction Tending to Corrode Iron Surfaces in Contact

Part III

Being the third of a series of articles on cylinder oils which will appear from week to week. Discussions are invited and the columns of THE AUTOMOBILE *are open to pertinent criticisms.*

By W. Jones

ONCE more referring to the list of twenty analyses of oils, which we again publish in extended form (Table A1), showing the viscosities at high temperatures already mentioned, and also the acidity of the oils, their corrosive action on the metal of the cylinder, and the percentage of sulphuric acid in the three oils in which it was found.

We will first call attention to the acids in the oils. **We find in these oils two classes of acids: First, we have an organic acid, which is produced from the oil itself; and second, we have the mineral, sulphuric acid, which has been added in the refining of the oil, and has not been wholly removed.**

The organic acids in the oils can be, and probably are, produced from the oxidation of the oil itself. This we have found to be the case even with the kerosene oil which is sometimes used in steam boilers for the purpose of softening the scale. In the heat of the steam, which is above 300 degrees Fahrenheit, the oil is readily oxidized to an acid resinous substance, which we can obtain from the water of the boiler. We can also produce this action by other means in the laboratory.

In a publication of the Bureau of Standards it is shown that pure mineral oil, under certain conditions, such as raising the temperature for 5 hours to 250 degrees Fahrenheit, or by exposure to the action of sunlight and air for about 30 days, is readily oxidized to a substance insoluble in petroleum with 'er, but it is not stated what the nature of this substance long—abo than that it is melted at a heat above 95 degrees ing also to e. This would indicate that it is the same resinous seen on the stree have obtained and that we find has not to the spokes as in Fig. 1. ' has a corrosive effect upon iron. th qes, served in place of substance that gives the acid reaction to the oil when sulphuric acid is not present and that this substance has the effect of corroding, to a slight extent, the inside of the cylinder.

The amount of iron taken up by these acids, as shown in Table A1, must be more or less approximate, as it is very difficult to keep a circulation in the oil without continued heating, especially if the oil is at all thick, and this heating is likely to produce the acid effect if continued any length of time. Therefore, the only use of determining the amount of iron corroded is to show that the acidity of the oil does have this effect upon the iron, and that oils of low acidity would be preferable.

We now come to the sulphuric acid, present in three of the oils under consideration. This, we think, is much more important, as it will be noticed that the amount of iron corroded is much more in each case. However, this sulphuric acid may, and undoubtedly does, exist in two forms, free and combined. We have in No. 1911b enough sulphuric acid to show an acidity of .0324 per cent, regardless of any acidity due to the oxidized oil, while the total acidity in the oil is only .01029, one-half of which is probably due to the oxidized oil, leaving only the balance due to free sulphuric acid. The excess of sulphuric acid beyond this figure must be considered combined, most likely, as sulphate of soda that has not been entirely washed out. This sulphate of soda should have no effect upon the metal of the cylinder. This is borne out further by the fact that if this acid were all in the free state, and capable of acting upon metal, we would find the oil to take up very much more iron than it has in either of the cases presented.

In taking up the flash and fire points, we notice the close relationship between these figures and the viscosity, and that, as a rule, **the higher the viscosity, the higher is the fire point.**

We do not, however, consider that these figures have any great bearing upon the value of an oil for use in the gas engine cylinder, however much it may be desired to have a high fire test for other purposes. The oil No. 1867 with a fire test of 358 degrees Fahrenheit seems fully as satisfactory as those having a fire test of 500 degrees Fahrenheit, and when we consider the high temperature of the cylinder, which is far above the burning point of any of these oils, and that any of these oils will be more or less burned, and would be practically all burned if there was air enough in the cylinder for their combustion, we cannot imagine any difference as far as the lubrication is concerned. But when we come to think of the products of combustion, or what we might better say, the partial combustion of these oils, we would consider that the heavier oils, those of a high fire point, would be somewhat more difficult to burn, and in the excessive heat these heavy oils would, to a certain extent, be decomposed into a lighter and more easily vaporized oil and solid carbon, and that this is the source of the carbon deposit in the cylinder, although a large part of it is carried away in the exhaust as smoke.

We have seen the statement that the whiter the oil is the less carbon it contains, and that the only way to get rid of this carbon in the oil is by very careful filtration. By this one would think that the oil contained the carbon in suspension in fine particles, which could be taken out by filtering. This, of course, is not the case. **The carbon deposited in the cylinder is not from suspended carbon in the oil, but from carbon produced from the decomposition of the oil by**

the heat of the cylinder. The lighter products are consumed, while solid carbon is deposited on the cooler parts of the metal. For this reason we notice that those oils which contain the most carbon, not in suspension, but in their chemical constitution, or those more easily decomposed by heat, give more carbon under the same conditions favoring decomposition, and this is the carbon that gives the trouble in the cylinder.

To determine the amount of carbon any oil will produce in the cylinder would not be possible, for many reasons; but by adopting conditions as nearly like the engine as can be had in the laboratory, and maintaining the same conditions for each oil, we can very readily determine the relative value of the different oils tested.

We have now taken up each item in the analysis, and have shown its bearing upon the value of the oil for lubrication in the gas engine cylinder. We have yet to examine these different brands of oil, obtained from different sources, so as to be able to show what variation we may expect in oils of the same brand, if any; also if it would be safe to purchase oil by the brand name, or if it would be better to purchase on a specification as to what the oil shall show by analysis. This we expect to do in our next article.

Old Oil Must Be Drained Off

Just about this time of the year the automobilist is seriously thinking over the problem of whether he shall keep his car in commission all winter or whether he shall put it in dead storage until a more favorable season for motoring shall again come around. **For those who have decided to keep their cars running it would be well for them to clean out the oiling system if this has not been done during the summer season.**

On cars that use a circulating oiling system this is especially important as it will not suffice to simply renew the oil that is burnt up or that leaks away. The old oil that gathers in the bottom of the crankcase will become waxy and dirty. It will lose the very features which render it desirable as a cylinder oil and will cause trouble by gumming up the piston rings and carbonizing. If the course of the oil that is led through a circulating system be followed it will readily be seen by the most inexperienced amateur that this cleaning out is a necessity and that its omission will entail undesirable consequences.

Take the average splash system that is used to a large degree upon the average priced American car. The oil supply is carried in a reservoir which forms the lower part of the crankcase casting. From this reservoir a copper tube or lead takes the oil to the suction side of a gear or plunger pump. This pump in most of the splash systems does not take the oil to any special bearing but allows it to flow into the crankcase. When it reaches this it is picked up by spoons on the bottoms of the rapidly revolving connecting rods and thrown up into the cylinders and over the other bearings within the crankcase. Where the leads from the oil pump go to some of the bearings the method is generally the same. After the oil leaves the bearing it flows into the splash troughs and is picked up by the bottom of the connecting rods in the same manner. After this oil has been used for lubricating the moving parts of the motor it drains to the bottom of the crankcase and is again mingled with the fresh oil in the reservoir. Before flowing again to the pump, the oil is passed through a fine wire mesh screen which is supposed to rid it of all the harmful impurities it may have picked up on its former course through the system.

After a time the oil becomes so impure that the addition of the fresh oil has little cleansing effect and the motor starts to become fouled. Long before this time has arrived the careful automobilist will have drained out every bit of oil in the crankcase and poured in a gallon of kerosene after closing the drain plugs. After the kerosene has remained in the crankcase overnight, start the motor and allow it to run for about 30 seconds. Drain out the kerosene and refill with fresh oil.

It is important to see if the screen through which the oil passes from the crankcase to the suction side of the motor is clean. If this should become clogged the supply of oil to the pump will be very seriously diminished and the supply to the splash troughs will not be as great as it should and as a result all the troubles that can accrue from an insufficient supply of lubricant will threaten the motor. Cleaning the oil supply every 1,000 miles is not by any means too much although it is sufficient to clean the screens, etc., once a season. There are many who neglect the renewal of the oil supply for such a length of time that the whole motor becomes worn much more rapidly than would otherwise be the case simply because there is not as much oil reaching the bearings as should be the case.

With force feed oiling systems where the oil does not recirculate an occasional inspection of the speed at which the oil is passing through the sight feed should be made as this is an indicator of the well being of the entire system. There the oil box is carried on the side of the motor and the feed is drop by drop down an independent lead to each bearing, it is not necessary to renew the entire supply but it is important that the sight feeds indicate that the oil is being fed continuously to the motor bearings.

Curing Faulty Lubrication of Steering Knuckle; Metal Enameling Described; Tip on Adjusting the Schebler; How to Eliminate Rattles; View of Automobilist on Left Drive; Mounting Ball Thrust; Dangers of Using Alcohol Solution

Steering Knuckle Squeaks

EDITOR THE AUTOMOBILE:—The steering knuckle on my car is oiled by a small oiler placed on top. I do not think that the knuckle gets sufficient lubrication as I have traced a squeak which proved troublesome for a long time to the knuckle. The squeak seems to be at the bottom of the knuckle I have used a considerably heavier oil, thinking that if I could get a lubricant with a little more body it would stay in place and would cure the trouble. The improvement was marked, but at the same time the squeak is still there to some extent. How would THE AUTOMOBILE suggest making a permanent cure?

Chicago, Ill. TROUBLED.

—If the trouble is where you state it could no doubt be remedied by fitting a grease cup at the point noted in Fig. 5. The pin should be removed and grooved at the bottom slightly to allow the grease to work its way down into the bottom bearing. A small grease cup should then be purchased and a hole drilled through the spindle of the same size as the opening in the grease cup. As cups of different sizes are sold throughout the country it is best to take this measurement from the cup rather than to give the standard diameter of drill. The hole is then counterbored for a sufficient depth to take the threads on the grease cup. After counterboring to the proper depth, the hole should be tapped and the grease cup can be fitted in place. When the grease cup has been located on the spindle fill it with grease and turn it down as far as it will go, refill and turn down three revolutions. After this a turn before each day's run will be enough.

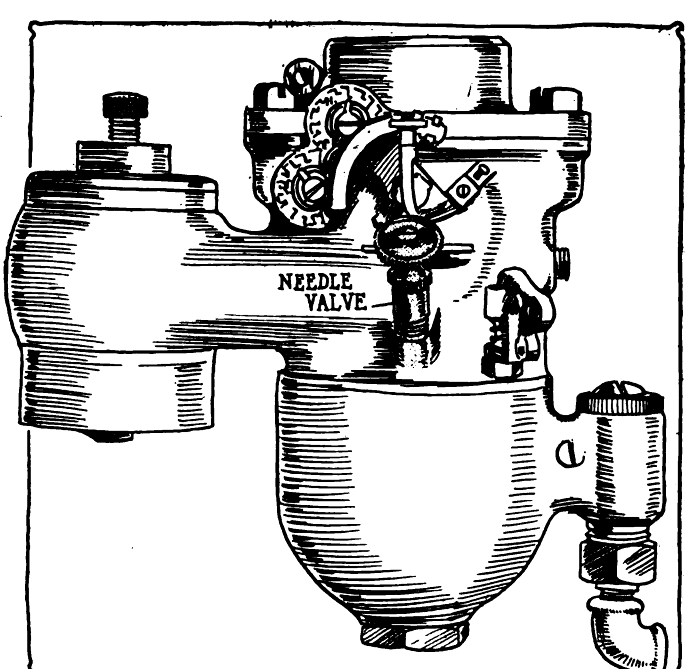

Fig. 1—Location of the needle valve on the Schebler L, Carbureter

Method of Enameling Metal

Editor THE AUTOMOBILE:—Will you please give me detailed information of the most up-to-date methods used for enameling metal? Also please give the formula for finishing metal in aluminum.

Philadelphia, Pa. J. H. ROHRER.

—The processes of metal enameling which are now in vogue vary exceedingly. This variation is not only due to the fact that the enamel which is designed to resist one condition is not satisfactory for another, but is also due to the various methods which are in use in different shops. An up-to-date method which is satisfactory for use on the motor body and especially on the hood and such parts that are exposed to the heat is as follows:

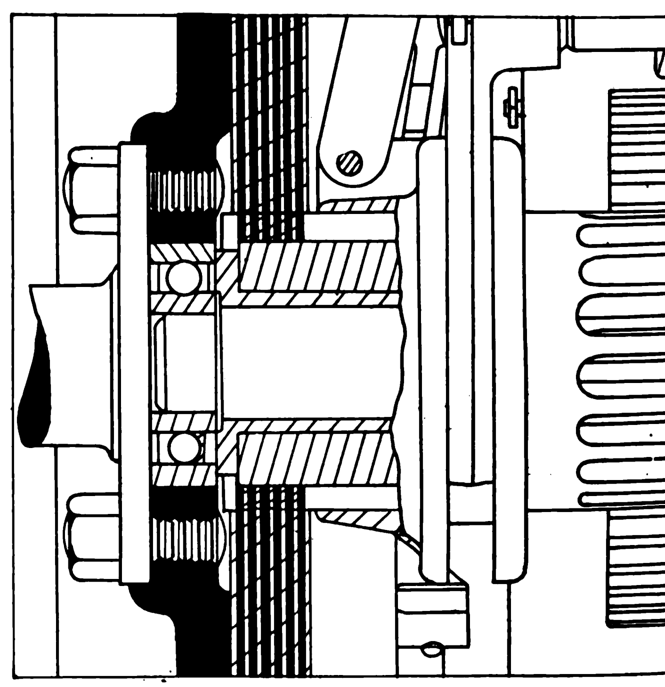

Fig. 2—Where the ball thrust is placed on a multiple disk clutch

The part that is to be enameled is first made free of dust and grease. This is so important that it must be done in the most particular manner. The part to be enameled is then prepared for the enamel. The enamel or japan can usually be secured at any local store and will generally be accompanied by a set of outlined directions which will contain the proper temperature that the enamel is calculated to withstand. Parts such as automobile frames are first rubbed with a rag saturated in spirits of tar until the entire surface is covered and are then placed in an oven at a temperature of 380 degrees Fahrenheit for about 20 minutes. They are then ready to receive the enamel. Larger parts can be rubbed down smooth with emery. This is a tedious operation by hand and any one who is going to do any extensive work should seriously consider the purchase of a special polishing bob. The finishing work is done with pumice or by a cloth and leather polishing bob. The surface is not ready to receive the enamel until it is perfectly smooth. After the japan or enamel is applied to the surface it is heated to a temperature of 290 degrees Fahrenheit for black and about 150 degrees for the lighter colors. The oven in which the heating is carried on should be lined with fire clay as brick gives off gases which absolutely prevent the securing of good results. When the enamel is heated the volatile base is first driven off. This generally consists of turpentine or methylated spirit. After the base has been driven off

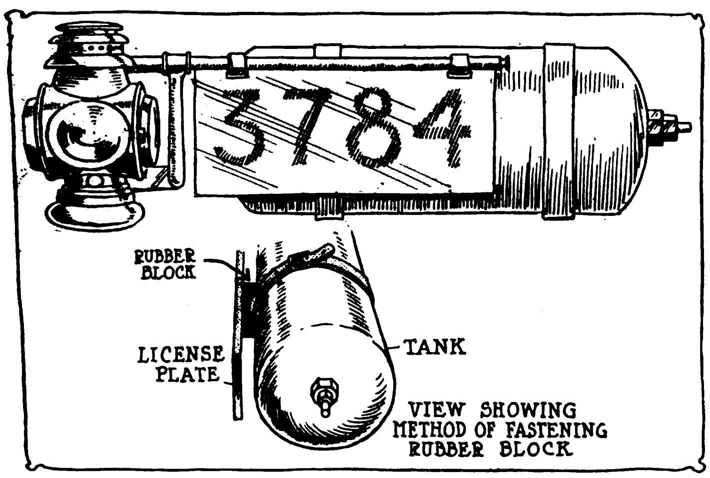

Fig. 3—License plate sometimes strikes acetylene tank. Cure shown

there is a gummy residue remaining. As the temperature is allowed to subside after the heating has been carried on for 1 1-2 hours, this coat will harden. After standing two days another coat may be applied. The third and last coat is a special finishing japan which is designed to provide a polish and is therefore made up largely of varnish. It is applied in the same manner as the previous coats. This is the general method used in the smaller enameling jobs. The details will vary slightly according to the part to be japanned, but if this plan is followed through a finished job can be turned out from the raw material in five or six days without trouble.

Aluminum finish for metals can be applied very satisfactorily by the use of any of the higher priced grades of aluminum paint on the market. These are applied according to the directions to be found on the can and will hold their color for a considerable length of time. When they start to wear off, they can be replaced by the addition of another coat.

Eliminating Noisy Rattles

Editor The Automobile:—While out in a friend's car recently we commenced to talk about the noises which are made by the average car. We were traveling along a road that could not be called bad, although not as smooth as it might have been. After a general discussion on the subject we commenced to listen to determine if we could diagnose the sounds that issued from different parts of the car while we were traveling along. After a time we determined we could hear the carbureter drawing in air, a slight tapping of one of the valves and a general hum that seemed to issue from the entire motor and was no doubt a combination of many small and unimportant noises. We then speeded the car up to 28 miles an hour, slipped the gears to neutral and threw off the switch allowing the car to glide along without a sound from the motor which was, of course, stopped. To our surprise we noticed a rattling sound from the rear of the car which we had not before noticed. After listening carefully we were able after some trouble to determine that the noises issued from two separate and distinct points. One was the

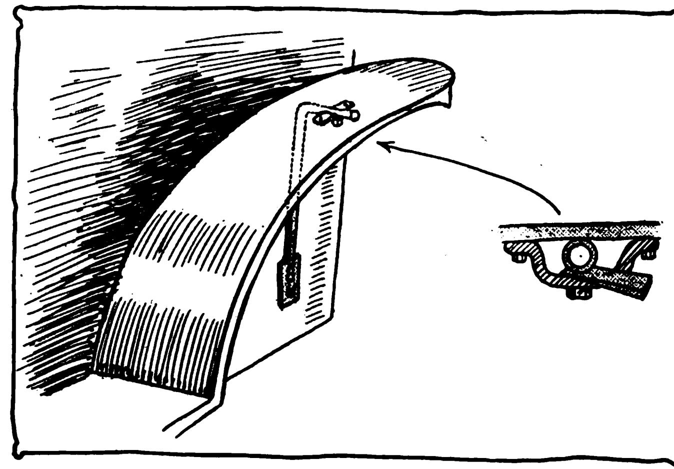

Fig. 4—Wedge will temporarily cure loose fender and stop rattle

license plate striking the Prest-o-Lite tank and the other was the fender over the rear wheel, which was loose.

The position of the license plate in relation to the acetylene tank was as shown in Fig. 3. There was about 1-4 inch space between the two and a road jar was sufficient to cause the license plate to strike the tank quite a hard blow. This was cured by inserting a block of rubber made from an eraser between the license plate and the tank.

The second rattle, that caused by the fender, was found to be due to the fact that the set screw which held the fender in place was too short. As shown in Fig. 4, this set screw fitted against the bracket and by turning it up hard held the fender rigidly in place. That is, it was supposed to do so, but the screw did not have sufficient length to bear tightly against the bracket. It was cured temporarily by the insertion of a wedge and afterwards permanently by the use of a longer screw. I think it would be a good plan for automobilists to state how they have rid their cars of troublesome noises of this nature, and I think that many will find noises which they never expected and which blended in with the motor noises while actually running if they tried the test outlined above.

Augusta, Maine. F. S. Hight.

More Views on Left Drive

Editor The Automobile:—I have read the argument on right and left control with great interest, but am forced even more strongly to the conclusion, based on ample experience with both right and left hand drive cars, that the right hand drive, with center cane handle control and both brakes operated by foot pedals, is the superior of any other form of steering and control arrangement, for both city and country driving. I can best give you the reasons for this belief by taking the points in your articles in series. I have had no experience whatever with motor trucks, and therefore am not in position to express an opinion as to which form of drive is preferable for them. What I shall say applies to pleasure cars of the open type only. It may be that even cars of the limousine type would handle better in traffic with the left hand steer, though I am inclined to doubt this, with the advantages of the right hand steer for other pleasure cars so obviously apparent.

For city driving. In few if any cities are all the streets as wide as they ought to be. A car for the widest range of usefulness with safety should seat the driver where he can watch all the possible danger points; not just some of them. The driver on the left side cannot watch the curb in the narrow street, but can only watch the oncoming car—and guess where the curb is from the look of it out ahead. The driver on the right can watch the curb close-hand (and in some cities the curb is lined with light and telephone poles) and he can also watch the oncoming car, for he is practically on a level with it, and he can judge the distance to the other fellow's fenders practically as close as if he were sitting on the left of his car. Here again

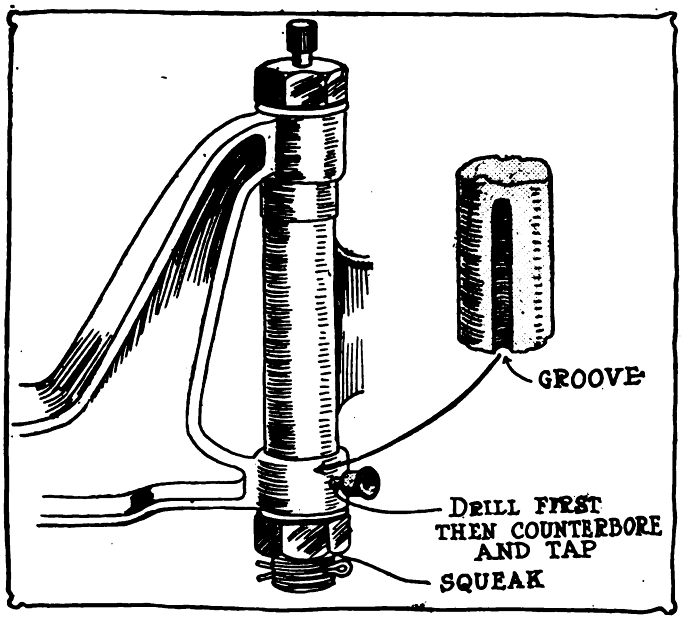

Fig. 5—Where the grease cup on the steering knuckle may be placed

comes in the point I have made before: The other car can move and has a driver to see that it gets through safely too, while the curbing is stationary, with no body to look out for it but the man in the car. There can be no question of the superiority of the right hand drive on country roads. In the anonymous communication on page 269 of your August 8 issue, I note the remark that party would much prefer the ditch to the oncoming car, if meeting on a narrow country road at speed. If such a meeting happened to take place in a narrow but deep cut such as is so often found in our roads, a position where the driver could not watch the drains at the side of the road might easily be the cause of a disaster to both cars.

There are, of course, some advantages in the left drive; if it were not so it would not have come to be adopted by some of the makers. But nearly all of the advantages claimed for the left drive can also be obtained in the right drive by proper construction and placing of control lever, proper clearance of steering wheel from seat, placing of doors, etc. Taking up the advantages claimed for the left drive, left side placing of control levers, as stated on page 210 of August 1 issue:

1. With right hand drive, center one lever control, both front seats are accessible from the curb.

2. The driver can get out more quickly than with any other construction, to open door and assist ladies to alight.

3. Is an advantage only as it concerns street cars or high loaded trucks, for one can always see ahead of a pleasure car which is being overtaken and passed, whether seated on the right or the left side. Also, he can see, before he tries to pass a car on a narrow road, whether he has room enough, whether seated on the right or the left. But if he essays to pass a car on a narrow road, his consideration must be for the car passed, not for his own car, and therefore the right hand drive car has the advantage here. In passing an approaching car, the advantage is all with the right hand drive, for I know from experience that I can accurately judge the distance between the fenders of my car and those of the car I am passing when driving from the right. And I can also see the curb and stationary vehicles, to whom my consideration, as the one in motion, is due.

4. There are few, if any, modern cars in which the weight of the driver on one side or the other can have any effect on the ease of driving or control, so this advantage of the left hand drive may be dismissed as immaterial.

5. Driver has a better view when turning to the left into a side street. Driver also has a poorer view when turning to the right into a side street, so these will balance each other well. It is true that when turning to the right into a side street, one must keep to the right anyway; but drivers on side streets usually drive all over the road and about as much caution is necessary as when turning to the left—and both sides of the street have a curb, on corners, that is easier to miss on one side with the left hand drive and on the other with the right hand drive.

6. It is not plain how and why it is easier to make the signal for the left hand turn from the left hand driver's position. As your writer points out, no signal is necessary when turning to the right, therefore any signal made means a turn to the left, and this is as easily made no matter which side the driver is sitting on.

Discussing the disadvantages of the right hand steer, center control, page 211 of same issue:

1. This, as experienced drivers can testify, does not comprise a disadvantage, as the distance between the fenders of the driven car and the met car can be accurately judged from the right hand driver's seat.

2. Is admitted, but balanced by the same objection to the left hand drive when turning to the right.

3. A driver should not want to pass a car going in the same direction without being sure there is room for such passing; but if he should attempt to pass, his first consideration must be for the car overtaken and not for his own car and the ditch on the left of the road. Therefore, in this item, the right hand drive is superior.

4. It is no difficult matter to design a lap robe that will fit over a center control lever, having a slot long enough to operate the lever through, and thus overcome this objection to the center control. I believe this is but a minor objection.

5. I know from experience that the left hand, after very little practice, is just as efficient as the right for gear shifting. It is a matter of habit.

6. By constructing the clutch and gearset mechanism so that the gears cannot be shifted until the clutch is entirely out, any possibility of the other passenger in the front seat tampering with the gear shift would be obviated.

Discussing the logical and illogical side of the right hand position in this country and abroad. Englsh drivers, before the day of the motor car, and Americans before they were Americans, became accustomed to sitting on the right of the vehicle they drove, and when the motor car came along we naturally put the steering apparatus on the right. That English and Continental laws require that vehicles turn to the left is but an incident; and it appears to this humble owner and driver that, if they would get the full advantage of their right hand drive cars, they should make their laws just opposite to what they are, making vehicles drive to the right, or built their cars with left hand drive—the one or the other.

Personally, I would never again buy a left hand drive car, preferring to buy a foreigner if necessary to get the right hand drive.

Fort Myers, Fla. C. L. Johnson.

How to Adjust the Stromberg

Editor The Automobile:—Would you kindly inform me through Letters Answered and Discussed how to adjust a Stromberg Model B3 carbureter.

New Madison, O. J. W. Coblentz.

—Before proceeding with the actual adjustment it is as well to make sure that no dirt is present at the gasoline connection as this is a not infrequent source of trouble. An examination can be made by removing the coupling C.

The Stromberg B type carbureter has two adjustments, one for high speed and the other for low speed. The two nuts for this purpose are shown at A and B in Fig. 6. In adjusting, first turn the nut A up or down until the spring A1, which it controls, seats the valve V lightly. See that the high speed spring B1 has plenty of play. Start the motor and turn nut A up or down until the motor idles properly. This is the low speed adjustment. Having found the correct position for nut A, advance the spark and open the throttle and if the motor back-fires through the carbureter turn the high speed adjusting nut B up until backfiring ceases. If the mixture is too rich and the motor smokes turn this nut down. This is the high speed adjustment. There should always be at least 1-32 of an inch play between the top of the spring B1 and the nut at the top of the air valve stem when the motor is at rest.

Mounting of Ball Thrust

Editor The Automobile:—In reading a description of a new car which is to be placed on the market I note that special mention is made of the multiple disk clutch with a ball thrust mounted between the end of the crankshaft and the gearset shaft. Will The Automobile show how such a bearing is mounted and what is its real purpose?

Larchmont, N. Y. J. J. Lessing.

—The ball thrust is often mounted as is shown in Fig. 2, which is a part section through the clutch used on the 1913 Marathon cars. The purpose of the ball thrust is exactly what its name would suggest. It is supposed to receive the end thrust which would be caused through the driving and engaging stresses of the clutch and which would cause undue friction if permitted to fall on the other members of the clutch. The use of the balls reduces the friction to a minimum. In every clutch there is some arrangement for providing a special part for receiving the end thrusts and the use of balls for this service has proved a great success.

Thinks Noise a Piston Slap

Editor The Automobile:—Replying to Mr. C. Summers, Baltimore, Md., four-cylinder car, with tapping in one cylinder, I think his trouble is in one of the cylinders. If the tapping (or slapping, as I would call it) is to be heard only after the car has been running for a while or when the engine begins to warm up, then it is due to a loose piston. When the engine is cold the oil is thick and prevents the piston from slapping against the cylinder walls, but when the engine warms up the oil gets thinner and the piston will slap against the cylinder walls and will cause a noise which is called a piston slap.

Chicago, Ill. L. Plein.

Horsepower of Peugeot Racer

Editor The Automobile:—In a recent article in The Automobile describing the Peugeot racer the cylinder dimensions are given as 4.3 x 7.8 and horsepower as 175.

1—How is it possible to get such a H.P. from such a size when ordinary cars with cylinders of about the same size do not claim anything like as much?

2—I understand horsepower equals:

$$\frac{P \times L \times A \times N}{33{,}000}.$$ Is this correct?

3—What are the chief factors in increasing r.p.m. of crankshaft?

4—Will you give comparative figures for two cars of some established make for, say, one 30 horsepower and one of 50 horsepower for:

Size carbureter.
Diameter inlet pipe.
Diameter valve opening.
Valve lift.
Cubic contents of space swept by piston.
Cubic contents of combustion chamber.
Clearance of combustion chamber.
Compression pressure.
Mean explosion pressure.
Power strokes (or crank revolutions per minute).
Weight or size flywheel.

5—Do designers still use 1,000 feet per minute piston speed as a basis in designing?

6—What is meant by the expression heavy duty motor?

New York City, N. Y. David W. Seaver.

1—High compression, high r.p.m., lightness of parts and good design render it possible to get a higher horsepower than would be secured with the average motor. It is possible to include such features in a racing motor while it would be impossible to get them in an ordinary touring car for instance. This is especially true of the high compression and piston speed.

2—This is the correct formula for the indicated or theoretical horsepower.

3—High compression, shorter stroke, larger valves to admit gases more rapidly, advanced ignition and open throttle.

4—

	30 horsepower	50 horsepower
Carbureter, Schebler scale	1 1-4 inches	1 3-4 inches
Diameter inlet port	2 1-8 inches	2 3-4 inches
Diameter valve, mean	1 3-8 inches	1 1-2 inches
Valve lift	5-16 inch	3-8 inch
Piston displacement	226.2	588.6
Clearance	1 inch	1 1-16 inches
Compression	60 pounds	75 pounds
Mean explosive pressure	Unknown	Unknown
Revolutions per minute	1800	1800
Weight of flywheel	75 pounds	90 pounds

These figures really show nothing of value as there are too many other considerations entering into the comparison of two cars of different horsepower. They are given, however, for what they are worth and are taken from two cars actually in existence.

5—No. This is the basis of the S. A. E. horsepower formula

$$\frac{D^2N}{2.48}$$

6—A motor of heavy horsepower but low speed. By the formula under question 2, it is evident that if N, is low, any one or more of the factors P, L or A, will be correspondingly large.

Alcohol Burst into Flame

Editor The Automobile:—Your answer to a question regarding non-freezing solution, page 839, October 24, brings to mind a personal experience with a 40 per cent. wood alcohol solution last December.

While pulling through rather heavy mud on low gear a thick volume of smoke and flame burst from under the hood with a roar. The car was stopped, I crawled under and turned the gasoline off. Opening the hood on the carbureter side everything was found normal. On the other side some oil and rubber connections were still burning, the destruction of the latter being the only damage.

The fire being on the magneto side, I am satisfied its cause was the ignition of gases produced by the overheated and possibly boiling fluid. After this experience I deem the use of wood alcohol in the cooling medium a dangerous practice.

Fulda, Minn. Emil King.

English Tendencies

THE AUTOMOBILE prints this week its first technical review of the European cars as at present exhibited at the annual Olympia Show now in progress in London. This review brings out many important facts in connection with the English design which show the trend of construction. The English engineers were slow in taking up automobile design, and the makers were slow in perfecting the car, both due to a considerable extent to the restrictions on road-racing in the British Isles and also to the unreasonable road regulation laws in the early days of the industry. Since proper government regulation of the motor vehicle on the English highway has been obtained, the makers have taken up the development of the car in a truly determined manner, and have been exhibiting John Bull tenacity for the last few years, their development being such that continental Europe is only now adopting features of design which the English engineer perfected some years ago.

Perhaps nothing could excite more curiosity than the fact that the six-cylinder car, which received its original impetus at the hands of English manufacturers, is diminishing in numbers, the statistics showing that there are fewer six-cylinder models of English production scheduled for 1913 than there have been on the market during 1912. The explanation, to a large extent, rests with the horsepower tax, the gasoline tax and cost of operation. The owner has reached the conclusion that the four, in its present improved form, is giving very desirable service. It consumes little fuel, it gives the flexibility asked for, and has the desired power. Those makers who continue with a large list of sixes are reducing the horsepower or eliminating the high-powered models entirely. By carefully compiled statistics it was shown last year that the horsepower of the European six-cylinder car was over 30 per cent. below the American six, these figures being averages. The same is apparently true for the coming season, although the placing on the market of several lower-powered sixes by American companies will considerably reduce the average horsepower for the American six.

The English manufacturer is at last seeing the commercial phase of the automobile, and is slowly recognizing the fact that to continue existing as a manufacturing factor, he must shape his manufacturing course along economic lines. To explain: There is a general reduction in the number of models listed by the English maker for 1913. In fact, statistics show but one maker who has increased the number of models listed over those of the present year, whereas there are several who have greatly reduced the number. Apparently the days are passing in the insular kingdom when the maker thinks he must build a special model for every half-dozen customers.

One paradox presents itself in the 1913 car program as shown at Olympia, namely, that there is an apparent return to bevel pinion drive in the rear axle over worm drive, which came to the front so spectacularly 2 or 3 years ago. Worm drive was introduced because of its quietness, the demand for the quiet car being greatly accentuated by the non-poppet valve motor campaign throughout Europe. The present slight reversion to bevel drive would seem to show that the efforts of manufacturers in quieting bevel gears have been productive of much good, so that now the bevel is practically noiseless. If this is so, the credit must be given to worm drive, which proved the stimulant for the great activity in better cutting of bevel gears, and better axle design, which insures permanent quietness. It is not expected that the worm drive will show any perceptible decrease, but there is a country-wide feeling that it will more and more come into vogue, and particularly on commercial vehicles.

The progress in ignition has been confined largely to the progress of the magneto makers. This is shown in more compact instruments, which are made more weather-proof, and consequently more trouble-proof. Approximate statistics bring out the fact that nearly 80 per cent. of the European models listed for next year will use the magneto as the only system of ignition. The remaining 20 per cent. will be equipped with the dual system and the double system comprising magneto and battery. The implicit confidence that the maker is placing on the single magneto as a source of current, is an excellent commendation on the progress that magneto builders have been making.

The small motor has made the four-speed gearset practically universal. With large size motors direct drive is generally on the fourth gear, but with smaller-size motors direct is on third, with the indirect fourth of a higher ratio than the direct, giving a vehicle with good speed ability for country travel.

Detroit Section of Automobile Engineers Meets

Three Papers Read—W. H. Barr Treats of Copper Alloys for Motor Car Service—M. Wolf Discusses the B. & L. Caster Front Axle and R. H. Manson Deals with High-Frequency High-Tension Ignition

DETROIT, MICH., Nov. 8, 1912—At last night's regular monthly meeting of the Detroit section of the Society of Automobile Engineers, at which Secretary and Treasurer Alfred A. Greenburg presided in the absence of Chairman E. T. Birdsall, three very interesting papers were presented. The first of these was given by William H. Barr, general manager of the Lumen Bearing Company, Buffalo, and chairman of the Alloys Division of the Society. The subject was **Copper Alloys for Motor Car Service,** and it was treated in a masterful manner by Mr. Barr, who gave a short history of copper. He stated that in the United States **the metal is usually classified in three grades: Lake copper, that brought from the Lake Superior region; Electrolytic copper, that refined by the use of the electric current; and Casting copper, that which is not entirely refined, but carries varying amounts of impurities, and as a result is rapidly disappearing from commercial fields.**

The United States produces more copper than any other country, or about 65 per cent. of the total production of the world, the total amount for 1911 being 1,090,000,000 pounds.

Mr. Barr also touched upon the production, refinement and commercial uses of the various metals which are alloyed with copper to make bearing metals, namely, tin, zinc and lead. Brasses and bronzes were taken up at some length and the action of such chemicals as arsenic, antimony and sulphur on these alloys was explained. These three elements have a detrimental effect upon bronze, but sulphur in proportions which have been carefully determined by metallurgists is a beneficial agent.

The high copper alloys, as related to motor car construction, may be divided into four classes: Soft phosphor bronze; hard phosphor bronze; red brass; yellow brass. The properties, uses and general composition of these were explained.

"From the standpoint of the automobile engineer, it would seem that the same detailed attention should be given to the non-ferrous alloys in motor car construction as is given to steel products and appliances. Too often, the decision as to what brass or bronze may be used is left to the purchasing department, where price alone governs the selection," said Mr. Barr.

In the discussion of the paper which followed it was asked if there would be any value to any means of hardening copper. Mr. Barr stated that no way has been found to harden pure copper. He also brought out that there are two concerns now making copper castings in which it is possible to guarantee an electrical conductivity of 85. Ordinarily a conductivity of from 45 to 60 is considered good.

C. C. Hinkley wanted to know if it were possible to get a combination of low shrinkage and high wear in a babbitt metal. To this Mr. Barr replied that an alloy containing not less than 90 per cent. of tin, 4 per cent. of copper and 6 per cent. of antimony would come as close to these requirements as any. Perhaps a little less tin could be used. The antimony serves to reduce the shrinkage.

When asked if a small percentage of nickel would be of advantage in these alloys, Mr. Barr stated that as a result of many tests he has come to the conclusion that **nickel is of little or no advantage. The effect of cobalt or any other similar element is about the same as that of nickel.** He does not believe in nickel babbitts.

This discussion was followed by a paper by Maurice Wolf, of the Anderson Forge & Machine Company, Detroit, which paper treated upon the **B. & L. Caster front axle, setting forth its construction and the advantages which are claimed for this type over the standard front axle.** A paper which was in the form of a discussion of that of Mr. Wolf was read by Ernest R. Fried, research engineer of the General Motors Company. Mr. Fried did not agree with all the claims made by Mr. Wolf.

A most comprehensive paper by Ray H. Manson, chief engineer of the Dean Electric Company, Elyria, O., entitled **High-Frequency High-Tension Ignition,** was next presented. According to Mr. Manson, the use of high-frequency, high-tension electric spark for ignition in the internal combustion engine introduces several unique and advantageous features. A high frequency discharge is in the form of electrical oscillations, these oscillations rapidly succeeding one another, each succeeding one being of less intensity than the one preceding, and gradually dying down to zero. **This electrical oscillatory action is similar to the mechanical vibration of a strip of metal or a tuning fork,** which is firmly held at one end in a vise and given a blow. Its first vibration is the maximum, those following finally reducing to nil. **The chief advantages Mr. Manson gave for this type of ignition are:**

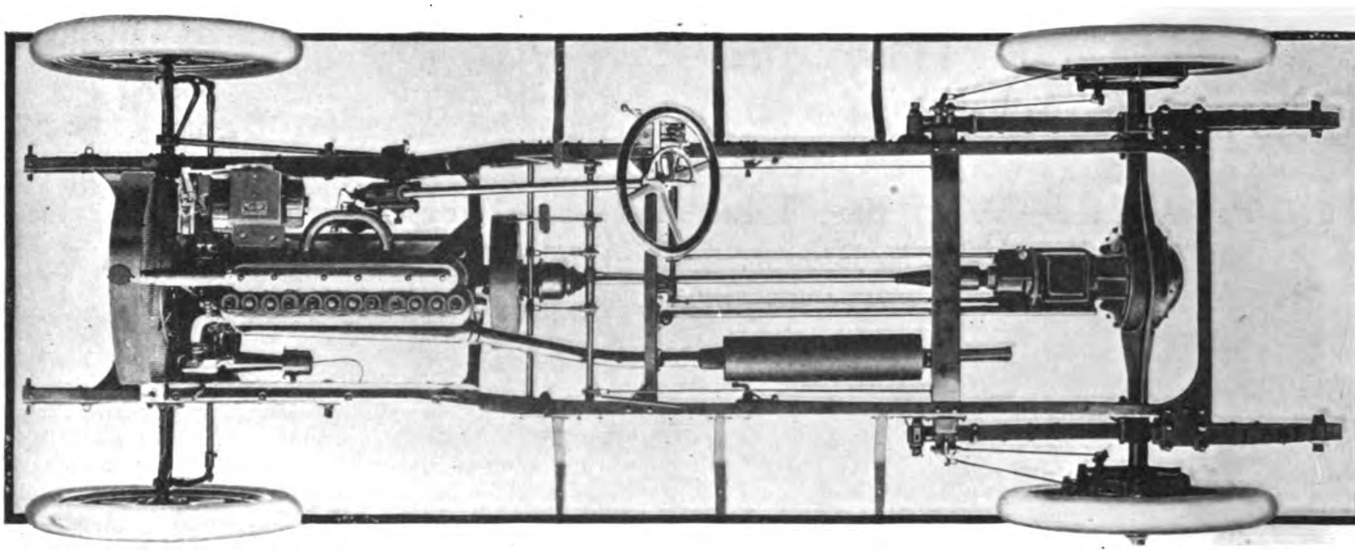
1—Cranking on magneto at very low speeds.
2—Throttling the engine down to extremely low speeds without missing.
3—Positive ignition of poor mixtures.
4—Less heating of engine, due to more rapid and thorough combustion of gases.
5—Fuel economy, due to ability to ignite lean mixtures positively.

The high frequency magneto system consists of a low-tension magneto with breaker box and low-tension distributer, built very similarly to a standard magneto with the exception that the armature is wound with fairly coarse wire and that the condenser is stationary. The latter is located on the front of the distributer.

In the case of the high-frequency system, spare resonators may be carried, if desired, and these may be mounted as readily as spark plugs. On the other hand, the repairing of a broken-down high-tension armature or a common transformer coil is very difficult and requires an expert.

In addition to touching upon the high frequency magneto system, Mr. Manson explained the high-frequency dual system, battery system and double system. The paper was an introduction to this new field of ignition. **Mr. Barr's paper on Copper Alloys for Motor Car Service will be reprinted in full in an early issue of** THE AUTOMOBILE.

Prize poster for the National Automobile Show to be held in New York City January 11-25



New six-cylinder chassis of Studebaker with monobloc motor casting and electric lighting generator

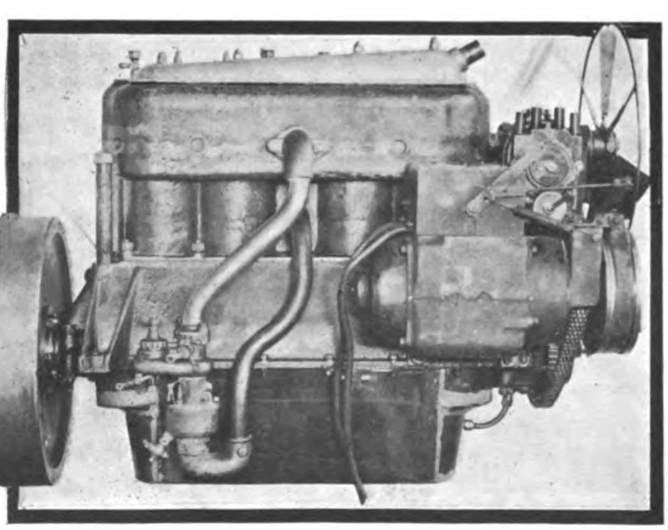
Three New Studebakers

New Motor Designs on Additional Models, Using Monobloc Cylinder Castings—Numerous Other Changes

Six-Cylinder Is One of New Types—Continue the Models 20 and 30 of this Year

THREE entirely new models have been added to the line of automobiles manufactured by the Studebaker Corporation, Detroit. These consist of two four-cylinder types, designated models 25 and 35, and a six-cylinder machine. They swell the offering of the Studebakers to five distinct chassis, models 20 and 30 being continued with no radical changes whatever, and embodying practically all the essential features which have distinguished them since their inception some 5 years ago. It is interesting to note that during the selling season just passed 42,000 of these two models left the Studebaker shops.

Particular interest centers in the three new models, since they are a brand new series and involve a number of features which are new to Studebaker construction. That this concern should enter the six-cylinder field at this time is but another striking instance of the belief of the big makers in the low-priced six.



Right side of Studebaker model 35 motor

Motors of the newcomers are all of the same design, being of the L-head monobloc type with the valves on the left side. The cylinder dimensions of the six-cylinder engine and of the twenty-five are the same—3.5 inches bore and 5 inches stroke. The larger four, model 35 has the same stroke, 5 inches, but the cylinder bore is 4 1-8 inches. On the block, these motors have shown a brake horsepower considerably in excess of that which the S. A. E. formula would give them. The table below gives some facts about the three new power plants:

Model	Bore Inches	Stroke Inches	B/S Ratio	Brake H.P.	Firing Order	Wheelbase
25	3.5	5.00	1.43	26	1-3-4-2	101
35	4.125	5.00	1.21	35	1-3-4-2	116
Six	3.5	5.00	1.43	45	1-5-3-6-2-4	121

The block cylinder castings present a very clean appearance. Intake and exhaust manifolds are cast integrally, but in somewhat different manner from that usually found in multiple-cylinder castings. The gas enters the intake channel on the side opposite from the valves, being led through the casting to the left side and thence to the intake ports of the various cylinders. In passing through the casting to these ports on the opposite side, the gas is somewhat heated due to the hot water in the adjoining jacket spaces, and to the heat of the neighboring cylinder walls.

This heating of the gas aids materially in its vaporization and amounts to virtually water-jacketing the intake manifold. Even distribution of the gas to all cylinders is provided for by the form of the intake channels. The carbureter is a Studebaker design and is very similar to that used on model 20. It is of the venturi-tube type.

The exhaust manifold on the left is not flush with the outer vertical wall of the waterjacket, but extends beyond it, making for free exhaust. This design has been carried out in other monobloc types, but not exactly in that way.

The pistons have polished, domed heads, that is, their faces are not flat, but are crowned. This construction is an aid in reducing carbon deposits. They are cast from the same grade of gray iron as is used for the cylinders. Four rings are fitted, three above the wristpin and one below. The drop-forged connecting rods are of I-section. Wristpins are fixed to the connecting-rods, the bosses forming the bearing surfaces.

The crankshaft is carried on three main, plain babbitt bearings in the four bearings in the six. The camshafts are similarly mounted in the three engines. The various bearing lengths follow:

Crankshaft Model	Front	Center	Rear
25	2.781	2.500	3.437
35	3.000	2.938	4.500
Six	2.781	2.500	3.437
Camshaft			
25	2.110	1.250	2.500
35	2.079	1.375	1.875
Six	2.110	1.250	2.500

Camshafts have integral cams and oil pump eccentrics for driving the plunger oil pumps. These camshafts are driven from the crankshafts by half-time gears, spirally cut and wider than those used on previous models. All are forgings except the camshaft gears, which are of cast iron. The different material is used to insure silence, since the running of hardened steel against the same material would not be conducive to noiseless operation. The wide faces of the gears and their spiral cut are other factors which aid in this respect.

Valves are of the beveled poppet type, the stems electrically welded to the forged heads. Their lift is 1-4 inch. Push rod guides are cast iron and are pressed into the cylinder castings. Valve springs and rods are completely inclosed by cover plates of pressed steel, which are removed by the taking off of two hand nuts. Valve details follow:

Model	Diameter	Length with Stems
25	1 13-16 inches	6 1-4 inches
35	2 5-32 "	7 13-16 "
Six	1 13-16 "	6 1-4 "

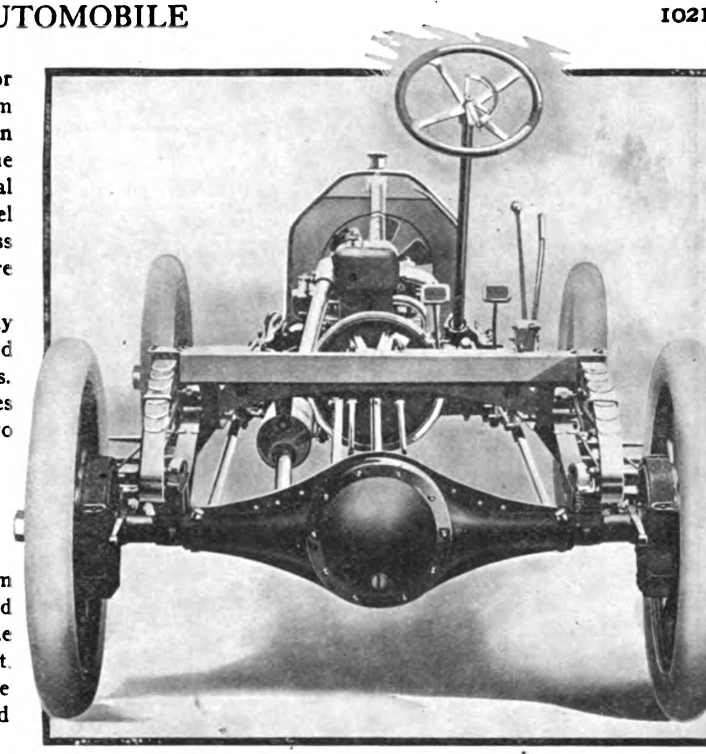
A feature of the motors which is distinctly a departure from previous designs of this concern is the location of the pump and magneto in front of the engines on brackets which bolt to the crankcases. Pump and magneto are driven by a transverse shaft. The magneto is mounted at the right end and the sump at the left. This cross shaft is driven by spiral gearing at its center and from the crankshaft.

The magneto is a Splitdorf. Batteries furnish starting ignition current.

The location of the water pump forward makes it possible to connect its outlet direct to the cylinder casting at the front. Water is forced into the jacket space in line with the valve pockets, insuring cool water around the valves. This is possible on account of the relatively high position of the pump, which is above the crankcase.

Lubrication is accomplished through the use of a circulating oil pump and the conventional connecting-rod splash. The oil is pumped from a reservoir at the bottom of the crankcase up through a sight feed gauge on the dash, and then through a lead to the magneto and pump shaft gear. It flows down over the timing gears and is eventually directed along the inside of the crankcase wall to the troughs which are in the false bottom of the crankcase. There is one of these troughs under each cylinder, and the lower ends of the connecting rods dip into them. The overflow from the troughs and from the bearings finds its way to the reservoir at the extreme bottom of the crankcase, where it is strained before the pump returns it to the sight feed, timing gears and troughs. All of the pipe line joints are fitted with Lavigne solderless pipe couplings.

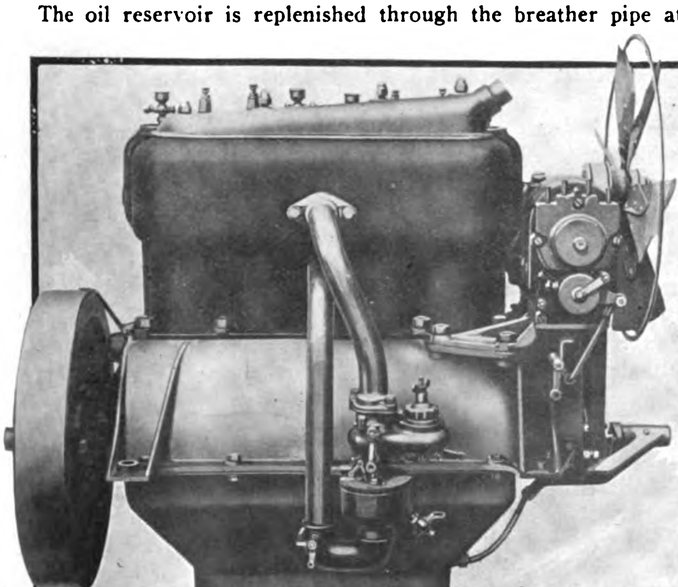
The oil reservoir is replenished through the breather pipe at the left side. Also at the side and extending up from the bottom of the reservoir, is the oil level indicator.



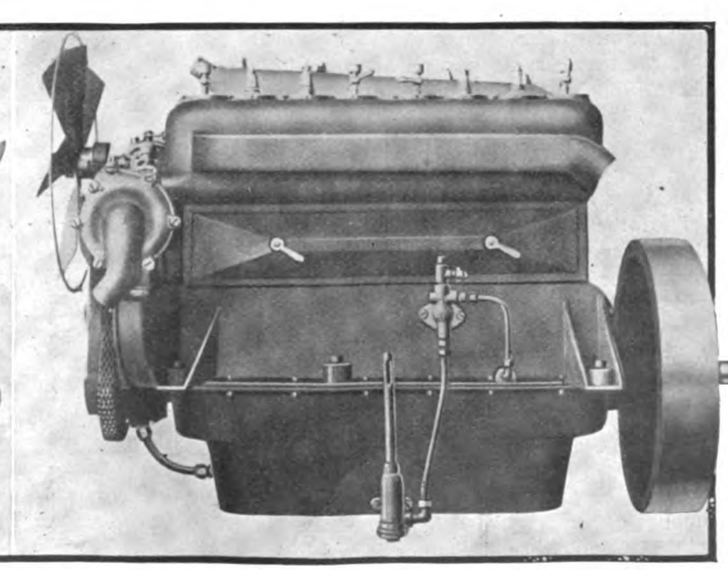
Rear axle construction on Studebaker model 35

The self-starter proposition has not been lost sight of in these new Studebaker offerings. On models 35 and six a combined self-starting and lighting system is installed, which system is manufactured exclusively for the Studebakers by the Wagner Electric Mfg. Company, St. Louis. In fact, the entire electric-starter output of this latter factory has been contracted for by the corporation.

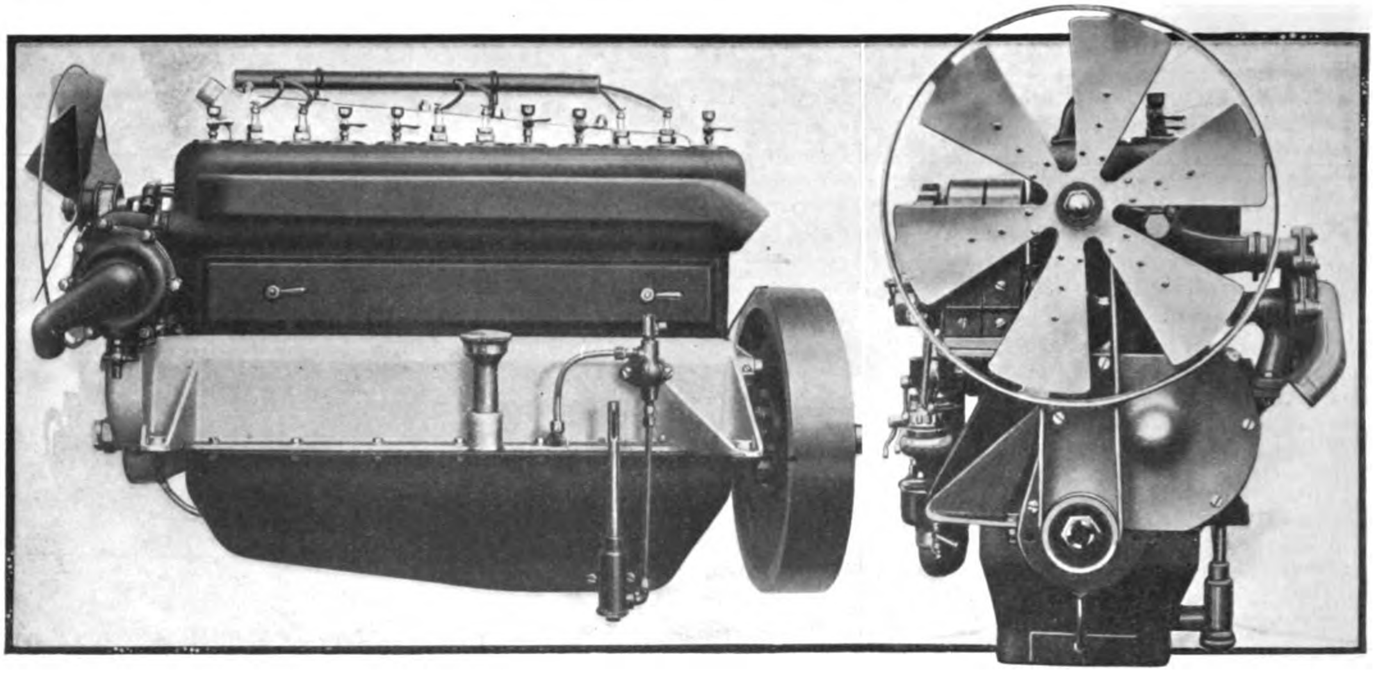
The starter is of the motor-generator type, placed at the right at the forward end, and connected with the crankshaft by silent chain. When used for generating current after the gasoline motor has been started, the generator is driven direct from the crankshaft, the gear ratio being 2.65 to 1. But when the electric motor is called upon to start the engine, a set of transmission gears are brought into play which reduce the driving ratio to 13.2 to 1, increasing the electric motor's torque and causing it to turn the crankshaft at a speed of about 80 revolutions a minute. When driven by the engine as a generator, the electrical unit will furnish current at a crankshaft speed as low at 300 revolutions per minute.



Intake side Studebaker model 25



Exhaust side Studebaker model 35



Exhaust side of Studebaker six-motor and end view of Studebaker design

A six-cell, nine-plate storage battery having a rated capacity of 60 ampere-hours and a voltage of 12 is used in connection with the generator-motor. When acting as a generator, the latter furnishes current to this battery, from which the energy is drawn for lighting the lamps and for driving the electrical unit as a motor when required for starting. The battery, when fully charged, will furnish sufficient energy to the motor-generator to turn over the crankshaft for several minutes continuously, or it will keep the lights burning for 13 hours.

The motor-generator has a self-contained automatic regulating device and by a carefully designed system of field winding and commutation, the current output of the generator is so controlled that it is impossible to overcharge the battery at any time. When the speed has reached 300 revoluions per minute an automatic cut-out mounted under cover on the generator closes the battery circuit. Charging continues until the engine speed drops below 300 revolutions per minute, when the automatic cut-out breaks the circuit again, preventing a discharge of the battery through the generator.

To crank the engine, the driver pulls up on a lever located on the steering column just below the wheel. This shifts a controller drum on the generator to a second position and simultaneously tightens a brake band around the cylindrical gearbox of the apparatus. The controller shift makes the starting connection, and the tightening of the brake band throws into operation the transmission gearing between the motor and the crankshaft, reducing the driving ratio to 13.2 to 1, as already pointed out.

The Studebaker engineers state that the only care necessary for the proper up-keep of this electric starting and lighting system is the addition of a little pure water every 2 weeks to each cell of the battery so as to keep the plates immersed. Acids should never be added. Further, a few drops of oil should occasionally be applied to the ball bearings of the motor generator, and periodically the controller and cut-out contacts should be inspected to see that they are clean and that no dirt or oil has found its way under their cover.

The storage battery is placed on the left running board, and the motor-generator is on the right side. Hence the additional weight of the starting system does not affect the car's balance.

On the 25 there is no starter, but an acetylene gas primer is installed as an aid to starting. This primer allows a certain amount of gas, regulated by a needle valve, to pass into the intake manifold when the motor is cranked.

Except for difference in wheelbase the design of the six-cylinder chassis and of model 35 is the same. Some variations are to be found in that of the smaller four-cylinder model.

The clutches used on these cars are of the cone type similar to that of the present model 30. It requires a force of 31 pounds to press down the clutch pedal of model 25 and engagement of this member on the other two models requires a force of 45 pounds.

It is in the transmission of the power from the clutch to the gearbox that the greatest difference between models 25 and the other two comes. The smaller car has its drive shaft enclosed within a torque tube whereas in the case of the 35 and the six a stamped-steel torque arm extends from a frame cross member back to the gearbox and parallel to the propeller shaft. These drive shafts are properly provided with universal joints one just back of the clutch and the other at the rear axle.

The gearsets of all three models are located at the rear axles, the gearcases bolting to the axle housings. The gearsets provide three forward speeds, operating selectively. On the two larger cars the gearset has two ball bearings in the front of the driveshaft and an extra large roller bearing back of the drive pinion. The countershaft is carried on plain bearings. The gearboxes as on models 35 and six are of aluminum and are cast with extensions forming the bases for the differential bearings, which is a new feature in Studebaker construction.

Model 25 has a semi-floating rear axle and on the other two a floating type. The differential pinion is placed on the shaft by sliding it to a position over the latter's splined end and fastening with a nut. A cover plate at the back of the axle housing provides for easy inspection of the differential gears and the driving pinion. In the floating construction the weight of the car is carried on the housings, the pinions having simply to perform the functions of driving the wheels. The direct drive ratio on all models is 3 1-2 to 1.

The brakes act on the rear wheels. The emergency brakes are internal expanding, while those for service use contract upon the drums. The brake dimensions are given:

Model	Brake drum diameter	Brake drum width
25	9 3-4 inches	2 1-4 inches
35	12 "	2 1-2 "
Six	12 "	2 1-2 "

Frames are constructed from hot-rolled sheet steel. They are narrowed in front to allow for shorter turning radius. Frames of the 35 and six have a rear kick-up. The frames are well braced at three points by cross-members, the rear member having gusset plates at its ends to which the ends of the side frame members fasten as well as the springs.

The turning radius for the smaller chassis is 16.5 feet, while it requires a circle 44 feet in diameter for the larger models.

The springs are outside the frames in the rear. Rear springs are elliptic on the 25 and three-quarter on the other two. Their dimensions follow:

Model	Length—Inches	Width—Inches	Type
25	Front 36 1-2	1 3-4	Half-elliptic
	Rear 35 1-2	1 3-4	Elliptic
35 and Six	Front 38	2	Half-elliptic
	Rear 50	2	Three-quarter elliptic

Right-hand control is found on all models, with brake and clutch pedals, spark and throttle levers, and so on, in standard form. The steering gear is of the worm-and-full-gear type, irreversible.

All wheels are of artillery construction, and on models 35 and six they are fitted with Booth demountable, quick-detachable rims. The rims of model 25 will not have the demountable feature as standard equipment. The felloes are slightly rounded, which adds to the general appearance of the wheels.

Tires on model 25 are 30 by 3.5 inches and on the other models 34 by 4 inches. All are of Goodrich quick-detachable make.

The designs for the bodies of all three cars are alike, in fact, the standard types for both the larger four and the six-cylinder car are identical. The standard model 25 body is a four-passenger type, and the other two machines will carry six. Two seats in the latter are auxiliary and are designed to fold out of the way when not in use.

Fenders on the 35 and the six will be crowned, which makes a pleasing effect. Running boards are of wood, lineoleum-covered with polished moulding around their edges on these two models, and model 25 is provided with pressed-steel running boards. All models are equipped with Dean electric horns mounted under the hoods. Buttons for operating them are placed on one of the spiders of the steering wheels. Equipment is complete in every respect.

Density Not Only Fuel Factor

There is a widespread opinion that gasoline of a certain density, say 68, 70 or 72 degrees Beaumé, is the best to use. The advocates of the theory that specific gravity, in other words, weight per unit volume, of fuel is a positive indication of its fuel value are very much mistaken. A fuel may be concocted to produce any desired density between 68 and 76 degrees, and yet have by no means the fuel properties which automobilists are used to attribute to gasoline of such weights. As a matter of fact, it has happened that gasoline producers have specially prepared inferior fuels of a specific gravity considered especially suitable by automobilists. The taking of specific gravity as the sole criterion in selecting fuel is as fallacious as the establishment of the flash test as exclusive basis in judging the quality of a lubricant. The high flash test of an oil in itself does not necessarily constitute a good lubricant. Likewise, only the chemical analysis of a fuel, which, of course, is out of the question in case of a small user, can show whether he gets what he expects and what he is entitled to, or not. It is the maximum contents of hexane in the gasoline which makes the fuel value, as this hydrocarbon combines high volatility with a fairly high hydrogen percentage, upon which the latent heat of combustion depends to a great extent.

Harking Back a Decade

FROM *The Automobile and Motor Review,* November 8, 1902: The 1903 model of the Stanley steamer has made its appearance at Newton, Mass. The motor has two cylinders and is of the ball-bearing, cross-head type. The engine is suspended horizontally under the boiler and is geared direct to the differential, the usual sprockets being replaced by spur gears.

The new automobile terms garage, meaning a storage warehouse; chauffeur, meaning a person who heats something; control, meaning a place or station where control is exercised and mechanician, meaning mechanic, proved rather confusing to the press at large during the recent reliability run to Boston and return. The words are generally pronounced by the non-French lay public as if spelled gar-aw-ish, with the accent on the middle syllable; sho-ffoor and me-can-i-can, with the accent on the second syllable. The meaning of control apparently escaped everybody but the officials and puzzled a number of them.

The competition of tractors for military purposes, announced some time ago by the War Department of the British government, has been postponed until October, 1903.

Reports are current in London that the American manufacturers of automobiles are planning an extensive invasion of the British market. The Oldsmobile already has quite a patronage in England and the Rambler is about to be introduced. The British trade take the position that the larger American cars can never have much sale because the British public refuses to buy cars that lack individuality. For instance if Jones has a Rambler and Smith wants one, he will refuse to buy because his car would be identical with that of his neighbor. American manufacturers are warned not to try to sell cars equipped with cross lever steering gear.

The Diamond Rubber Company, of Akron, O., denies that it contemplates the installation of a factory at Glasgow.

W. Byrd Raymond, a professional driver of New York was sentenced to 6 months in jail without option of fine for alleged negligence in driving his Winton car which figured in a collision with a street car near Yonkers, October 26. Mr. Byrd was sent to the Kings County penitentiary; his hair was clipped and moustache shaved and he was forced to don striped clothing. Twenty-two persons were slightly hurt in the crash. Raymond was released from the penitentiary on a writ of habeas corpus almost immediately on the ground that there was reasonable doubt that the automobile was responsible for the car's derailment.

The Ohio Automobile Company, of Warren, has changed its name to the Packard Motor Car Company and has had plans drawn for two large one-story buildings to be erected at Warren immediately. It is asserted that when these are completed, the company will have one of the largest plants in the country. A circular letter has been sent out that the rumored removal of the plant from Warren to Detroit is in error.

Three of the largest tire companies of the country have consolidated. They are the Hartford Rubber Works Company, Indianapolis Rubber Works and Morgan and Wright. The brands of tires made by the companies include: Hartford, Dunlop, G. and J., and Morgan and Wright. Lewis D. Parker has been elected president.

Laycock's Motor Uses Dumb-Bell Valves

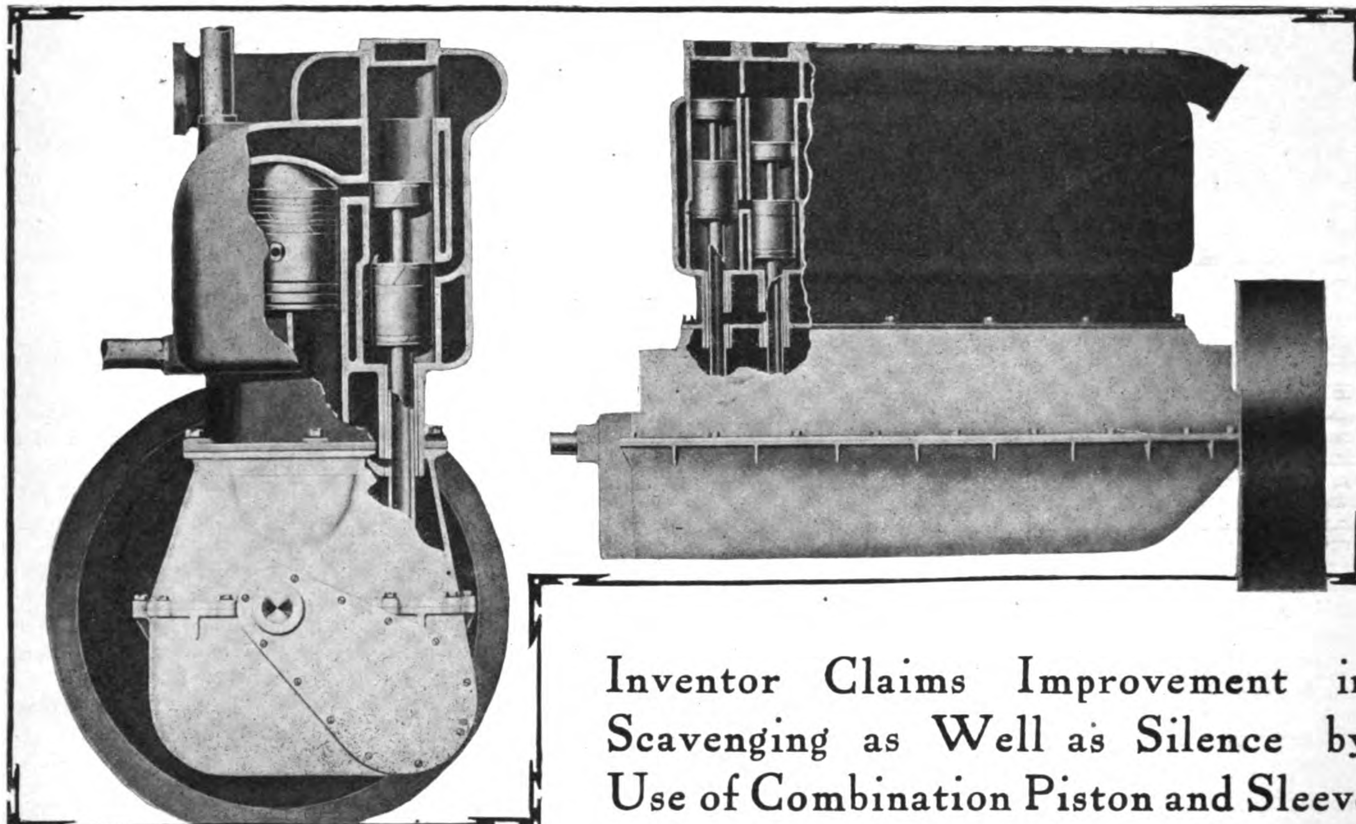

Fig. 1—Transverse section of the Laycock Motor
Fig. 2—Partial section and longitudinal view

Inventor Claims Improvement in Scavenging as Well as Silence by Use of Combination Piston and Sleeve Valve; Small Piston Head Clearance

ARTHUR M. LAYCOCK, of Detroit, has brought out a motor which is attracting considerable attention on account of the novel valve arrangement. As will be seen in the accompanying illustrations there are two separate piston valves used with each cylinder, one for the intake and one for the exhaust. These valves are of the dumb-bell piston type and may be counted on the same or opposite sides of the cylinder.

In exterior appearance the motor does not vary greatly from the regular poppet type. The piston and connecting rod assembly is identical with a motor of the latter type except that, as is shown in Fig. 1, the head of the piston is much closer to the top of the cylinder. According to the inventor the clearance between the cylinder and the piston at the top of the stroke is only about 1-16 inch, or just sufficient to contain enough gas to carry a flame. This will reduce to a minimum the volume that can be occupied by the burnt gases after combustion, and there is consequently a minimum of scavenging work to be done. The waterjackets are made to extend over the cylinder head and around the valve ports in the manner shown in Fig. 1.

The valves are actuated from a camshaft which may be placed in any desired position. In Figs. 3 and 4 the camshaft shown is placed on a level far below the axis of the crankshaft. In this construction the valve passages and the cylinders are parallel with one another and as may be seen the valve mechanism requires a long space. This can be shortened, however, by allowing the axial lines of the cylinders and the valve passages to diverge downwardly.

The valve passages as shown in Fig. 4 are in two parts. The upper part contains the piston valves, while the lower part contains the operating sleeves which are contained in anti-frictional tubes and reciprocate therein. The valve stems are operated at their lower end by connecting rods off the cam-shaft. The manner in which the valves are driven however, is arbitrary and does not alter the principle of the motor in the least. If the camshaft is driven by gearing it is so arranged that the speed of the camshaft is one-half that of the crankshaft.

In Fig. 4, the motor is shown at the end of the scavenging stroke. The piston is about to move downwardly and the exhaust valve is moving up. The crankshaft and the camshaft both turn to the left with the camshaft turning at one-half crankshaft speed. At this part of the cycle the exhaust port is closed by the outer portion of the exhaust valve and the space between the upper and lower part of the exhaust valve is filled with explosive mixture, as will be described. As the piston starts down on the suction stroke, the exhaust valve moves up and prevents any circulation through the exhaust port. While the exhaust valve is going up the intake valve is coming down, as shown by the dotted lines in Fig. 4, the exhaust and intake valve cranks being 90 degrees apart. At the end of the suction stroke the exhaust valve will be at the top of its stroke, while the intake valve will be at the same height as the exhaust valve, as indicated in Fig. 1.

As the exhaust valve was rising a vacuum was created beneath it within the tube containing the hollow valve stem. As will be seen in Fig. 1, there is a port in this valve stem and also one in the tube which contains it, the latter port leading to the intake valve and being connected thereto by a short tube. When the port in the hollow valve stem registers with the port leading to the intake pipe, the explosive gases will rush in and fill the space below the exhaust valve. When the valve descends the gases are compressed in the hollow portion below the valves and at the bottom of the stroke are allowed to pass around the valve into the space between the two parts of the dumb-bell, as shown in Fig. 1. The by-pass will be noted on the left side of the exhaust valve in Fig. 1. These new unburnt gases will force out the remaining dead gases through the upper passages in the same manner that a two-cycle motor is scavenged by the admission of the fresh gases. In case it is desired to scavenge the cylinder with air instead of with the fresh charge it is merely necessary to remove the pipe that connects the intake with the port leading to the hollow valve stem and allow air to pass through in the same manner as described for the fresh charge. In case this is done the carbureter adjustment will have to be altered to take care of the leaner mixture that would result should the charge be allowed to mingle with the air that will fill the valve passages. The scavenging work of the motor will be appreciated with this arrangement in connection with the greatly reduced clearance between the top of the piston and the cylinder head when the piston is on the top of its stroke.

At that point of the cycle when the motor is ready for the explosion stroke the the explosive gases are contained within the small space between the top of the piston and the cylinder head and within the exhaust and inlet valve passages. When the explosion of the gases within the dumb-bells takes place there will be no undue strain on the valves because they will be balanced, the areas of the upper and lower parts being similar. During the entire working or expansion stroke of the piston the valve spaces will be in communication with the cylinders so that the space between the upper and lower portions of the valves are an active part of the expansion or combustion space. At the end of the expansion stroke both the intake and exhaust valves are on the down stroke. The exhaust valve uncovers the exhaust port and leaves it uncovered during the entire scavenging stroke. This completes the cycle and leaves the piston and valves in the position first mentioned. The most important of Mr. Laycock's patent claims are as follows:

Important Claims in Laycock's Patents

1. In an internal-combustion engine, the combination of a cylinder, a piston therein, a valve-chamber adjacent said cylinder and connected thereto by a port, said chamber provided with an inlet port at its lower end for the admission of air, an exhaust port intermediate its ends for the exhaust of the air, and a by-pass in its wall, a valve movable in said chamber and formed of two parts so as to constitute a receptacle for the compressed explosive mixture at the time of the explosion, the lower part of the valve controlling the passage of air through said by-pass and exhaust port of the valve chamber.

2. In an internal-combustion engine, the combination of a cylinder, a piston therein, a valve-chamber adjacent said cylinder and connected thereto by a port, the lower end of said valve-chamber forming a compression chamber having a by-pass in its wall and a port opposite the upper end of the by-pass, a valve in said chamber formed of two cylindrical parts, means to so position the valve that the space between its parts will be opposite the cylinder port during the working stroke of the piston, and to so move the valve that said space will be in line with the upper end of the by-pass and the port opposite the same so said space may be scavenged after each explosion.

3. In an internal-combustion engine, the combination of a cylinder, two cylindrical valve-chambers adjacent thereto and connected thereto by ports, a valve movable in each chamber and comprising two connected pistons, a hollow stem for each valve, a guide therefor having an aperture registering with a port in said stem when at the upper end of said stroke, said stem having a second port which opens into the lower end of the valve chamber when the stem is at the upper end of its stroke, and means to actuate said valves.

4. In an internal-combustion engine, the combination of a cylinder, two cylindrical valve-chambers adjacent thereto and connected thereto by ports, a valve movable in each chamber and comprising two connected pistons, a hollow stem for each valve, a guide therefor having an aperature registering with a port in said stem when at the upper end of said stroke, said stem having a second port which opens into the lower end of the valve chamber when the stem is at the upper end of its stroke, and means to actuate said valves, each valve-chamber having a by-pass in its wall to permit communication around the lower valve-piston when at the lower end of its stroke, and an exhaust passage which is opened by said lower piston when at such lower end of its stroke.

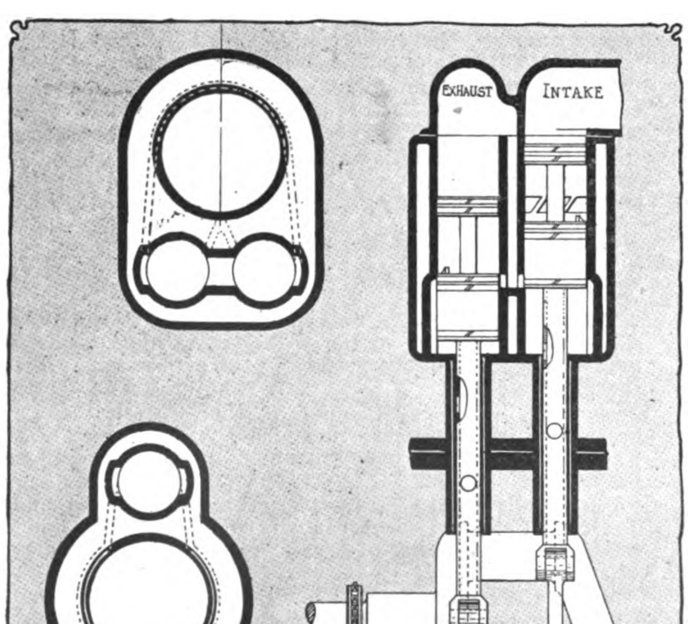

Fig. 3—Plan and elevation of the valve mechanism

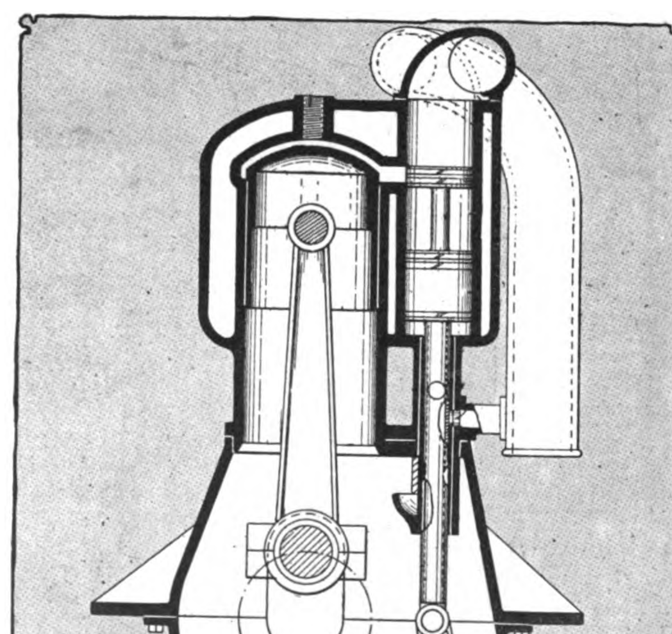

Fig. 4—Complete transverse section through the motor

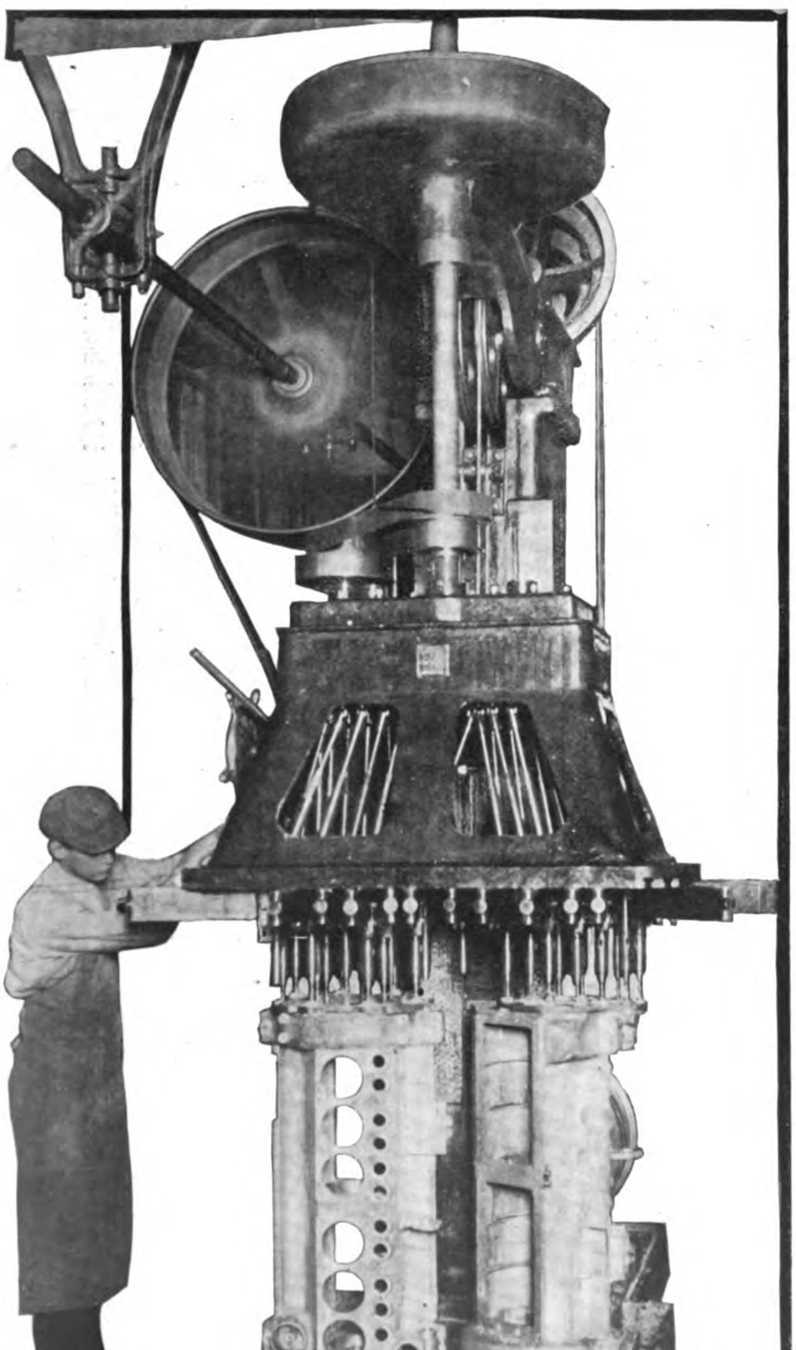

Giant multiple-spindle drill installed by the Chalmers Motor Company in its Detroit plant. The machine has thirty spindles and works on several crankcases. The drill is more than 12 feet high, including the driving and controlling mechanism

QUANTITY production is a much used expression these days, although but few realize the vast amount of ingenuity required to attain it. Nowhere is this shown better than in some of the tools that are used by the large manufacturers. The accompanying illustration depicts the multiple spindle drill recently installed by the Chalmers Motor Company, Detroit, Mich. It is one of the largest multiple-spindle drills ever built. The Chalmers company uses this machine to drill crankcases. Two crankcases can be operated upon at the same time. The machine in the illustration has twenty-seven spindles working simultaneously, while the total capacity of the machine is thirty spindles. An idea of the size of the machine may be obtained from the fact that the operator is 6 feet tall. Turning out two fully drilled crankcases every 15 minutes this machine can produce eighty finished crankcases per day. It takes but one man to handle it and the saving of time and money over the smaller machines is in the neighborhood of 25 per cent.

PATHFINDER'S FACTORY—The Motor Car Manufacturing Company, Indianapolis, Ind., maker of the Pathfinder car, expect to occupy about December 1 the new factory buildings now being completed in connection with the present Pathfinder plant in West Indianapolis. The accompanying illustration shows the addition under construction.

St. Louis Company's Plant—The St. Louis Tire & Rubber Company, St. Louis, Mo., has secured a site and will build a large factory.

Truck Company Building—The Toledo Motor Truck Company, Toledo, O., is erecting a one-story structural steel building, 54 feet by 236 feet.

Cutting Doubling Capacity—The Cutting Motor Car Company, Jackson, Mich., is making arrangements to double the size of its plant at Jackson.

Lamp Company Adds—The C. M. Hall Lamp Company, Detroit, Mich., maker of automobile lamps, is completing a large addition to its factory.

Three Shifts for Ford—The Ford Motor Company, Detroit, Mich., is considering the adoption of a three-shift day of 24 hours as a regular operating program.

Detroit Company's Factory—The American Auto Trimming Company, Detroit, Mich., has let a contract for a factory on Meldrum and Berlin avenues, that city.

Bulldog Tire May Build—The Bulldog Tire Company, Ltd., Toronto, Ont., has been organized to manufacture automobile tires. Plans for a factory are being considered.

Marathon Doubles Capacity—The Marathon Motor Company, Nashville, Tenn., which has a present capacity of thirty cars a week, is increasing its plant to double this capacity.

Batavia Company Adds—Work was begun this week on the addition to the Batavia Rubber Company's building, Batavia, N. Y., on Robertson street. The structure is to be of brick.

V-Ray Installing Machinery—The V-Ray Company, Marshalltown, Ia., maker of the V-Ray spark-plug, is installing new machinery and augmenting its force, in order to increase the 1913 output.

Nashville Chemical Plant—The Rex Chemical Company has moved its plant from Newport, Ky., to Nashville, Tenn. The Rex company manufactures metal polish and body polish for automobiles.

Chevrolet's $50,000 Plant—The Chevrolet Motor Company, Detroit, Mich., has secured a site at Flint, Mich., and contemplates the erection of $50,000 plant for the manufacture of automobile bodies.

White's Machine Shop—The White Automobile Company, Cleveland, O., has awarded the contract for the erection of a new one-story brick and steel machine shop, 160 feet by 240 feet, to cost $40,000.

Frame Company's Addition—The Parish Manufacturing Company, Detroit, Mich., has awarded the contract for the construction of a brick addition to its plant. The company makes automobile frames.

Sandusky Gets Addition—The completion of the addition to the new plant of the Sandusky Automobile Parts Company, Sandusky, O., manufacturer of trucks, will practically double the capacity of the institution. The new building will be used as an assembly and paint shop.

Lauth-Juergens Doubles Output—The Lauth-Juergens Auto Truck Company, Fremont, O., soon expects to double its present output of one truck a day. It will increase the output by having its engines made by outside parties.

Schultz Opens Factory—C. R. Schultz, inventor of a punctureless tire preparation, has opened a small factory at Harold, S. D., to manufacture his product, which he says does not interfere with the resiliency of tires.

Macomber's Plant—The Macomber Motor Company, Los Angeles, Cal., will erect a plant near Los Angeles for the manufacture of the Macomber gas engine for automobiles. Uri B. Curtis and W. G. Macomber are among the directors.

Auto Parts Company's Plant—Structural steel for the addition to the Auto Parts Company's plant, Pontiac, Mich., has arrived, so that the work of construction can be resumed. The foundations and cement floors have been completed and the steel work and roof will go up rapidly.

Will Build Truck—J. P. Cannon, of Detroit, Mich., has formed a concern to be known as the Cannon Motor Company, which announces that it will build an automobile factory in Des Moines, Iowa. According to the promoters they will from the first build a light truck and a roadster.

Amplex Doubling Capacity—The Amplex Motor Car Company, Mishawaka, Ind., is planning to double its factory capacity so that all parts of its cars will then be made at the Mishawaka factory, including aluminum bodies. The company will in a short time put on a larger force of workmen.

Citizens Want Factory—The citizens of St. Louis, Mo., have succeeded in raising $25,000 for a new automobile factory to be conducted under the management of W. H. Kilto & Son, of Toledo, O. Work on the factory will be started soon. The company will manufacture six-cylinder trucks and touring cars.

Garford's Warehouse—The Garford Company, of Elyria, O., is rushing the erection of a reinforced concrete storage warehouse, 85 feet by 210 feet. The building will house materials and parts, with one section devoted to finished car storage and loading dock. The new structure will add another unit to the big Garford plant.

Renovating Kissel Plant—Work in renovating the recently-acquired auxiliary plant of the Kissel Motor Car Company, Milwaukee, Wis., is reported to be progressing rapidly, and it is expected that it will be ready for occupancy within 2 or 3 weeks. The improvements and additions to the Kissel plant at Hartford, Wis., are nearly completed and already partly in use.

Makes Ford's Tools—The Fox Typewriter Company, Grand Rapids, Mich., has closed a contract with the Ford Motor Car Company, Detroit, Mich., to furnish tools to that concern. Although the Ford company has a force of 100 tool makers in its own shops and 100 more outside it is unable to meet the demands of its 7,000 employees. The Fox company will put on fifteen additional tool makers for the contract.

Adds Workmen—The Wald Manufacturing Company, of Sheboygan, Wis., recently incorporated for $30,000, has increased its capacity and added a large number of workmen to its force. The company specializes in the manufacture of a tire tool, pedal grips, luggage carriers and mud guards. Considerable new equipment has been installed and a 4,000-pound stamping press and complete nickel-plating outfit purchased. The company formerly was known as The Wald Company.

Brown Erects Addition—The John W. Brown Manufacturing Company, located at Center avenue and West Broad street, Columbus, O., will soon award a contract for the erection of a large addition to its plant. The company has a contract to furnish the Ford company with all lamps for the season of 1913. The erection will be completed by January and will be the third large addition erected in the past year and a half.

Henderson Plant Busy—One of the busiest automobile plants in Indianapolis, Ind., is that of the Henderson Motor Car Company. Pending the occupancy of the new addition to its factory, which will be ready November 1, it has leased 13,000 square feet of space in the Industrial building at Tenth street and the Canal. The paint shop was moved from the factory the first of the week and all the painting will be done in the Industrial building until the busy season has passed. The floor in the present factory that housed the paint shop has been turned into a final assembly department.

The Automobile Calendar

Shows, Conventions, Etc.

Nov. 16-25	Atlanta, Ga., Annual Show, Auditorium-Armory, Atlanta Automobile and Accessory Association.
Jan. 2-10	New York City, Importers' Salon, Hotel Astor, Importers' Automobile Alliance.

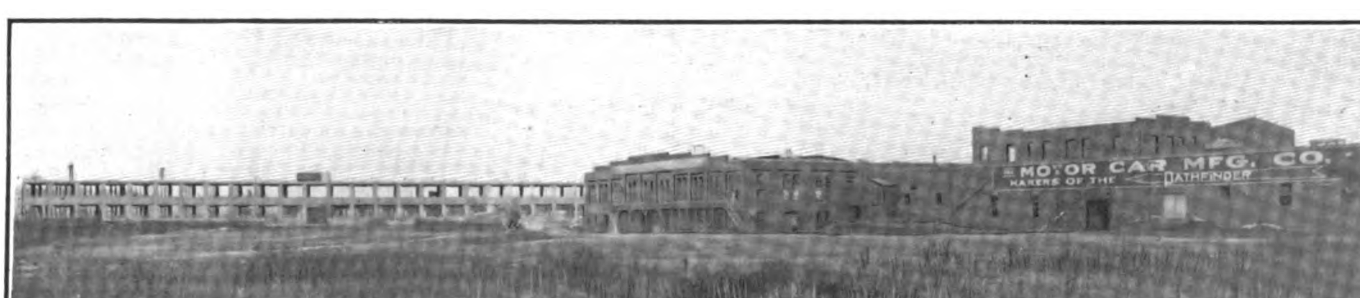
April	Barcelona, Spain, International Exhibition.



New factory building in West Indianapolis, Ind., which will be occupied a fortnight hence by the Motor Car Manufacturing Company

Peerless 3-ton truck used by J. Sercombe, a landscape gardener of Toronto, Ont. He has found that the motor truck is practicable for use in fields and on soft ground

PEERLESS ON FARM—That the motor truck can successfully replace the horse for work in the fields and upon the soft ground has been demonstrated by J. Sercombe, of Toronto, Ont., a landscape gardener who has employed a 3-ton Peerless truck at such work with large profit to himself for several months. The accompanying photograph shows the truck in use.

Harris with Hupp—F. A. Harris has taken the position of assistant manager of the Hupp Motor Car Company, Detroit, Mich.

Guston with Velie—E. E. Guston, formerly with the Studebaker corporation, has accepted a position with the Velie Chicago, Ill., branch.

Longstreth Moves—The Longstreth Motor Car Company, Philadelphia, Pa., distributer of the Alco car, has moved to 2126 Market street, that city.

Menefee Anderson Manager—The Anderson Electric Car Company, Detroit, Mich., has appointed S. W. Menefee manager of its New York branch.

Buick in Savannah—The Buick Motor Company, Flint, Mich., has established a branch at Savannah, Ga., and has placed J. E. Finney in charge.

Shelton Branch Manager—T. B. Shelton has been appointed manager of the Fresno, Cal., branch of Don Lee, California distributor of the Cadillac.

Elliott District Manager—The Lippard-Stewart Motor Car Company, Buffalo, N. Y., has appointed J. R. Elliott district manager for Washington, Idaho and British Columbia.

Lu Lu Club's Run—Following out the idea successfully inaugurated last year, the Lu Lu Temple Automobile Club will conduct its second annual turkey run on Thanksgiving.

Ballou & Wright's Store—Ballou & Wright, Portland, Ore., are opening a branch store in Seattle, Wash., which will be in charge of A. H. Jones. They will handle automobile accessories.

Sievert with Grossman—L. J. Sievert, of Toronto, Can., has been engaged by the Emil Grossman Company, New York City, to act as the Canadian representative of that company.

Green Zero 40 Distributor—The A. Hazen Green Company, 1686 Broadway, New York, has been appointed New York City distributor for the Zero 40, a non-freezing fluid for use in radiators.

Combination Electric and Bulb Horn—Comprising a trumpet using one acoustic diaphragm in common with an electric sound exciter.

Large Tire Order—Backdahl & Company, of Stockholm, Sweden, have just contracted to supply 750 sets of United States tires for taxicab service in Norway, Sweden, Denmark and Finland.

Forsyth Sales Manager—R. L. Forsyth was recently secured as wholesale sales manager by the Thomas Flyer Company, which handles the Abbott-Detroit line at San Francisco, Cal.

Walz with McCullough—C. H. Walz has been appointed general manager of J. H. McCullough & Son, dealers in automobile supplies and accessories, 219 North Broad street, Philadelphia, Pa.

Germany Industry Statistics—The German automobile industry shows a steady and material growth. In 1909 and 1911 the German aggregate exports were, respectively, 19,983,000 marks and 49,013,000 marks.

Holly Kelly Manager—A. S. Holly, former manager of the truck department of the Packard company, Detroit, Mich., has been made manager of the New York branch of the Kelly Motor Truck Company.

Parker Represents Pathfinder—Frank R. Parker, of Boston, Mass., is now New England representative of the Motor Car Manufacturing Company of Indianapolis, Ind., maker of the Pathfinder pleasure and commercial cars.

Elmer Leaves Grant—Of interest to the automobile industry in general is the recent resignation of Harry H. Elmer as director and general manager of the Grant Motor Car Company and the Grant-Lees Machine Company, both of Cleveland, O.

Smith in Advertising Firm—Harold Smith has given up his position as advertising manager of the General Motors Truck Company, Pontiac, Mich., entering the Carl M. Green advertising agency, from which concern the advertising of the truck company will be handled in the future.

Fenner Branch Manager—D. C. Fenner was appointed New York branch manager of the International Motor Company recently.

Waite with Paterson—G. S. Waite has been engaged as sales manager of the W. A. Paterson Company, Flint, Mich., manufacturers of the Paterson line of cars.

Sugden Leaves Thomas—J. L. Sugden has resigned from the E. R. Thomas Company, Buffalo, N. Y., and has joined the Lord & Thomas Advertising Company, Chicago, Ill.

New Frisco Quarters—The Carl Christensen Motor Car Company, San Francisco, Cal., distributers of the Detroiter, has taken new quarters at 561-567 Golden Gate avenue.

Jacoby with Pullman—C. W. Jacoby has resigned the position of eastern sales manager of the Standard Electric Company, to assume the general sales management of the Pullman Motor Car Company, York, Pa.

Conklin Joins Remy—O. F. Conklin has become associated with the Remy Electric Company, Anderson, Ind., in the capacity of consulting engineer of the Remy electrical starting device for application to automobile engines.

Kempton Remy Manager—P. E. Kempton of San Francisco, Cal., has been appointed manager of the San Francisco Remy branch to succeed A. J. Rogers, who becomes manager of the New York branch to succeed F. M. Henkel, resigned.

Smith Production Manager—C. D. Smith has been appointed production manager of the Winton Motor Car Company, Cleveland, O. W. H. Doddridge succeeds Mr. Smith as manager of the company's repair and service departments.

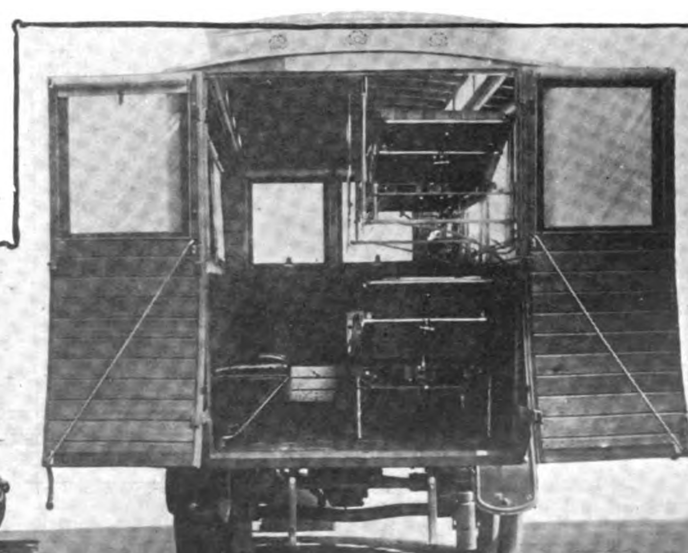
Organizes Engineering Agency—H. L. Croy, formerly mechanical engineer of the Woods Motor Vehicle Company, Chicago, Ill., has organized the Toledo Engineering Agency, Toledo, O. The agency will handle high grade positions in all the engineering fields.

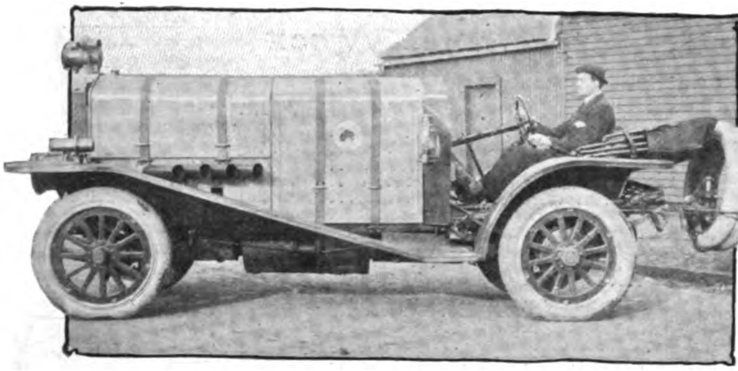
Age Limit Eighteen—No one who is under 18 years of age may operate an automobile in the state of Maryland, even though accompanied by his or her parents, who may be duly licensed, according to an opinion delivered by Judge Frank I. Duncan, in the Circuit Court at Townson, Md.

New Cincinnati Law—Chief of Police Capelan of Cincinnati, O., has just issued an order which forbids automobile owners to leave their cars standing for more than 5 minutes in the district bounded by Elm on the west, Main on the east, and between Fourth and Sixth avenues. The rule applies to all other vehicles.

Columbus Road Doings—At the annual meeting of the Ohio Good Roads Federation, held in Columbus, O., recently, strong resolutions were adopted pledging the members to continue the fight despite the fact that the proposed amendment to the Ohio constitution was defeated at the polls. A number of different plans of action were discussed, and it seemed to be the feeling that the best scheme was to go before the Ohio General Assembly and ask for a direct levy for road purposes.

Exterior and interior views of the new De Dion ambulance recently delivered to the Government of the Philippine Islands. The chassis equipped with a 25-horsepower, four-cylinder motor, giving the car a speed of 30 miles an hour. It is fitted with an air-cushion shock-absorber. Inside the body, which was made by the DuPont Company of Paris, there are two stretchers with an apparatus for hot and cold water and a complete medicine chest. The stretchers may be removed and patrol wagon seats fitted. The apparatus is to be used in Manila and vicinity.





Special racing car built by S. P. Blackiston, of Canton, O. Among the unique features of the car are the two radiators, mirrors arranged for driver to see past the high hood, universal joint on the steering column which is so heavy that it takes two men to lift it and a powerful electric searchlight which illuminates the road for .25 mile

Fire Engine Arrives—The first of the three motor-driven fire engines that were recently ordered by Nashville, Tenn., has arrived.

Baltimore, Md.—Because of increased business the Oakland Motor Car Company, Baltimore, Md., has leased the large warehouse at Biddle Park and Howard street.

Pennsylvania's Road Repairing—The Pennsylvania State Highway Department has repaired approximately 6,000 miles of main state highways, or about 75 per cent. since the department took over the 296 routes covered by the Sproul highway law June 1 last.

Garage Capacity Doubled—Jones & Indra, 149-151 North Broadway, Green Bay, Wis., who erected a large new garage a year ago, have started work on an addition which will double the capacity. Part of the new building will be devoted to repairs and reconstruction.

Fireproof Garage Built—A large new garage is being erected by John L. Snyder on Third street, Newport, Pa. The building will be fireproof, built of cement blocks, with cement floor and steel roof. The Perry Concrete Company has the contract for the erection of the garage.

Overland in Phoenix—Phoenix, Ariz., men have incorporated the Overland Auto Company and opened a new garage on Third avenue. Overland machines are handled exclusively. It has been several years since the Overland was represented in Phoenix. A. S. Earhart is manager of the new company.

Erect Hartford Garage—Charles H. Lohr and Howard Danielson have leased the Hacker, Hartford, Wis., building and remodeled it into a garage and repair shop. The firm has the district agency for the Ford in Dodge and Washington counties. Mr. Danielson has been associated with the factory of the Kissel Motor Car Company at Hartford for several years.

Ohio Plans Two New Laws—The Ohio state association of automobile owners is laying plans to secure two new laws which it is hoped to have enacted at the meeting of the Legislature next winter, which will have a far-reaching effect and which will be of special interest to all owners of motor cars. One of the desired laws will make it a penitentiary offense to steal an automobile.

Beloit Satisfied with Truck—The Common Council of Beloit, Wis., is arranging for the provision of funds in the new budget for the purchase of another combination hose, chemical and squadron motor truck. The Council is enthusiastic over the results obtained from the present motor-driven fire apparatus and has found it to be cheaper to maintain motor-driven apparatus than that pulled by horses.

Wants Better Laws—The Automobile Club of Maryland has started a vigorous campaign for a more sane and just motor vehicle law. With this object in view the club has communicated to each of the 1,000 members to lend their individual help to take before the Legislature of 1913 a sane, just and fair motor vehicle law. Another thing the club will ask the next Legislature is to give reciprocal relations with the motorists of the District of Columbia.

St. Louis Maxwell Changes—In the future the Maxwell line will be handled in St. Louis, Mo., by an agency instead of a branch house as in the past. The agency will be known as the Maxwell Motor Sales Company and will occupy the quarters formerly occupied by the branch house. B. R. Ford will be at the head of the new agency. Frank R. Tate, formerly manager of the branch house, has made connections with the Ford Motor Company.

Omaha Plans Show—The regular annual meeting of the stockholders of the Omaha, Neb., Automobile Show Association was held on Tuesday, October 29. The coming automobile show, from February 24 to March 1, was the topic most generally discussed. It was decided that the expenditures for decorations, lights and other necessities will be materially increased this year, thereby making this year's show the biggest and best that has ever been held in Omaha.

Governs Vehicle Use—The Common Council of Manitowoc, Wis., has passed an ordinance governing the use of vehicles on city streets. The ordinance embodies all of the well-known rules of the road, but adds a provision obliging motorists to use a silencer or muffler and refrain from unnecessary use of gongs, bells, horns or signals of any kind. The Milwaukee ordinance is copied in that it requires drivers of all self-driven vehicles to stop behind any street car which is taking on or discharging passengers.

Wants Fire Truck Estimates—The common council of Beloit, Wis., has authorized the committee on fire and police to begin negotiating for the purchase of a second combination hose, chemical and flying squadron motor truck. The first has now been in use 17 months and shows so large a saving that at this time, when more equipment and apparatus is made imperative, and the choice lay between horses and motor-propelled vehicles, the motor was unanimously chosen. The committee will receive estimates from manufacturers at once.

Club Established Quickly—San Jose, Cal., has established something like a record in the quick organization of a motor club. At the beginning of the present month a number of enthusiasts decided that the Garden City ought to have an automobile organization and a club house. Promptly they got together and organized a country club. Within the next 2 weeks they secured a membership of 275, raised $45,000 in actual cash, bought 90 acres of foothill land near Alum Rock Park, and let a contract for the erection of a handsome clubhouse and the laying out of extensive golf links. There will also be a large and elaborate garage.

Indiana Club Plans—Members of the Indiana Automobile Manufacturers Association, Indianapolis, Ind., will send their exhibits to the New York show in January by special train. This was decided upon at a meeting of the association held in Indianapolis on the evening of October 31. A New York show committee to arrange the plans for the train and for exhibiting at the show was appointed, as follows: J. Guy Monahan, of the Premier Motor Mfg. Company; Harold Hyde, of the Empire Motor Car Company; William Esterly, Firestone Tire Company. Another meeting of the association will be held in Indianapolis on the evening of November 21 to discuss the proposed run to be made to the Pacific coast next summer.

Automobile Incorporations

AUTOMOBILES AND PARTS

Boston, Mass.—Eliot Motor Car Company; capital, $250,000; to deal in automobiles. Incorporators: Roscoe G. Houston, Wm. D. Wallace.

Cleveland, O.—Lozier Sales Company; capital, $30,000; to deal in automobiles and accessories. Incorporators: W. H. Miller, A. H. Weaver, W. B. Anderson, V. C. Erman, J. H. Brown.

Farmington, Me.—Metcalf Automobile Company; capital, $10,000; to deal in automobiles. Incorporators: J. C. Metcalf, John G. Morton, H. W. Barker.

Louisville, Ky.—Rommel Motor Car Company; capital, $15,000; to deal in automobiles. Incorporators: John Rommel, H. E. Rommel, Joseph H. Kaltenbach.

New York City.—Beaver State Motor Company; capital, $300,000; to manufacture automobiles. Incorporators: P. Combs, J. L. Bailey, J. A. Johnson.

New York City, N. Y.—Miller-Brisben Company, Inc.; capital, $25,000; to deal in automobiles, etc. Incorporators: Irving Jaffee, John McNeil Brisben.

New York City, N. Y.—Peets-Homan Corporation; capital, $2,000; to manufacture and sell all kinds of motors, engines, etc. Incorporators: John A. Bolles, Clifford S. Peets, Frank D. Homan.

New Orleans, La.—J. A. Landry Motor Car Company; capital, $25,000; to manufacture automobiles. Incorporators: J. A. Landry, J. B. Avergo, Roger J. Montrose.

Troy, N. Y.—Automobile Salvage Corporation; capital, $2,000; to deal in second hand automobiles. Incorporators: Michael Kennedy, Theodore P. Low, Mark F. Nichols.

Washington, D. C.—Michigan Motor Company; capital, $10,000; to manufacture automobiles. Incorporators: T. Oliver Probey, J. H. Stuart, George R. Stuart, F. C. Sibbald, E. G. Powell.

GARAGES AND ACCESSORIES

Boston, Mass.—Amherst Garage Company; capital, $15,000; to conduct a general garage business. Incorporators: Henry E. Paige, Louis E. Smith, Charles H. Buell.

Five Heinz Trucks Sold—The H. J. Heinz Company has just closed an order for five 3.5-ton G. V. trucks.

New Orleans Uses Sprinkler—A new motor-driven sprinkling wagon has been put in service by the municipal authorities of New Orleans.

Posts Road Signs—The Owego, N. Y., automobile club has just completed its campaign of posting signs on various roads leading to that town.

Gotshall Manages Lozier—N. S. Gotshall, western traveling representative of the Lozier Motor Company, Detroit, Mich., has severed his connection with the Lozier Motor Company to accept the management of the St. Louis Lozier Company.

Luce Leaves Velie—Morton H. Luce, manager of the Chicago, Ill., Velie branch, has resigned that position to become sales manager for the American and Marion Sales Company, New York City.

Set Utica Show Date—December 15 has been set as the day for the annual convention of the New York State Automobile Association, which will be held this year in the Hotel Utica, Utica, N. Y.

Evans Leaves Lozier—J. M. Evans, who for the past year has occupied the position of advertising manager of the Lozier Company, Detroit, Mich., has severed his connection with the Lozier interests.

Gramm Goes to Cuba—Cuba has been found a profitable field of endeavor by the Gramm Motor Truck Company of Lima, O., and contracts were recently signed for the delivery of a half dozen cars to Havana.

Kelly in Seattle—Factory distributing headquarters for the states of Washington, Oregon, California, Idaho and Montana and the province of British Columbia for Kelly motor trucks have been located in Seattle.

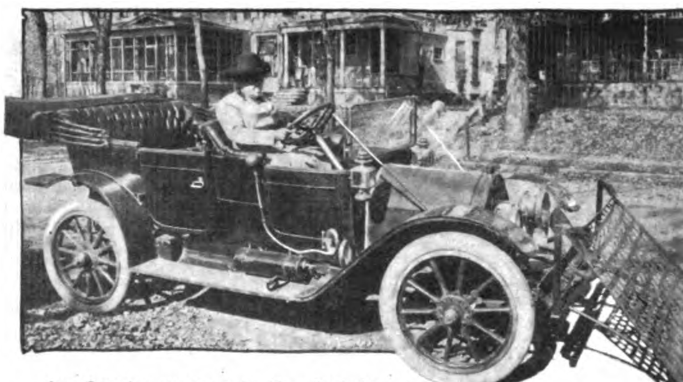
New Oldsmobile Quarters Ready—The new quarters for the Oldsmobile Company on Broad street near Bacon avenue, Providence, R. I., are practically completed, and the company will occupy them in a few days.

Appoint New Manager—B. F. Morris has been appointed manager of the local factory branch of the Republic Rubber Company, of Youngstown, O., which recently took over the interests of the Bison Rubber Company.

Schonacker Leaves Marvel—A. G. Schonacker, general manager of the Marvel Carbureter Company, Flint, Mich., has resigned his position on account of his condition of health, and expects to locate in the West.

Sugden Leaves Thomas—J. L. Sugden, formerly connected with advertising section of the E. R. Thomas Motor Car Company has severed his connection with that concern and is now with Lord & Thomas, of Chicago.

Montreal Supplies Cars—It was resolved by the Montreal Que., Board of Control recently to accede to the request of the three section superintendents of the roads department to supply them with small automobiles costing $2,000 each.



An Omaha woman is the first to use a fender on her automobile. The above illustration shows Mrs. Joseph Weeth in the car which she has had equipped **with a device for scooping up the Nebraskans who would have otherwise been crushed beneath the wheels of the car**

Richardson a Manager—Malcolm B. Richardson, formerly with the Remy Magneto Company, has been appointed district sales manager in the Southern territory for the Franklin Automobile Company. He will make his headquarters at Atlanta, Ga.

Davis in the Field—A. H. Davis, formerly with the Rochester branch of the Franklin Automobile Company and later engaged in selling motor cars in Buffalo, has rejoined the staff of the Franklin Automobile Company and will act as a special field representative.

Fix Age Limit—The city codifying commission of Dayton, O., is planning an action which will exclude boys and girls under 18 years from operating automobiles. There is also some talk of barring women from driving gasoline cars. The matter is now up to the city council.

Ohio's Road Figures—Figures compiled by State Highway Commissioner James Marker show that Ohio has so far this year contracted for the construction of more than 150 miles of road. Between now and January 1 contracts will be let for the construction of about 25 more miles.

To Handle Paige—The combining of the Carpenter Motor Sales Company and the Thomas Motor Car Company, of Los Angeles, Cal., was accomplished last week. New quarters have been secured at Eleventh and Flower streets. This company will distribute the Paige car in California.

Jacobs Goes Into Bankruptcy—Volney J. Jacobs, who has represented various makes of cars in Boston, Mass., for the past few years, has filed a petition in bankruptcy. His liabilities amount to $19,483, of which $13,572 is secured, and there is due about 80 creditors $5,892. His assets are given as $50.

Piggins in Frisco—A branch of the Piggins Motor Truck Company, of Racine, Wis., has been established in San Francisco to serve as a distributing depot for the entire West, Hawaii and the Orient. J. I. McLaughlin is manager. Besides the Piggin truck the Inter-State pleasure cars will be handled.

Railroads Too Slow—The Willys-Overland Company, Toledo, O., has had considerable trouble in shipping its cars to its dealers, due to the inability of the railroads to supply cars for transportation. The dealers have solved the question by going to the factory and driving the cars to the customers.

Responsible for Employee's Injuries—An automobile owner who requires an employee to ride with him in his automobile must be responsible for injuries that may result from such a ride, according to the Supreme Court of Minnesota. A. H. Patterson, chauffeur, received a $4,500 verdict in the lower court. The award is sustained. While driving fast the owner, who was in the car, the machine turned turtle and injuries resulted to the chauffeur.

Novel Use for Motor Truck—Unique among the varied uses the motor vehicle has been put to is the work L. S. Davidson, of Portland, Ore., has applied his 1-ton Little Giant truck. Equipped with a complete motion-picture outfit, the power wagon was piloted out of the city recently to visit towns where electric lights are not used. With the power from the gasoline motor, a 110-volt dynamo generated enough electricity to run the moving picture outfit and one arc light. His equipment weighs 1,500 and the truck is rated at 25 horsepower.

Automobile Incorporations

BROOKLYN, N. Y.—Brooklyn Auto Top & Supply Company; capital, $5,000; to manufacture automobile tops and accessories. Incorporators: Beatrice H. Marron, Jacob Seigel, Edgar E. Chinnock, Jr.

BROOKLYN, N. Y.—H. J. & S., Inc.: capital, $1,000; to manufacture and deal in rubber, rubber articles, etc. Incorporators: Joseph Mattison, Harry Jacobson, Siegfried Glass.

BROOKLYN, N. Y.—Sea Gate Garage & Automobile Corporation; capital, $2,000; to conduct a general garage business. Incorporators: Joseph F. Curtin, H. O. Coughlan, Thomas K. Mallaby.

CHICAGO, ILL. Auto Combination Lock Company; capital, $50,000; to manufacture nut locks and supplies. Incorporators: Howard L. Mason, Harry W. Snow, Francis W. Robinson, William J. Liddy.

NEW YORK CITY, N. Y.—Cahill Auto Works; capital, $6,000; to conduct an automobile repair shop. Incorporators: Andrew J. Cahill, Charles E. Trainor.

NEW YORK CITY, N. Y.—Seager's Garage, Inc.: capital, $1,000; to conduct a general garage business. Incorporators: James H. Seager, Albert Seeley, Henry B. Ecerson.

NEW YORK CITY, N. Y.—Tuxedo Tire Company: capital, $8,000: to manufacture tires. Incorporators: Augusta Hermann, Emilie Waltenberg, Adolph Waltenberg.

CHANGES OF NAME AND CAPITAL

CINCINNATI, O.—Price Hill Garage & Auto Company; increase of capital from $1,000 to $100,000.

DETROIT, MICH. Warren Motor Car Company: increase of capital from $300,000 to $600,000.

MARSHALLTOWN, IA.—Marshalltown Motor Material Manufacturing Company; change of name to V-Ray Company, Inc.

Champion Priming Spark Plug; Brolt Lighting Generator; J. H. Windshield for Tonneau Passengers; Gilmer Pliers and Cleaning-Tool; New Electric Horn; Automobile Turntable for Garage Use

Fig. 1—New Champion priming spark-plug

STARTER plugs which combine the office of sparking with that of a priming cup have become fairly common during the last year, a number of these devices having been announced. It stands to reason that the principal problem in the construction of such a plug is to obtain absolute tightness of the various parts, so that the provision of a priming cup does not bring with it a leak of compression when the engine is in operation. In the Champion priming plug, Fig. 1, this end has been realized by using for the priming cup a brass plug bored as shown, through which the gasoline injected for starting enters; out of the central bore of the cup, the fuel runs down toward the wall of the bored shell in which the cup is fitted. The upper portion of the brass cup is screw-threaded to fit into the steel extension of the sheel, while the lower end is formed as a plain needle which, when screwed down upon its seat, makes a close fit with it. As the engine heats up, the brass cup expands to a greater extent than the steel bore in which it is in position, a tight fit being obtained in this way. The ghost view, Fig. 1, illustrates the simplicity of the construction of this plug, which is composed of very few parts; the latter are manufactured in a standard way and therefore interchangeable. The Champion Spark Plug Company, 132 Upton avenue, Toledo, O., is the maker of this plug. This spark-plug is manufactured in the regular sizes, and may be used without in any way altering the gas and wiring connections to the various cylinders, as compared with other plugs. It must be remembered, however, that the brass cup is designed for priming with liquid fuel only and not for the admission of acetylene.

Brolt Electric Lighting Generator

Among the new lighting systems which have made their appearance on the other side is the electric generator outfit sold under the name Brolt by the Brown Brothers Limited, Great Eastern street, London, E. C. This generator is designed to give a constant current output, the regulation being obtained by the use of purely electrical means. Figs. 6 and 7 show the principle on which the device operates. The dynamo is constructed with two main poles N and S which are excited by a shunt winding connected to the brushes, while auxiliary poles N1 and S1 are not wound, but are excited by the cross-magnetization due to the current in the armature. Fig. 7 shows the brushes B which are in a neutral position respective to the main poles and which short-circuit several armature coils during the period of commutation, as shown by the black dots in Fig. 6. When the armature revolves, a voltage induced between the brushes causes current to be delivered to the battery. The armature current induces a cross-magnetizing flux in the poles N1 and S1 which are provided to receive the same. The armature coils short-circuited by the brushes cut the cross flux, and a short-circuit current is induced in them proportionate to the speed of the armature and the cross flux, and tending to demagnetize the main poles. Thereby the main field is demagnetized in just the same degree as the output tends to increase, the latter thereby being kept constant. The dynamo is constructed for sparkless operation and ordinary brushes are used; the generator runs at a speed 1.5 times that of the engine. The generator requires lubrication about as frequently as the magneto, and medium heavy oil is filled in the dynamo bearing cups O. Positive and negative terminals are shown at P and N, respectively, in Fig. 7.

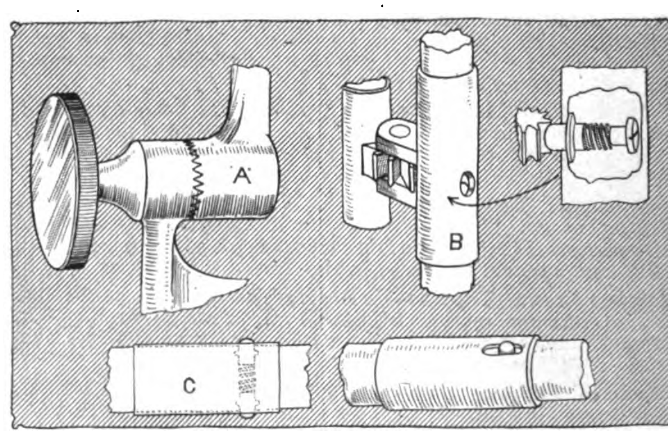

Fig. 3—Details of J. H. tonneau windshield mechanism.

J. H. Tonneau Windshield

The protection of the passengers of a tonneau from the wind, when the driver's shield is not up, is the purpose of the J. H. shield, Fig. 4, which is made by the J. H. Tonneau Windshield Company, 225 West Forty-ninth street, New York City. This figure shows how the shield is carried on two rods the ends of which are hinged to the rear of the driver's seat and on which the tonneau shield proper is slidable. The shield consists of three sections, the central one being of glass and the lateral ones of celluloid, and all are carried in wooden frames of circular section. The whole shield may be turned to any angle, relative to the horizontal, around the lower edge of the central portion, a fulcrum being formed by the two members holding it to the horizontal rods, shown at A, Fig. 3. The angle of the side portions against the central piece is also variable, the shield section being able of remaining in any desired position relative to the central one, by the use of the dog hinges B, Fig. 3. The details of these parts are so clearly illustrated that no explanation is necessary: A consists of two jaw clutches capable of facial engagement and B of a spring-pressed pin which drops into the gear pivoted between the two shield-section frames. C, Fig. 3, serves for keeping the shield in place when it is not in use. The parts A are carried by sleeves sliding on the horizontal rods fixed to the driver's seat; these sleeves are slotted and permit the spring-separated plungers, which are located near the point where the rods are fastened to the body, to drop into them. The sliding fit of the sleeves on the rods permits of pushing either side of the shield toward the driver's seat, when a passenger wants to leave the car on either side. A waterproof curtain shielding the passengers' feet against rain depends from the lower edge of the middle section of the shield.

Mineral Anti-Freezing Water
